During the greater portion of the digestive period, the enormous diluting and buffering power of a normal meal will, of course, prevent the acidity from rising very high. But what prevents the acidity from eventually becoming excessive? A significant new possibility is suggested by the work of Wilhelmj, McCarthy and Hill (8), Griffiths (9), Day and Webster (10) and Crider and Thomas (11), all of whom have observed that the introduction of HCl in the duodenum will depress the further secretion of acid by the stomach. This would provide a truly automatic mechanism for the regulation of gastric acidity.

A combination of the above acid inhibition and intestinal regurgitation mechanisms, offers a most attractive compromise theory, which may be considered to operate as follows. When the acidity of the chyme entering the duodenum becomes too high, the further

production of HCl is inhibited. At the same time the acid acting from the duodenum inhibits gastric motility, relaxing both the pyloric antrum and sphincter (12). This permits regurgitation of alkaline fluids from the intestine, which results in a rapid diminution in the acidity of the gastric contents. It would seem that both processes are important, for, in the absence of regurgitation, the secretion of a greatly reduced quantity of juice of an equally reduced acidity could only very slowly accomplish a significant reduction of the acidity of the whole gastric contents, and until the acidity was restored to normal, the acid acting from the duodenum would markedly retard evacuation. On the other hand, if acid secretion continued unabated, the volume of intestinal fluids being regurgitated into the stomach would have to be almost as great as the volume of gastric juice being secreted into the stomach, a condition which would also interfere with gastric evacuation. However, by a proper coordination of the two processes, namely, inhibition of acid production and neutralization by regurgitation, the regulation of gastric acidity could be most efficiently accomplished.

It would be of interest to know whether the mechanism by which acid in the duodenum inhibits gastric secretion is reflex or humoral in nature. It would also be of importance to determine whether a disturbance in this process is responsible for clinical hypersecretion.

John S. Gray.

Book Review

Clinical allergy, manifestations, diagnosis and treatment. By A. H. Rowe. Philadelphia, Lea and Febiger, 1937, 812 pages.

THIS book should be of great interest to all physicians who see many patients with gastro-intestinal disease. Rowe has done much pioneering in the field of food sensitiveness and he here sums up in very readable form the wisdom which has come to him during the years. In addition he gives the student easy access to a large literature.

Those gastro-enterologists who are using Rowe's elimination diets will be interested to see the modifications that he has made in them. They are particularly useful in cases of migraine in which the diet may have to be continued for some time in order to tell whether or not the attacks are going to disappear.

Some readers may disagree with Rowe's view that ordinarily one must keep up the diet for weeks or a month or more before one can tell whether or not it is doing any good. The reviewer's impression is that ordinarily, at least in cases of indigestion, abdominal pain and soreness, if the relief does not come in twenty-four hours, it is not going to come with the particular elimination diet being used.

Many physicians will doubtless find helpful Rowe's instruction for the taking of histories. The questionnaire which begins on page 664 should be very useful.

It is nice to find Rowe stating now that in many cases the skin tests are of little help, especially in the diagnosis of food sensitiveness.

We are particularly pleased to see the large number of recipes for the preparation of food. They should be very helpful particularly to mothers who have to cater to children with marked sensitiveness to milk, eggs, and other commonly used foods.

On page 170 Rowe wisely points out that the enthusiastic allergist must always remember that many of his patients, and even those who have definite allergic symptoms may be suffering mainly from nervous complaints, and they may be markedly psychopathic or "relatives of the insane." Unfortunately the markedly allergic person is commonly tense and nervous and hypersensitive to everything, and the handling of his problems calls for a tremendous amount of skill, understanding, and patience on the part of the physician.

Certainly Rowe's book should be owned and read and consulted frequently by every busy clinician. There is no question that as civilization advances, and man has to come in contact with more hundreds of substances gathered from the four corners of the world, there will be more cases of allergic disease, and physicians will always have to keep thinking of this type of sensitiveness as a possible cause of illness. Allergic sensitiveness is now being found to explain some common and very annoying symptoms such as canker sores in the mouth for which there was formerly no explanation and no useful or logical treatment.

About the only suggestion that a reviewer might make for future editions of this book is that Dr. Rowe then base his statements more on his own experience and less on the statements which he finds in the literature.

SEYMOUR, WILLIAM B. AND LIEBOW, AVERILL A.

"Abdominal Intermittent Claudication" and Narrowing of the Celiac and Mesenteric Arteries. Ann. Int. Med. Vol. X, pp. 1033-1041.

The correlation of the clinical and pathological data of a case of gradual occlusion of the celiac, mesenteric and left iliac arteries is presented by the authors.

A spinster of 76 was admitted to the medical ward complaining chiefly of abdominal pain after eating. Numbness in the left calf upon exertion, tingling sensations in the fingers, and constant tinnitus had been noticed for six months. The abdominal pain began three months before admission. Immediately upon the ingestion of any food except water and fruit juices there would appear a sharp steady pain in the region of the umbilicus radiating to the symphysis pubes, left lower quadrant and back. The pains would last 5 to 30 minutes and were followed by a constant slight dull ache in the epigastrium. On two occasions she had been nauseated and had vomited a thin colorless fluid. One week before admission she had had a watery diarrhea of two days duration. She thought her stools had been black at times. There had been no abdominal distention.

Physical examination revealed marked arteriosclerosis of the retinal vessels and the arteries of the extremities. The left lower extremity was cooler than the right, and the blood pressure and pulse were unobtainable in it. In the region between the umbilicus and mid-epigastrium just to the left of the vertebral column a firm, but vaguely defined, immovable, pulsating mass was felt.

A positive guaiac test of the stools and a leucocytosis of 13,000 was found. A gastro-intestinal X-ray series showed atony of the stomach with 15% retention of the gastric contents in six hours, and motor delay throughout the small intestine.

Nine days after admission the patient vomited 300 c.c. of coffee ground material which was weakly positive for guaiac. Exploratory laparotomy was performed at which nothing of particular note was found. Eighteen hours later the patient died.

At postmortem the entire gastro-intestinal tract was distended with dark red, malodorous fluid. A loop of ileum adherent to the posterior wall of the bladder was almost black, and so soft it tore easily upon an attempt to loosen it. Microscopically the mucosa of the small intestine had undergone complete necrosis. The aorta showed marked atheromatous change with ulceration and calcification. About the mouth of the celiac axis was deposited a rosette of very hard material which virtually obliterated the ostium. The mouth of the superior mesenteric artery likewise was narrowed to an opening of pinpoint size by a hard incrustation in its wall. A firm, fresh, laminated, red and gray thrombus completely obstructed the proximal 5 cm. of the vessel. The lumina of the left common and external iliac arteries were reduced to mere crescentic slits because of tremendous thickening of the intima. A fresh thrombus partially occluded the left common iliac artery. The heart showed considerable atherosclerosis of the coronary vessels, but no occlusion.

Accompanying this report is a tabular summary including those cases in the literature of abdominal pain associated with vascular disease in which the findings at necropsy are stated.

Liver Function in Rheumatoid (Chronic Infectious) Arthritis: Preliminary Report. Ann. Int. Med., Vol. X, pp. 1021-1027, Jan., 1937.

One hundred patients were studied to determine whether any disturbed liver function occurred during the toxemia of rheumatoid (chronic infectious) arthritis. The Azorubin S test was selected for the liver function test, which is performed in the following manner. The duodenal tube is passed in the morning on a fasting stomach. When the tube reaches the duodenum and a yellowish-brown bile begins to flow 1.0 c.c. of 1.0 per cent solution of Azorubin S is injected intravenously. Five minutes after the injection of the dye 40 c.c. of a 25% magnesium sulphate solution is injected through the duodenal tube. In normal individuals a characteristic, deep red bile appears about 17 minutes after injection of the dye. From 15 to 30 minutes was accepted as the normal appearance time of the dye. Less than 15 minutes and more than 30 minutes indicated liver dysfunction in proportion to the decreased or increased appearance time of the dye.

In analyzing the 100 cases the authors report that in four cases the appearance time was less than 10 minutes; in 32 it was 10 to 15 minutes; in 45, 15 to 30 minutes; in four, 30 to 35 minutes; in nine, 35 to 40 minutes and in six, over 40 minutes. Of the entire number studied 55 per cent showed some liver dysfunction.

From these figures, although it appears that liver dysfunction is parallel to the severity of the disease, there was no relation between the duration of the disease and the liver function. A quantitative determination of serum proteins was made in patients showing liver dysfunction and in most cases, there was a slight reduction of the total serum protein and a reversal of the albumin-globulin ratio. In the majority of cases studied, there was a correlation between liver dysfunction, the reduction of serum proteins and reversal of the albumin-globulin ration.

The authors conclude that liver dysfunction as determined by the rate of excretion of Azorubin S, was present in 55% of 100 patients with rheumatoid arthritis and that it occurred with greater frequency in patients with a severe than with a mild form of the disease.

The interpretation of liver dysfunction in patients with a *decreased* appearance time is based upon the findings of Whipple, Peightal and Clark who reported a hypersecretion of phenoltetrachlorphthalein with small doses of phosphorus which they attributed to the irritative effect of the phosphorus on the parenchyma of the liver. Whether this irritative effect can also be attributed to the Azorubin S, in the reviewers opinion, merely is conjectural without further substantive proof. If this opinion is correct, it would materially alter the results of the 100 cases studied by the authors, reducing their evidence of liver dysfunction in rheumatoid arthritis from 55 per cent to 19 per cent.

KANTOR, JOHN L. AND COOPER, LENNA F.

The Dietetic Treatment of Constipation with Special Reference to Food Fiber. Ann. Int. Med., Vol. X, pp. 965-978, Jan., 1937.

The thesis of this paper is that constipation should be treated as thoroughly as possible by diet before calling upon artificial products for assistance. For this reason, and because of their recognized superior laxative properties, fruits were selected as the subject of this study. Cowgill has laid down the general procedure for the study of laxative substances on a fiber-equivalent basis, and has suggested that for normal men the physiological fiber minimum for adequate laxation corresponds to a daily intake of 90 to 100 milligrams of fiber per kilogram of body weight. This experiment was

planned, therefore, to determine the relative usefulness of three fruits (prunes, apples and bananas) on a fiber-equivalent basis.

The subjects selected for this study were nine hospital dietetians. The experiment was divided into eight periods of at least nine days each; in the first period the diet was uncontrolled while in the seven following periods there was a variation of fiber content and combination.

The laxation (number of stools) were recorded for each day of every period by each subject. In this paper the laxation is expressed in terms of stools per week per person.

The total colon emptying time was observed roentgenographically in five of the subjects during the first six periods of the experiment.

The normal total colon emptying time was determined from a review of 844 private patients. It was found to be 72 hours.

The weight of the stools was determined in the last two periods by actual measurement immediately after passage.

Experimental Conclusions: According to the average laxation and colon emptying time, the laxative power of the three fruits when tested on a strictly fiber-equivalent basis (66 mg. per kg.) may be rated as follows: First, prunes with laxation of 7.7 and colon emptying time of 91 hours; second, bananas, with laxation of 6.8 and colon emptying time of 98 hours; third, apples, with laxation of 6.1 and colon emptying time of 115 hours.

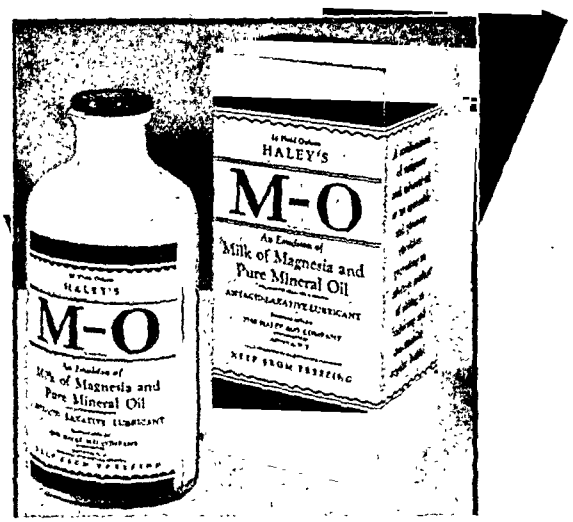
It is probable that the simultaneous employment of several sources of fiber is superior to the use of a single variety. This is suggested by the fact that laxation was freer in the preliminary period of this experiment when the sources of fiber were more freely chosen than in most of the subsequent periods when the sources were restricted.

Clinical applications: Accompanying this article are three tables showing the fiber component of fruit, vegetables and cereals not only as a percentage, but as it occurs in the average serving portion.

According to the Cowgill standard of 100 milligrams of fiber per kg. body weight, a man of 70 kg. will normally require 7 gm. of fiber daily. The exact procedure of selection may be outlined as follows:

1. From the list of fruits, three varieties may be chosen, preferably one for each meal. Assuming that apples, prunes and bananas are taken, it will be noted that the fiber in the average portions adds up to 2.2 gms. (1.0 gm. plus 0.6 gm. plus 0.6 gm.).

2. Four vegetables should be selected including one serving of potato (0.4 gm.). If to this are added string beans (1.05 gm.), spinach (0.45 gm.) and asparagus (0.35 gm.) the total from this source becomes 2.25 gm.



3. For the cereal food stuffs one whole grain cereal such as shredded wheat (0.78 gm.) with perhaps a slice of whole wheat bread (0.36 gm.) should be taken for breakfast. At each of the other two meals two slices of bread (0.72 gm.) may be used. The foods used in the example give a daily total of 7.03 gm. of fiber.

The authors conclude that an adequate fiber intake is important in the dietetic treatment of constipation. This fiber is supplied by three classes of foodstuffs — fruits, vegetables and cereals.

With the aid of the data furnished in the fiber-content tables, constipation diets may be planned on a quantitative basis.

For the relief of many, if not most cases of simple constipation, ordinary servings of fruit should be taken three times daily, preferably as deserts. It is suggested that the daily use of ap-

Help the Family Budget by Prescribing KARO

FOR INFANT FEEDING

Any prescribed food which abundantly fulfills the baby's need—and is available at low cost—is a boon to the mother, a blessing to the father. And the baby thrives! Karo Syrup is an effective carbohydrate. It is well-tolerated, practically non-fermentable, quickly utilized. The low price of Karo is based on its cost—not on its high value as an ideal infant food.

★ Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

For further information, write

CORN PRODUCTS SALES COMPANY, Dept. DN3, 17 Battery Place, New York, N. Y.

proximately 2 gm. of fruit fiber in addition to the "average" diet containing four vegetables and some whole grain foodstuffs, suffices in such cases. This amount would be supplied for example by six prunes, one banana and one medium-sized apple.

RANKIN, F. W. AND GRAHAM, A. S.

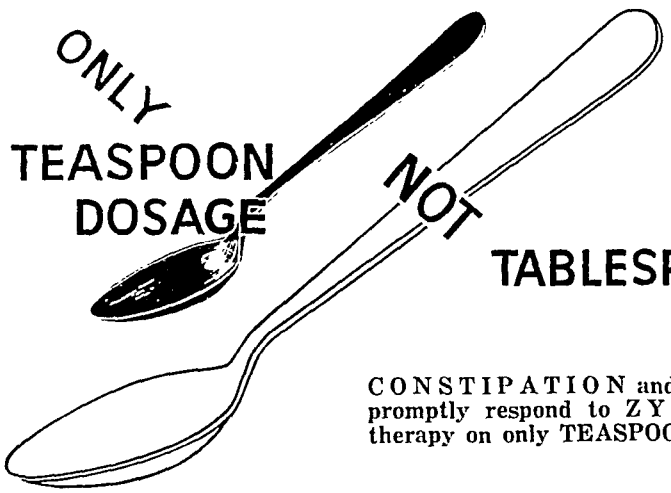
Closure of Colostomy. S. G. O., Vol. 64, No. 1, pp. 59-62, Jan., 1937.

In the experience of the authors more than one-half of the cases in which obstructive or exteriorization type of colon resection was done the colostomy closed spontaneously after a period of from 6 weeks to two months. Failure of the colostomy to close may be due to spur formation, attachment of the mucosa to the skin edges, or to obstruction beyond the colostomy.

The preparation of the patient for insertion of clamps should be as elaborate as that for the primary resection. The author uses long curved Kelly forceps which are inserted and closed to the first notch. Each subsequent day the clamps are tightened one notch. Usually the septum is cut through in 5-6 days, but occasionally a forcep will hang on for 8-9 days. It should never be pulled out—they should be allowed to fall out.

In closing the colostomy an elliptical incision is made through the skin, around the stoma down to the fascia. The index and middle fingers are now inserted into the two ends of the bowel, using them as retractors. The dissection is now carried down to the peritoneum on all sides. The margin of skin which has been left on the ends of the bowel are cut away and the stoma closed with two rows of chromic catgut sutures places transversely. A third row of sutures may be used if there is ample room, or it seems necessary. Any disparity between the size of the two segments of bowel may be overcome by splitting the wall of the smaller one. After flushing out the wound with saline and later ether, the fascia is closed by interrupted sutures. The skin edges are loosely approximated and rubber tissue drains are inserted down to the fascia. The percentage of closure by primary union is remarkably high.

Three figures accompany the article.



In discussing the transformation of gastric ulcer into gastric carcinoma the authors feel that the criteria by which such a diagnosis is arrived at are very difficult to evaluate. From their observations in the Gastro-Enterological Clinic of the Fourth Medical and Surgical Divisions of Bellevue Hospital during the last eight years they are obliged to question whether a gastric ulcer ever becomes malignant.

They reviewed 118 cases with carcinoma of the stomach. The diagnosis seemed quite certain. The average age of the patients was 56.7 years; 83 per cent were males. The average duration of symptoms was 45.3 weeks. In a review of 104 cases of gastric ulcer the average age of the patients was 47 years; 88% were males. The average duration of symptoms was 6 years. In this group of gastric ulcers 17 per cent were in the pyloric region—the region in which Holmes and Hampton thought carcinomatous degeneration most apt to occur. Those cases have been followed on the average of 15 months and the authors feel that they run no risk of carcinomatous degeneration.

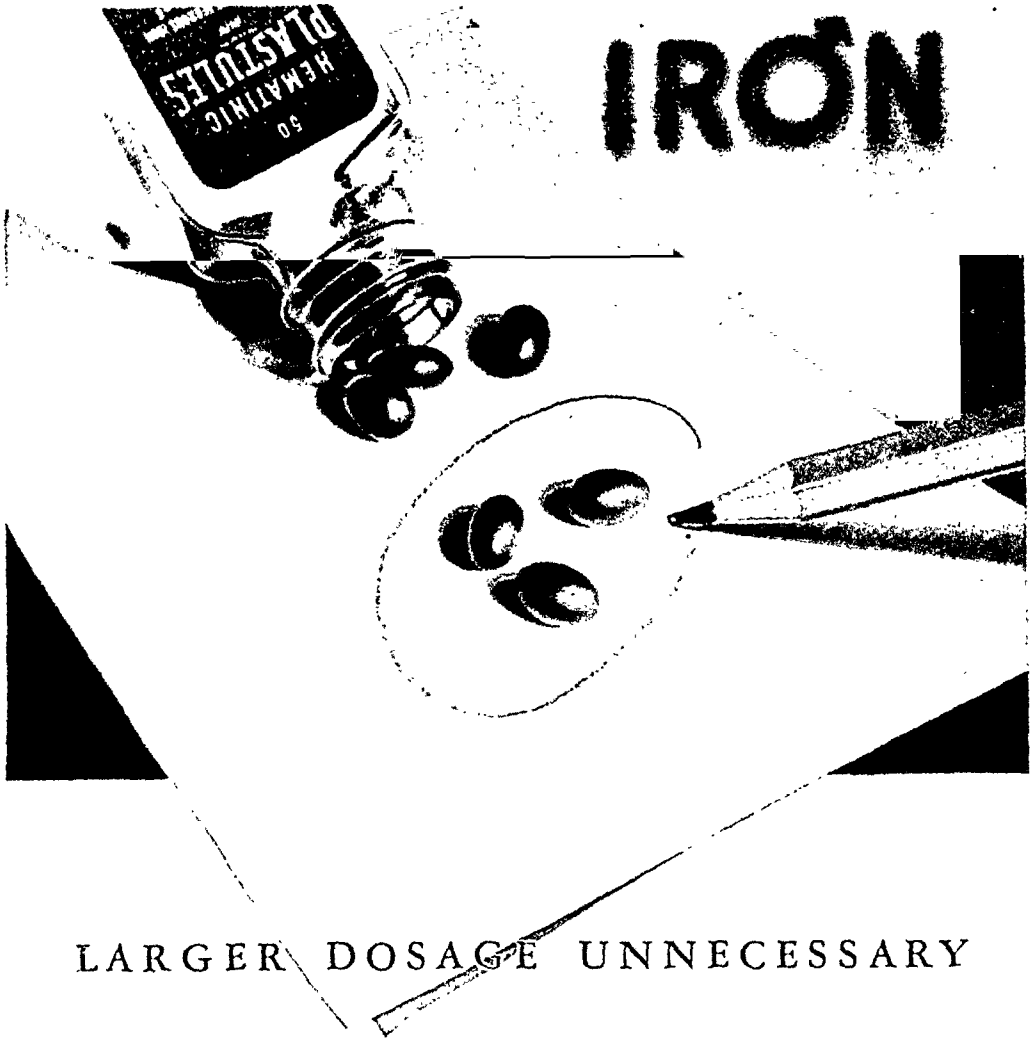
The author concludes that once a gastric ulcer always a gastric ulcer, but realizing that in an occasional case it is difficult to determine whether the lesion is a true benign ulcer or an early ulcerating carcinoma. Questionable cases, which should not constitute over 7 to 8 per cent of those coming under one's observation, should be submitted to resection.

N. M. Percy, Chicago.

AID NORMAL EVACUATION
WITHOUT ROUGHAGE or DRUGS

CONSTIPATION and COLITIS promptly respond to ZYMENOL therapy on only TEASPOON dosage.

ZymenoL—A stable, palatable emulsion of the Enzymes and Vitamins B-G of Brewers Yeast in Mineral Oil, is well tolerated and if desired mixes well in milk, water and infant feedings.



- No Irritant — No Phenolphthalein
- No Cascara — No Purgative
- Sugar Free — Ideal for Diabetics
- No Leakage — Less Expensive

Changes intestinal bacterial flora through catalytic activity of Enzymes of Brewers Yeast. Fecal mass becomes soft and bulky and regular evacuation results from natural impulse with well formed stool without gripe, strain or irritation.

Write for Samples!

HINTON, J. W. AND TRUBEK, M.

The Transformation of Gastric Ulcers into Gastric Carcinoma. S. G. O., Vol. 64, No. 1, pp. 16-21, Jan., 1937.

At the Central Emergency Hospital in Moscow the author has treated 426 patients with acute perforated ulcers during the period for 1933 and 1934. Less than two per cent of the patients were women. According to decades the greatest number occurred between the ages of 31 to 40; next in order of frequency of cases was the age group from 21 to 30. The number of perforated gastric ulcers increased with each decade up to the 5th, in which it outnumbered the perforations of duodenal ulcers. The greatest number of perforations occurred during the spring. The number during the summer, autumn and winter was about the same.

Because the incidence of cure of duodenal ulcer by gastric jejunostomy fell to 50 per cent when the patients were examined ten years after operation, and because those patients later were so frequently subjected to a radical gastrectomy under difficult conditions, and because of the high incidence of gastrojejunal ulcer after operation, the author has been convinced that primary partial gastrectomy with removal of the upper part of the duodenum in the majority of cases is the treatment of choice. In elderly or debilitated patients with extensive peritonitis, simple suture of the ulcer with gastro-enterostomy is done.

The type of resection employed is the Billroth I in about 80 per cent of the cases; the Polya-Balfour in about 20 per cent. The mortality from the resection cases in 1933 was 8.5 per cent in 210 cases. In 1934 it was 6.6 per cent in 121 cases. The mortality for all operated cases was 12.8 per cent.

Four figures accompany the article.

SANDWEISS, DAVID J.

Dietetic, Parenteral and Surgical Treatment in Peptic Ulcer. J. A. M. A., Vol. 108, p. 700, Feb. 27, 1937.

This report is based on observations made on 291 patients with peptic ulcer who were treated during 1,019 attacks. This group varied in age from fourteen to seventy-four years, consisted of both sexes and was made up of both private and clinic cases. They were divided into two groups: acute, or those with ulcer symptoms for less than five years; and chronic, or those with ulcer symptoms for more than five years.

The author found that approximately 90 per cent of private patients became symptom free with the dietetic-alkali management, and 75 per cent of the clinic ones. Of those who did not respond to the diet-alkali regimen, approximately 60 per cent became symptom free after injections of stock vaccine, larostidin or synodol. In twenty-two patients, distilled water was injected with comparable results. The author believes that the beneficial results obtained with the parenteral treatment were due to the psychic effect, not any intrinsic something in the material used. Some patients did not respond to any form of treatment, but when relieved of stresses and strains they became symptom free. Most of the patients in this series returned with recurrences, the period of remission being shortest in those treated by parenteral methods. This was probably due to the fact that the diet was not controlled as well in these cases.

It is believed that the diet should be restricted during the symptom free intervals as well as during recurrences. Of 155 patients treated medically and surgically, there were only five who were symptom free at the end of five years. The author believes that the parenteral method is indicated only in those cases which do not respond to diet and surgery, only where complications are present. At the present time, all one can hope to do is to relieve symptoms, delay relapses and pre-

SORICIN IN THE BOWEL

The physiological action of Soricin in the bowel has not yet been fully explained. This much *is* known: Soricin by mouth is non-toxic and harmless even in large doses. Soricin definitely aids in the treatment of such conditions as colitis, hypersensitivity of the intestinal tract and toxic absorption from the bowel as evidenced by symptoms of migraine, vertigo, and urticaria.

Soricin is effective because it is a detoxifying agent particularly adapted to internal administration. Its use is based on the clinical work of Dorst and Morris, Burger, Baker, MacQuiddy, Brown, Kline, Jackson, Mateer and others.*

Soricin (sodium ricinoleate) is available in two dosage forms:

Soricin Capsules (Enteric Coated):

10 grain size:
boxes of 20 and 100 capsules each

5 grain size:
boxes of 40 and 100 capsules each

Soricin Tablets (Enteric Coated):

5 grain size: bottles of 100 tablets

A Helpful Vehicle in Diabetic Diets

KNOX GELATINE (U.S.P.)

Diabetic diets can be lifted out of their monotonous rut with the aid of Knox Gelatine (U.S.P.). Forbidden foods are not missed so readily when a diabetic patient receives a varied diet containing tasty, pleasing, gelatinized salads and desserts.

Knox Gelatine is 85% protein, making it a simple task to compute any gelatinized dishes. As Knox Gelatine contains no sugar or flavoring, when planning a diet do not confuse it with a ready-prepared jelly powder. Specify Knox Gelatine and be certain.

KNOX GELATINE . . .

is scientifically made from selected long, hard, shank beef-bones — surpasses minimum U.S.P. requirements — contains no carbohydrates — fat content less than 0.1% — odorless — tasteless — bacteriologically safe.

Send the coupon below to receive helpful, informative literature and more fine recipes such as given below.

No Change in Blood pH Value

No Secondary Acid Rise

Because it produces acid fixation by a physical process rather than by a chemical reaction, Creamalin is not absorbed, and produces no change in plasma CO_2 or pH values. It may therefore be given in effective quantities, without danger of alkalosis.

* *

Creamalin—the distinctive colloidal cream of aluminum hydroxide—fixes 12 times its volume of N/10 HCl in less than 30 minutes. The constant and unvarying gastric anacidity so produced quickly leads to disappearance of pain and distressing pylorospasm. Healing is permitted to proceed rapidly—7 to 12 days with the continuous drip method (for which a special device, the Creamalin Automatic Drip Control, is offered), 3 to 6 weeks under oral administration. By using Creamalin in your next case of peptic ulcer, we can assure you a pleasant surprise, Doctor.

Reprints of published reports, together with sample of Creamalin, sent on request.

OPPENHEIMER, GORDON D., GLASS, AMEIL AND NETTER, FRANK.

Status of Cholecystogastrostomy in Obstructive Jaundice. J. A. M. A., Vol. 108, p. 707, Feb. 27, 1937.

A study was made of thirty-four patients on whom a diagnosis of carcinoma of the head of the pancreas, the common bile duct or the ampulla of Vater had been made. After laparotomy, a diagnosis of carcinoma of the head of the pancreas was made in thirty cases. All patients had a cholecystogastrostomy done except one who had a choledochoduodenostomy done. In all cases, the gall bladder was tense or distended.

"Of the thirty cases diagnosed as carcinoma of the head of the pancreas at operation, all with the exception of five were found to show this condition, or carcinoma of the common bile duct below the cystic duct or carcinoma of the ampulla of Vater. These five cases presented the following conditions: (1) cirrhosis of the liver, (2) subacute yellow atrophy, (3) carcinoma of the stomach with liver metastasis, (4) hepatosplenomegally, and, (5) chronic pancreatitis. The operation of cholecystogastrostomy was probably not indicated in the first four of the aforementioned cases."

Within the past year punch biopsies or small incisional biopsies have been done with the idea that early cases may be treated by a two stage operation.

The operative mortality was 41.3 per cent, while seventeen of nineteen patients discharged were known to be dead in three to twelve months after operation.

The author believes this operation is indicated in those cases in which there is a nonremovable obstructive lesion of the common bile duct below the cystic duct. It is also indicated in carcinoma of the pancreas or the ampulla as a palliative measure.

Francis D. Murphy, Milwaukee.

SMITH, FERRIS.

Lipoma of the Tongue. J. A. M. A., Vol. 108, p. 522, Feb. 13, 1937.

Lipoma of the tongue is a very rare condition, there being forty-four authentic cases in the literature. It has been found to occur at almost any age, some of the cases being congenital and appearing shortly after birth. It is more frequent in the male when a pure lipoma, but more frequent in the female when a fibro-lipoma. It may originate from the small masses of fat in the genioglossus muscle, in the preepiglottic fat or by a metaplasia of the connective tissue which separates the muscle bundles. The tumor is benign, the size varying from that of a grain of rice upward, and is usually located on the edge of the tongue and may be submucous, interstitional or intermuscular. The author reports a case of seventeen years duration which was cured by surgical removal of the growth.

Francis D. Murphy, Milwaukee.

DAY, P. F. AND DARBY, W. J.

Inverse Relation Between Growth and Incidence of Cataract. J. Nutrit., Vol. 12, 387, 1936.

Day and Darby gave 200 young rats a diet deficient in vitamin G. After a period of two weeks, daily supplement of vitamin-containing foods were given to all except a control group; 86 per cent of the controls developed cataract. The animals receiving vitamin supplement were grouped according to growth, and an inverse relationship between growth and cataract appeared. That is, the greater the growth, the lower was the incidence of cataract. Only a small amount of the vitamin was required to prevent cataract.

BOLKER, HERMAN, JACOBI, MENDEL AND KOVEN, MORRIS T.

Primary Carcinoma of the Liver with Bone Metastasis. Ann. of Inter. Med., Vol. 10, pp. 1212-1221, Feb., 1937.

A search of the literature only revealed nine cases of primary carcinoma of the liver with bone metastases. These nine reported cases are listed together with a detailed report of the history, physical and laboratory findings and autopsy findings of the authors' case.

The tumor from the authors' case is a parenchymal hepatoma, similar in gross appearance to several of those previously reported, though it did not occur in a previously cirrhotic liver. It is the only case with bone metastases in a woman, and occurred at 29 years of age, while seven of the nine others occurred in patients over 45 years of age. Characteristic extensive vascular invasion and bile production in the metastases were present. Metastases in the lung bed were not found after extensive search, which suggests a specific affinity of the neoplastic cells for the bone marrow in these cases.

The origin of this type of neoplasm is probably in the benign adenoma whether this be of the congenital type, or due to proliferation in the parenchyma distorted by cirrhotic change.

The tumor acts like an organ rather than tissue in its metastases and it is suggested that the metastases might have the physiologic activity of the original organ.

The authors call attention to the liver as a focus for metastatic bone neoplasm *in obscure* cases.

PROTECTION OF VITAMIN C IN CANNED FOODS AGAINST ENZYMATIC DESTRUCTION

• One of the unusual features of modern food preservation by canning is the high degree of protection afforded vitamin C during the canning procedure. Of all the vitamins, C is probably the most readily destroyed. Spinach, for example, will lose one-half its vitamin C content upon standing three days at room temperature and practically all of its antiscorbutic potency in seven days' time (1).

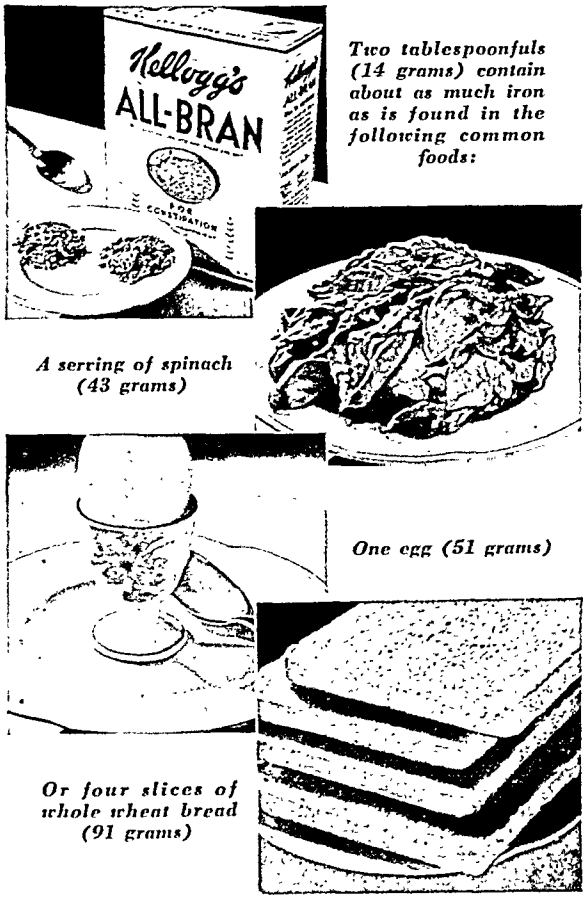
Oxidation is the principal factor operating in the destruction of vitamin C. The rate of oxidation depends—among other things—upon temperature, degree of exposure to oxygen, and presence of substances which catalyze the oxidation reaction. Chief among the catalysts is the enzyme known as ascorbic acid oxidase. This enzyme is instrumental in the loss of physiologically active forms of cevitamic acid (ascorbic acid) by catalyzing the transformation of this latter substance into dehydrocevitamic acid (dehydroascorbic acid), which is more readily decomposed by a nonenzymic reaction into a compound having no anti-scorbutic activity. This enzyme is apparently widely distributed in the vegetable kingdom, having been found in cabbage, carrots, lima beans, parsnips, peas, pumpkin, spinach, squash, string beans, sweet corn and swiss chard. Fortunately, the cevitamic acid oxidase is completely inactivated by heating to 100°C. for one minute (2).

In modern canning practice field crops are harvested at the optimum stage of maturity and canned as rapidly as possible—usually within a few hours' time. Early in every canning procedure the product receives either a blanch or a pre-cook or exhaust, the primary purpose of which is to drive out air from biological tissues and to establish a vacuum by expanding the contents of the can by heat, contraction upon cooling resulting in a partial vacuum within the can. These preliminary heat treatments together with the heat process serve both to destroy oxidative enzymes and to remove most of the air from the can.

Thus, the various practices in the canning procedure combine to afford excellent protection for this most labile accessory food factor known as vitamin C.

AMERICAN CAN COMPANY

230 Park Avenue, New York City



(1) 1935, Food Research, 1, 1 (2) 1936, J. Biol. Chem., 116, 71

This is the twenty-seventh in a series of monthly articles, which will summarize, for your convenience, the conclusions about canned foods which authorities in nutritional research have reached. We want to make this series valuable to you, and so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

Kellogg's ALL-BRAN furnishes iron for the blood

IRON is one of the important elements of the blood. Laboratory analyses show that Kellogg's ALL-BRAN is an excellent source of iron, in easily available form. It contributes a substantial amount of the iron needed daily.

This laxative cereal also furnishes vitamin B, which helps to maintain the muscular tone of the intestines. And ALL-BRAN also supplies generous "bulk." Within the body, ALL-BRAN absorbs twice its weight in water, and cleanses the system.

ALL-BRAN may be served as a cereal with milk or fruits, or cooked into recipes. Sold by all grocers. Made by Kellogg in Battle Creek.

ALT, HOWARD L. AND SWANK, RAY L.

Thrombopenic Purpura Associated with Catarrhal Jaundice: Report of a case. Ann. Int. Med., Vol. 10, pp. 1049-1053, Jan., 1937.

A patient has been observed in whom an acute thrombopenic purpura occurred simultaneously with an acute catarrhal jaundice.

A male, age 24, was admitted to the hospital complaining of malaise, epistaxis and jaundice which followed an upper respiratory infection one month before, and the gradual development of anorexia, muscular aching, constipation, discomfort in abdomen, highly pigmented urine, lighter colored stools and petechial spots for three days prior.

The significant laboratory data show an absence of blood platelets; no clot retraction; increased bleeding time; 3+ bile in the urine; a strongly positive benzidine test for occult blood in feces and in urine; increased quantitative van den Bergh; increased icterus index and a marked increased dye retention on functionally testing the liver. On duodenal intubation and administration of 100 c.c. of magnesium sulphate, a thin greenish mucoid secretion was obtained.

The patient was treated by transfusion of citrated blood and an injection of whole blood. Subsequently calcium gluconate, viosterol, and liver extract were given each day. He became entirely well and was discharged from the hospital three weeks after admission. There has been no recurrence of symptoms one and one-half years after the illness occurred.

Accompanying this report is a discussion of the etiologic relationship between thrombopenic purpura and catarrhal jaundice. Also evidence is presented which suggests a relationship between thrombopenia and liver disease.

SIXTEENTH ANNUAL SESSION AMERICAN CONGRESS OF PHYSICAL THERAPY TO BE HELD IN CINCINNATI IN SEPTEMBER

Cincinnati and its medical groups will be host to the American Congress of Physical Therapy which meets at Netherland Plaza Hotel, Cincinnati, September 20 to 24, 1937.

Never before has there been such interest and enthusiasm for an annual session as is being displayed this year for the September meeting. Plans are being made for a very large attendance which will be comfortably cared for at the Netherland Plaza Hotel.

Of special interest is the scientific program with its diversified symposia, clinical conference groups, demonstration clinics and sectional meetings. Every specialty in medicine and surgery will be adequately represented. The Scientific exhibits will be extensive and varied and should comprise an important part of the entire session. The technical exhibits will prove profitable in information to those who seek familiarity with the newer apparatus and equipment in physical therapy.

From every standpoint the 16th annual session offers an intensive "refresher" course in which will be embraced subjects like short wave diathermy, ultraviolet radiation, low voltage currents, exercise, massage, etc. Featured symposia include fractures, vascular diseases, poliomyelitis, fever therapy. There will be no registration fee but the meeting is open only to duly licensed physicians and properly vouched for technical assistants. Plan now to attend the Congress session in September.

SULFANILAMIDE

★

Outstanding Medical Development of a Decade

THE specific bactericidal action of Sulfanilamide on streptococci, particularly β-hemolytic streptococci, offers an opportunity to treat with every expectation of a favorable outcome many conditions formerly considered of grave clinical prognosis. Indications may include streptococcal cellulitis wherever encountered, puerperal sepsis and bacteremia, upper respiratory streptococcal infections, erysipelas, and certain forms of arthritis.

Recent reports on the use of Sulfanilamide in gonococcal infections are so encouraging as to suggest that a chemotherapeutic specific has been found for this type of infection also.

Tablets Sulfanilamide, Lilly, 5 grains (0.325 Gm.) are supplied in packages of 40, 100, and 500.

ELI LILLY AND COMPANY

Principal Offices and Laboratories, Indianapolis, Indiana, U. S. A.

ratory in the Research Department of the Company. The book, NUTRITIVE ASPECTS OF CANNED FOODS, has been prepared for doctors and scientific workers with canned foods. The earlier book, FACTS ABOUT COMMERCIALLY CANNED FOODS, was published last year.

The book is a general summary of facts about tin containers and canned foods. It is divided into two sections. The first deals with the preservation of foods, dietary requirements, the mineral and vitamin conservation in canned foods, infant nutrition, and the safety of canned foods under modern methods of packing. Section two takes up the manufacture of the cans, including the tinplating, enameling, and a description of can sizes. It also discusses the canning procedure from the raw materials through the sealing of the cans and the heat processing.

The back of the book contains an appendix of reference tables of all kinds. There are charts on human energy expenditures, dietary requirements, mineral and iodine content of various foods, and analyses of canned foods of many kinds. A bibliography contains an appendix of references to the more complete works on each phase of the industry as well as the general texts used in preparation of the book.

SUMMER DIARRHEA IN BABIES

Case C (calcium caseinate), which is almost wholly a combination of protein and calcium, offers a quickly effective method of treating all types of diarrhea, both in bottle-fed and breast-fed infants. For the former, the carbohydrate is temporarily omitted from the 24-hour formula and replaced with 8 level tablespoonfuls of Casec. Within a day or two the diarrhea will usually be arrested, and carbohydrate in the form of Dextri-Maltose may safely be added to the formula and the Casec gradually eliminated. Three to six teaspoonfuls of a thin paste of Casec and water, given before each nursing, is well indicated for loose stools in breast-fed babies. Please send for samples to Mead Johnson & Company, Evansville, Indiana.

"CONNOTATIONS"

Thomas Vicory, wrote in 1577, "The Chirurgeon must know the anatomie for all authors write against those surgeons that work in man's body not knowing the anatomie; for they be likened to a blind man that cutteth in a vine tree, for he taketh away more or less than he ought to do."

Our present knowledge of carcinoma of the gall bladder, except for detailed histologic studies is derived from the writings of Musser (1890), and Ames (1894).

Maxon, in 1868, reported a villous carcinoma of the gall bladder in a male child four years of age. Numerous writers refer to this unusual case. Maxon in his report, did not mention the age, although he did state that the patient was intemperate and a brush maker by trade.

Chaufford, in 1899, stated, "there is no disease of the gall bladder and ducts; the only disease is that of the liver cells themselves."

Glisson, in 1861, intimated that a sphincter of the common bile duct existed. In 1887, Oddi in an attempt to explain the cause of dilatation of the biliary tree observed and described the sphincter in both man and animals. Gage an anatomist described the sphincteric arrangement of the muscle fibers in 1879.

Brown-Sequard reported to the Societe de Biologi in Paris. June 1, 1889, the effect of subcutaneous injections of an extract of the testes which resulted in a remarkable increase of physical and mental powers. The subject was 72 years of age and oddly he himself was the patient. He is credited as having laid the foundation in theory and in clinical practice of the doctrine of internal secretion.

As early as 1797, Saunders stated because of the oblique manner in which the common duct traversed the duodenal portion of the intestinal its method of emptying is influenced by intestinal peristalsis. Concerning this observation much experimental work has been done and yet this question remains unsolved.

Comparison of the calcium content of liver bile and gall bladder, bile was first reported by Hoppe-Seyler in 1878.

The first case of displaced epiphysis of the femur was recognized by Brousseau in 1867. This was an accidental postmortem finding in a boy aged fifteen, who had received his fatal injury when a bicycle passed over his hip joint.

H. J. Sims, Denver.

CHEMICAL NATURE OF VITAMIN E ESTABLISHED

Important progress in establishing the chemical structure of vitamin E has been made by Dr. E. Fernholz at the Merck Research Laboratories, according to a statement issued recently by George W. Merck, President of Merck & Co., Inc., Rahway, N. J.

The work was undertaken at the suggestion of Dr. Herbert M. Evans of the Institute of Experimental Biology at the University of California, where much of the original work on the isolation of vitamin E and the investigation of its biological activity has been done in recent years. A report of this work by Dr. Fernholz has just appeared in the Journal of the American Chemical Society for June.

The work of Evans and his collaborators, starting in 1927, on the specific relation between a form of "habitual

In Constipation from "Restricted" Dietaries

MUCILOSE

(STEARNS)

Supplies Needed Bland, Hemicellulose-Bulk*

When constipation occurs as a result of special restricted dietaries, Mucilose supplies the bland *hemicellulose* (vegetable gum) which, according to Williams and Olmsted meets the deficiency.

Mucilose is bland, hygroscopic, lubricative, non-irritating, and makes the stool bulky, plastic and easily evacuated.

Mucilose is prepared by a special process from the Plantago loeflingii. It is now available in two forms, Mucilose *Granules* and Mucilose *Plain.* Both forms are as easily taken as breakfast foods.

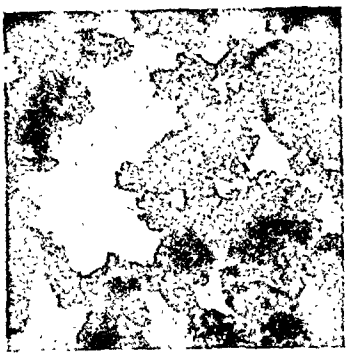
abortion" in lower animals and a deficiency in the diet, has demonstrated the presence of vitamin E in wheat germ, cottonseed and palm oils, and in lettuce. The lack of this vitamin in the diet of rats leads to a progressive disturbance in the nutrition of fetal placenta and to maceration and resorption of the fetuses in the uterus without affecting estrus and the faculty of fertilization. The administration of vitamin E in the form of wheat germ oil or suitable concentrates during the earliest stages of pregnancy is capable of anticipating and preventing this fetal destruction. Considerable evidence has been presented in the recent literature as to the efficacy of wheat germ oil in habitual abortion and stillbirth in women.

Last year Evans and his co-workers, O. H. Emerson and G. A. Emerson, succeeded in isolating from cottonseed oil a group of alcohols with the biological activity of vitamin E. These alcohols, the alpha-, beta-, and gamma tocopherols, appear to be isomeres with the empirical formula $C_{29}H_{50}O_2$, in which one of the oxygen atoms is present in a hydroxyl group. Evans and his collaborators have shown that these alcohols have characteristic absorption spectra which resemble that of hydroquinone. Tocopherols are easily oxidized with methyl alcoholic silver nitrate to give colored substances whose ultra-violet spectrum is suggestive of benzoquinone.

Fernholz, one-time student of Windaus in Gottingen, later Merck fellow at Princeton University, who has made important contributions to the chemistry of sterols, bile acids, and sex hormones, and who is now working in the Merck Research Laboratories, has recently studied the action of heat on this group of biologically active alcohols. Fernholz has found that, when alpha-tocopherol is heated, decomposition occurs with the formation of a crystalline compound which was identified as durohydroquinone, a well-known coal-tar product. This thermal degradation seems to be best explained by assigning to alpha-tocopherol the structure of a mono-ester of durohydroquinone. The ultra-violet spectrum of alpha-tocopherol, its insolubility in alkalies, and its high-reducing power as well as the lack of reducing properties in its esters, are in good agreement with such an assumption. Up to now it was generally assumed that vitamin E was chemically related to sterols and sex hormones. This work now establishes that no such relationship exists.

Within the past few years the intense attack on the structure of the vitamins has been eminently successful in leading to methods for their synthesis. The recent elucidation of the structures of vitamins C, B_2, and B_1 (cevitamic acid, riboflavin and thiamine) was followed rapidly by successful syntheses. Vitamin B_1, the anti-neuritic principle, and vitamin C, the antiscorbutic factor, are now being produced by Merck & Co., Inc., for medicinal and industrial use.



THE AMERICAN COLLEGE OF PHYSICIANS WILL MEET IN NEW YORK CITY, APRIL 4-8, 1938

The Twenty-second Annual Session of the American College of Physicians will be held in New York City, with headquarters at the Waldorf-Astoria Hotel, April 4-8, 1938.

Dr. James H. Means, of Boston, is President of the College, and will have charge of the program of general scientific sessions. Dr. James Alex. Miller, of New York City, has been appointed General Chairman of the Session, and will be in charge of the program of clinics and demonstrations in the hospitals and medical schools and of the program of Round Table Discussions to be conducted at headquarters.

Bisiodide

IN THE ORAL TREATMENT OF SYPHILIS

(High power view (x120°) of crystalline Bisiodide.)

Bisiodide is a chemical entity, not a mixture of substances. It is given by the mouth and safely replaces the painful injections of bismuth, furnishing also a distinct iodide effect. Bisiodide is brought to the attention of gastroenterologists because it does not upset even the most sensitive stomachs, and constitutes an efficient treatment of Syphilis.

Bisiodide may be ordered through the ethical drug trade.

Pablum is rich in minerals and vitamins. It is noteworthy that the calcium - phosphorus ratio of Pablum is 1.2:1, similar to that of average whole milk, which is considered the most favorable ratio for retention.

These figures are included to illustrate ordinary nutritional values. Calories, carbohydrates, fats, and proteins no longer constitute a serious nutritional problem.

†PABLUM (Mead's Cereal, thoroughly cooked) contains nine minerals (principally calcium phosphorus, iron, and copper) and vitamins B and G in substantial amounts—in addition to abundance of protein, fat, carbohydrate and calories. Pablum is palatable and requires no further cooking. Supplied in 1 lb. packages.

Protamine Insulin Compared to Regular Insulin in the Treatment of Diabetes Mellitus*

By

ABEL LEVITT, M.D., F.A.C.P.

and

CHRISTY F. CASTIGLIA, M.D.

BUFFALO, NEW YORK

THIS study is a review of 104 cases of diabetes mellitus in which protamine insulinate has been used since March, 1936. Regular insulin is rapidly absorbed and utilized so that it is almost impossible to produce a comparatively constant level of blood sugar. It was not until Hagedorn and his co-workers introduced protamine insulinate that this fluctuation of blood sugar levels was lessened to conform more closely with the normal. The history of protamine insulinate has been thoroughly reviewed in recent literature and, therefore, needs no further comment. The purpose of this paper is to give a comparative clinical evaluation of regular insulin, plain protamine and protamine zinc.

TYPES OF CASES STUDIED

We have attempted to study this subject not only in cases of uncomplicated diabetes mellitus, but also in cases where diabetic patients have been admitted to the wards of the Buffalo City Hospital for associated conditions. Therefore, we shall present our findings in five groups:

Group I. Those cases of diabetes mellitus where clinically there were no associated conditions.

Group II. Diabetes mellitus accompanied with degenerative changes such as arteriosclerosis, arteriolar-nephrosclerosis, coronary sclerosis, and peripheral vascular disease.

Group III. Diabetes mellitus associated with chronic pulmonary tuberculosis.

Group IV. In acute infections accompanying diabetes mellitus, among which were acute streptococcic infections, diphtheria and furunculosis.

Group V. This group we have designated "miscellaneous" and includes those cases where operative procedures were required.

At the outset of our study, the knowledge of the greater stability of the combined protamine and heavy metal product was not known. Therefore ,our reports will show comparative data obtained with the regular insulin, plain protamine insulin and the protamine zinc insulin.†

DIET

Previous dietetic management of our diabetics consisted of a diet high in carbohydrate, moderate in protein, and low in fat, with the caloric value being approximately 30 calories per kilogram of body weight daily and with an equal division of carbohydrate for the three meals. With the use of protamine zinc insulin we allowed the same caloric value but apportioned our carbohydrate in the ratio of 1/5 for breakfast, 2/5 for lunch, and 2/5 for supper. Hagedorn and his co-workers in their original work gave only about 100 grams of carbohydrate in a ratio of 2/5, 2/5, and 1/5, but we have found that as much as 260 grams, distributed as previously mentioned, does not predicate signs of hypoglycemia.

METHOD OF REPLACEMENT

At the inception, the problem of replacing the regular insulin by the protamine product was speculative. Hagedorn and his co-workers attempted substitutions of protamine insulin before supper with a reduction of the carbohydrate at this meal. Later, many investigators on the other hand, gave the protamine insulin alone in the morning, in sufficient dosage to approximate the previous amount of regular insulin used, or in conjunction with old insulin. Among our replacement methods, we included these plans. In our first use of protamine only those diabetics who had previously used regular insulin were studied. The regular insulin has been replaced by the protamine in the following ways:

1. To one group of patients, plain protamine was given as the evening dose, one hour before the evening meal but supplemented with the regular insulin before breakfast.

2. To a second group, we gave protamine zinc insulin one hour before breakfast, and for the first day or two, supplemented the protamine zinc with a small dose of regular insulin given ½ hour before breakfast, in order to allow for the slow action of the protamine material upon the carbohydrate of that meal.

3. To another group of patients, all severe diabetics, we found it necessary to divide the protamine zinc into two doses, giving one dose one hour before breakfast and the other, one hour before the evening meal.

Before protamine zinc became commercially available, we replaced the protamine standardized patients with regular insulin before they were discharged from the hospital and found this reversion to be well tolerated.

EFFECT ON BLOOD SUGAR

From our study, we have found that the lowest blood sugar level occurs from 18 to 24 hours following the injection of protamine insulin. Thus, if given before breakfast, the lowest blood sugar level will occur during the early morning hours; similarly, if protamine insulin is given with the evening meal, the lowest blood sugar level will occur in the late afternoon. We have used both of the above methods and in

*From the Diabetic Service, Buffalo City Hospital and Department of Medicine, University of Buffalo.

†The protamine zinc insulin was so supplied that each cubic centimeter contained forty units of insulin and approximately 0.08 mg. of zinc in combination with protamine in a precipitated form.

Submitted March 24, 1937.

our opinion the morning injection is preferred, for should hypoglycemia develop as a result of the cumulative effect of the protamine insulin, it could be more readily managed by the patient when at home, than if at work. As with regular insulin, there is a fluctuation of the blood sugar curve throughout the day, and a constant normal level of blood sugar is difficult to maintain with protamine zinc alone. This can be obviated by a supplementary dose of regular insulin. However, this practice necessitates an increased number of injections and tends to nullify one of the most valuable assets of the protamine product.

NUMBER OF INJECTIONS

The slowly soluble protamine insulin is injected into the subcutaneous tissue from which gradual absorption takes place over a considerable period of time. By this method there is a distinct prolongation in the time in which all the injected substance is utilized, resulting in a reservoir of insulin for the diabetic to drain and reducing the daily number of injections. In a reported series of 45 cases by Richardson, Russell & Bowie, it was found that the average number of injections of regular insulin was 2.3 and of protamine insulin 1.4 daily. We have obtained similar results in our series with a reduction from 2.15 injections daily of the regular insulin to 1.45 of the plain protamine and 1.05 injections of the protamine zinc product. In severe diabetics, it was frequently necessary to use as many as four doses daily of the regular insulin, with the fourth injection usually at midnight. Seven of our cases had required such administration with the regular insulin, a feature which was not necessary with the protamine zinc since a single dose was sufficient.

REACTIONS

The blood sugar variations in diabetic individuals which have been difficult to control with regular insulin are frequently maintained closer to normal levels by the use of protamine. The blood sugars reported in our study with protamine are the averages obtained from those taken just before berakfast, lunch, and the evening meal. While the sugar level may frequently go much lower with protamine insulin and may even at times descend to 30 milligrams, the severe symptoms of shock are not as evident. Our findings are consistent with those reported in the literature, that shock is much less frequent with protamine than with regular insulin. Instead of the rapid onset which has been noted in the past with regular insulin, the onset of shock with protamine insulin has been more gradual. This is doubtless due to the gradual lowering of the blood sugar to hypoglycemic levels rather than the rapid fall which occurs with the regular insulin. The most frequent complaint of patients in this series with hypoglycemia was a feeling of uneasiness, weakness and visual disturbance. Diaphoresis in a mild degree usually occurred later in the hypoglycemic state. In several instances sensory disturbances, such as numbness around the mouth and a paresthesia of the fingers and toes was noted. In some cases headache preceded the shock by hours, while in others it followed the treatment for hypoglycemia. Hypoglycemia due to protamine insulin, when it does occur, necessitates prolonged and frequent treatment in order to combat the prolonged effect and continuous supply of the protamine zinc insulin.

The following tables include our results with the groups as previously indicated:

TABLE I

Uncomplicated diabetes

	Cases	Av. Daily Units	Av. Daily Inj.	Av. Bld. Sugars
Reg. Insulin	48	47.45	2.46	205
*Plain Prot. Plus Supplementary Reg. Insulin	20	47.45	2.46	205
Reg. Insulin Before use of *Plain* Protamine	9	53.4	2.66	195.4
Plain Protamine Used Alone		51	2.1	153
Reg. Insulin before use of Protamine Zinc	22	47.3	2.5	193.3
Protamine Zinc Used Alone		35	1.16	150.6

*Three of the cases of this group of 20 were later treated with protamine zinc alone. All plain Protamine insulin given one hour before supper, and supplementary regular insulin given one-half hour before breakfast.

In a study of the comparative value of the regular insulin used in conjunction with plain protamine or with the protamine zinc compound in 48 cases of uncomplicated diabetes mellitus, it can be seen that the average daily number of units of regular insulin used was 47.45, while the average number of injections was 2.46 and the average blood sugar 205 mg. When plain protamine was supplemented with regular insulin in 20 cases out of the above 48, there was no change in the number of units, injections or blood sugar level. Nine cases of this group which required an average of 53.4 units of regular insulin daily, were reduced to 51 units of plain protamine while the average number of injections of 2.66 in these cases was reduced to 2.1 and the blood sugar level which had previously been 194 mg. was reduced to 153 mg. So that plain protamine insulin when used alone seemed beneficial in every way. 22 patients of this group who required an average of 47.3 units of the regular insulin, required only 35 units of the protamine zinc. The average number of daily injections dropped from 2.5 to 1.6 and the average blood sugars from 193.3 mg. to 150.6 mg. It can, therefore, be seen that in this group of 48 cases of uncomplicated diabetes mellitus with plain protamine alone there was a reduction in the number of daily units required, the number of daily injections and also a lower level of blood sugar prevailed. This was still further improved with the use of the protamine zinc product (Table II). In this group there were 19 cases of diabetes mellitus complicated by the cardiovascular-renal sclerotic syndrome. When placed on regular insulin with a maintenance diet these patients were sugar free with average daily units of 33.3 of regular insulin and required an average of 2.15 injections daily. This kept the blood sugar at an average of 178.4 mg. Twelve of these cases were then placed on plain protamine supplemented with the regular insulin and in order to keep them sugar free, they required an average of 43.4 units daily, while the average number of injections was reduced to 2 and

the blood sugar ranged about 161.2 mg. It is thus evident that the plain protamine in conjunction with the regular insulin results in an increase in the total amount of insulin used, but reduces the average number of daily injections and blood sugar levels. Six

TABLE II

Diabetes mellitus with degenerative diseases

	Cases	Av. Daily Units	Av. Daily Inj.	Av. Bld. Sugars
Reg. Insulin	19	33.3	2.15	178.4
Plain Protamine Plus Supplementary Reg. Insulin	12	43.4	2	161.2
Reg. Insulin Before use of Plain Prot.	6	34.5	1.93	161
Plain Prot. Alone		33	1.6	163
Reg. Insulin Before use of Protamine Zinc	3	37	2.5	208
Protamine Zinc Alone		12	1	162.2

patients of this group under regular insulin required an average of 34.5 daily units, with an average of 1.93 daily injections and showed average blood sugars of 161, and when placed on plain protamine alone showed a reduction of units to 33, reduction of injections to 1.6, while the blood sugars remained at 163 mg. Three cases of this group were then placed on protamine zinc alone and as seen from the (Table II) there was a marked reduction in the total amount of insulin required, the average daily number of injections and the height of the blood sugar.

TABLE III

Diabetes mellitus associated with chronic pulmonary tuberculosis

	Cases	Av. Daily Units	Av. Daily Inj.	Av. Bld. Sugars
Reg. Insulin	12	57	1.9	154

Reg. Insulin Before use of Plain Prot.	2	21	1.15	146.5
Plain Prot. Used Alone		19	1.5	171

Twelve cases of active pulmonary tuberculosis associated with diabetes required on an average of 57 units of regular insulin daily with an average of 1.9 injections. Their blood sugar hovered around 154 mg. Eleven of this group were then placed on plain protamine supplemented with regular insulin and the average daily units were reduced to 54, the number of injections remained the same but the blood sugar increased slightly to 158 mg. In this group due to the presence of the pulmonary activity and the general mental attitude of the patient, it was extremely difficult to obtain full cooperation in maintaining dietary requirements, so that there was considerable fluctuation in the results. Two patients of this group required an average of 21 units of the regular insulin daily and 1.15 daily injections, which resulted in an average blood sugar of 146.5 mg., but when placed on plain protamine the average daily units were reduced to 19, while the number of injections increased to 1.5 and the blood sugar increased to 171 mg. This, however, is too small a series from which to draw any conclusions.

Only one case has been given protamine zinc insulin and this is reported as a special case study and not included in Table III.

TABLE IV

Diabetes mellitus complicated by acute infections

	Cases	Av. Daily Units	Av. Daily Inj.	Av. Bld. Sugars
Reg. Insulin	12	37.2	2.3	194.6
Plain Prot. Plus Supplementary Reg. Insulin	9	38	1.4	147
Reg. Insulin Before use of Plain Prot.	3	26.5	2	211
Plain Prot. Used Alone		16	1	130
Reg. Insulin Before use of Protamine Zinc	4	46.9	2.84	274.9
Protamine Zinc Used Alone		32.9	1	133.9

A group of 12 diabetics previously controlled with the average daily units of 37.2 of regular insulin and requiring 2.3 injections and showing an average blood sugar of 194.6 were admitted to the hospital at different times with acute infections. Nine of this group were placed on plain protamine supplemented by regular insulin and required 38 units on an average daily, 1.4 injections and their average blood sugar was reduced to 147 mg. These, therefore, required a slight increase in the amount of insulin, but the injections and sugar levels were reduced. Another group of 3 patients who had required an average of 26.5 units daily of regular insulin with 2 injections and had an average blood sugar of 211 mg. were then placed on plain protamine alone and this resulted in a reduction of the average units to 16, the number of injections to 1 and the blood sugar to 130. Four patients of this group were then placed on protamine zinc alone. These four, while on regular insulin required on an average of 46.9 units daily with 2.8 injections and showed a blood sugar of 274.9. When changed over to protamine zinc the average daily number of units became subsequently reduced to 32.9, the number of injections to 1 and the blood sugar to 133.9 mg.

This group tends to show that with plain protamine supplemented by regular insulin the total number of units is increased but the average number of injections and blood sugar is reduced. Furthermore plain protamine alone results in a general reduction, while even better results are obtained with protamine zinc.

...Three diabetics who were admitted to the hospital

for some surgical procedure, following the operation were placed on their previous maintenance diet. It can be seen from the data above that with plain protamine, the total number of units and the number of

TABLE V

Plain Prot. Used Alone		14	1	135

injections were reduced without much change in blood sugar.

We have reviewed 104 cases of diabetes under treatment with protamine insulinate. The average daily number of units of regular insulin required by the entire group was 39.59, while the average daily injections were 2.15. This brought about an average blood sugar of 171 mg. Fifty-three cases of this group were placed on plain protamine supplemented with regular insulin and the average daily units were 43.97, the average daily injections were reduced to 1.95.

TABLE VI

Summary

	Cases	Av. Daily Units	Av. Daily Inj.	Av. Bld. Sugars
Reg. Insulin	104	39.59	2.15	171
Plain Prot. Plus Supplementary Reg. Insulin	53	43.97	1.95	162.4
Reg. Insulin Before use of Plain Prot.	22	30.24	1.88	162.78
Plain Prot. Used Alone		26.6	1.45	150.4
Regular Before Use of Protamine Zinc	29	43.7	2.61	228.9
Prot. Zinc Used Alone		26.6	1.05	148.9

This corresponds to our findings in the individual groups, where the total insulin was increased, but the average number of injections and blood sugar levels were decreased. In 22 cases, where plain protamine was used alone, the average daily units were reduced from 30.24 to 26.6 and the number of injections from 1.88 to 1.45. With the protamine zinc alone in 29 cases the average number of units of regular insulin was reduced from 43.7 to 26.6 and the number of injections from 2.61 to 1.05.

One difficulty we have noted is that we were unable to determine how much of a cumulative action we would obtain from protamine zinc. As we are now discharging patients standardized on protamine zinc on the wards to our outpatient clinic, we not infrequently have some return with reports of hypoglycemia. It is, therefore, essential that these cases be constantly observed for a considerable period afterwards in order to determine the amount of protamine zinc they require in carrying out their usual activities.

More recently we have had an opportunity to use U-80 protamine zinc insulin. This preparation seems more efficient in controlling the blood sugar level than the U-40 material reported above. In comparing the U-40 and U-80, in a group of five patients who required 67.4 average daily units of the former, this was reduced to 60.8 of the U-80 and the blood sugar levels reduced from 103.6 to 100.9. It has an added advantage to patients who require large doses of insulin.

CONCLUSIONS

1. Our studies tend to show that protamine when supplemented with regular insulin results in an increase in the total number of units per day but there is a slight reduction in the number of injections, and most important a lower and more normal blood sugar level.

2. When plain protamine is used alone there is a considerable reduction both in the amount of insulin and in the number of injections, while the blood sugar level is not only reduced but frequently is considerably below the normal level approximately 24 hours after the injections.

3. Protamine zinc gives the best results in all of the above mentioned points.

CASE REPORTS

Case I. L. M., a colored female, 43 years of age, was admitted to the diabetic service of the Buffalo City Hospital with a history of diabetes of six months duration. No family history of this disease.

Physical examination revealed a moderately obese colored female not acutely ill, no physical abnormalities were noted. The diagnosis was diabetes mellitus and moderate obesity. The patient weighed 161 pounds and was placed on a diet of 160 grams of carbohydrate, 70 grams of protein and 80 grams of fat. Her blood sugar upon admission was 362 mg. per 100 c.c. of blood and there was 9.2 grams of urinary sugar present. At this time she was given regular insulin, 10 units in the morning and 8 units at night. This insulin was increased to 12 units in the morning and 12 units in the evening and blood sugar at that time was 198 mg. while there was still glycosuria. Protamine zinc was started and the patient received 20 units one hour before breakfast, which was gradually decreased to 10 units in one injection one hour before breakfast. The blood sugars varied from 90 to 138 mg. throughout the day and there was no glycosuria. This patient is a mild diabetic and was standardized within ten days and has remained with same dose of protamine since discharged from the hospital.

Case II. B. L., a white female, 59 years old, was admitted to the diabetic service with a history of diabetes for the past five years. She had had polydypsia, polyuria, weakness, pruritus and a loss of 40 pounds of weight over this period of time. Physical examination was essentially negative. Her weight was 127 pounds and she was placed on a diet of 220 grams of carbohydrate, 70 grams of protein and 70 grams of fat. Her blood sugar on admission was 246 mg. and urinary sugar 7.5 grams. Regular insulin 18 units before breakfast and 15 units before supper was given which was increased to 35 and 25 respectively and at this time her blood sugar was 262 mg. and the urinary sugar was 4 grams. Since the blood sugar remained persistently high and glycosuria continued, this patient was

placed upon 55 units of protamine zinc one hour before breakfast followed by 14 units of regular insulin one-half hour before breakfast and 10 units of regular insulin one-half hour before supper. The protamine zinc insulin was gradually decreased to 35 units in one daily injection given one hour before breakfast. Her blood sugar values with only one injection varied from 92 to 118 mg. throughout the day and her urine remained sugar free.

Case III. M. H., a white female, age 19, was admitted to the acute communicable service with a history of an upper respiratory tract infection of one month duration with nasal discharge and sore throat one week prior to admission. She had had diabetes for the past 5 years. Physical examination revealed a well developed white female acutely ill with a temperature of 101.4, pulse 120 and respiration of 36. Her pharynx and larynx were inflammed and the tonsils cryptic, pus was present in both nares and the turbinates enlarged. The chest was clear and resonant and the heart was regular but rapid.

There was no skin eruption and the remainder of the examination was essentially negative. Positive nose and throat cultures for diphtheria were obtained and these proved to be virulent by the guinea pig test. The diagnosis was (1) acute laryngitis and pharyngitis and (2) diphtheria carrier.

The patient weighed 142 pounds and was given a diet of 160 grams of carbohydrate, 70 grams of protein and 80 grams of fat. Her blood sugar at time of admission was 562 mg. and there was 34.5 grams of urinary sugar. Regular insulin therapy was instituted in a dosage of 35 units in the morning and 24 units before supper and 10 units at midnight which was gradually increased to 70 units before breakfast, 15 before lunch, 40 before supper and 10 at midnight, during which time blood sugar never fell below 400 mg. and there was persistent glycosuria. Protamine zinc insulin was started in dosage of 65 units in the morning and 25 units at night. Eventually the night dose was discontinued and the patient was given only a single injection of 80 units one hour before breakfast. Following the use of the protamine zinc the blood sugars approached normal and in no instance following the use of this product did it go above 153 mg., while the urine remained sugar free. At present the patient is up and about, the temperature, pulse, and respirations are within normal limits, but nose and throat cultures remain positive for virulent diphtheria organisms.

Case IV. R. W. is a white male, age 13, who was admitted to the tuberculosis service with a history of diabetes of 2 years duration. His father died of chronic pulmonary tuberculosis and diabetes mellitus. Physical examination revealed an acutely ill and emaciated white male. Positive findings on examination were bilateral apical infiltration with cavitation. His heart was rapid but regular and the other systems were essentially negative. His weight at this time was 53 pounds while his temperature was 103, pulse 130 and respiration 26. He was diagnosed as (1) Chronic pulmonary tuberculosis, (2) diabetes mellitus, (3) malnutrition and (4) anemia. All sputa were positive for tubercle bacilli and X-ray showed bilateral apical infiltration with multiple cavitation. He was given a diet of 230 grams of carbohydrate, 80 grams of protein and 110 grams of fat, and placed on regular insulin 30 units before breakfast, 10 before lunch, 30 before supper and 5 at midnight. His blood sugar at this time was 440 mg. and there was 62 grams of urinary sugar. Because the blood sugar remained persistently high the regular insulin was increased to 60—30—30—10 and at this time the blood sugar was 210 mg. and glycosuria persisted. Therefore, it seemed advisable to inaugurate protamine insulin therapy and he was given at the beginning 75 units of protamine zinc one hour before breakfast and 25 units before supper. Within four weeks the evening dose was discontinued and the patient controlled upon 85 units of protamine zinc insulin one hour before breakfast. The blood sugar levels were lowered to within normal limits and the urine remained sugar free. At the present time the patient weighs 79 pounds and the most recent X-ray shows a tendency toward fibrotic healing in both apices.

The Authors wish to express their appreciation to Dr. Allen A. Jones for his constructive comments and to Dr. D. Levy for his assistance in compiling the statistics and graphs.

The Effect of Nicotine on Intestinal Peristalsis

By

WALTER C. ALVAREZ, M.D.*
ROCHESTER, MINNESOTA

YEARS ago I began using nicotine in an attempt to learn more about the structure and function of the intestinal plexuses. I could, of course, read in any textbook the statement that nicotine blocks the peristaltic waves while it leaves unchanged the rhythmic contractions, and that it blocks the effects of stimulating the vagal and the preganglionic sympathetic neurones while it does not block the effects of stimulating postganglionic sympathetic fibers. But I knew that in recent years a number of these old accepted statements had come to be questioned, I knew that the whole conception of synapses and the effects of drugs on them was changing, and besides, there were a number of interesting questions that might yet be answered by further study of the action of nicotine on the bowel. I wanted to see how its action on the neurones of the gut would compare with that of

*Division of Medicine, The Mayo Clinic, Rochester, Minnesota. With the technical assistance of Mildred Bennett and, in some of the experiments, of Kiyoshi Hosoi and Eola Woolley.
Submitted June 2, 1937.

anoxemia. Using rabbits as test animals and anoxemia as an injurious agent, I had found that some mechanism, probably a nervous one, interrupted by synapses, and very helpful in the production of peristaltic rushes, became disrupted from ten to thirty minutes after the stoppage of the circulation. What appeared to be nervous conduction along short conducting paths was lost in about two hours, while nervous conduction through long unbroken pathways, and the rhythmic contractions of the muscle began to fade out only after seven hours or more. In all these experiments the tissue was kept at 38° C. in aërated Locke's solution.

I here report the results of using nicotine much as I used anoxemia to obtain information as to the structure of the enteric nervous system (3). Before describing the experiments, it will be helpful to stop for a moment to see what one can hope to accomplish with nicotine. Years ago, when I began to work with it, I assumed, as do most writers of articles and textbooks, that it would block transmission through sympathetic ganglions and across such synapses as are believed to exist between the vagal nerve endings and the neurones in the plexuses of the heart and intestine; but the more I read, the less certain I became that nicotine could be counted on always to do the things that have been expected of it. Thus, years ago, Langley (49) and others noticed that it commonly did not interrupt the transmission of reflexes through centers in the medulla and spinal cord, and that sometimes it did not have the expected effects even on the nerve centers in the bowel (Langley and Anderson).

Recent studies have shown also that the drug can affect nerve endings, and that the disturbances of respiration are not due to the disruption of synapses in the center in the medulla but to a curare-like effect on phrenic nerve endings in the diaphragm (Dixon, Langley and Dickinson, Thomas and Franke, Franke and Thomas, Gold and Brown, and Ing). Still more disturbing was the discovery that in large doses it actually improves the transmission of stimuli from the vagal neurones to those of the myenteric plexus (Langley and Anderson, Thomas and Kuntz (74), Mulinos, Henderson). To be remembered also is the fact that, in very large doses, it can block transmission through nerve fibers (Pi-Suner and Raventos, and Raventos (67, 68)) and it can injure muscle (Lapicque) and other tissues (Greenwood).

Often a dose which will interrupt synapses in one ganglion or set of ganglions, as in the heart, will leave others, as in the intestine, unaffected; or with a certain dosage, the effects of vagal stimulation on the heart will be blocked while transmission of stimuli from one vagus to the other through the center in the medulla can still be effected (Pi-Suner and Raventos). Furthermore repeated doses commonly fail to produce the effect of the first dose (Gold and Brown).

Writers on the subject commonly assume that nicotine paralyzes ganglion cells, but Langley (49) could not be sure of this, and I have been unable to find much evidence of it in the literature. For that matter, I cannot find much on how one would tell when a ganglion cell has lost its function. Perhaps the best evidence that nicotine can injure a ganglion cell was obtained recently by Heinbecker and Bishop while studying the heart of Limulus. In this organ, as is well known, the beat of a muscle, itself capable of rhythmic activity (Carlson and Meek, Garrey, Crozier and Stier, Heinbecker and Bishop), is normally influenced by outside ganglion cells (Heinbecker). Here nicotine promptly blocked the usual effects of stimulating the extrinsic inhibiting and accelerating nerves; after from fifteen to thirty minutes, the electrical record of discharges coming from the ganglion cells faded out, and from five to fifteen minutes after this the heart ceased beating, although the muscle was still responsive to electric stimulation of the median nerve-cord.

These observations indicate that the synapses between the extrinsic nerves and the local ganglion cells are most sensitive to attack by nicotine; next in susceptibility probably come the ganglion cells, next the function of rhythmicity in the muscle, and last of all the functions of conduction in local nerve fibers and their endings, and of irritability in the muscle. Instructive also in this regard is the old experiment of Carlson (1909) who found that a 1:1000 solution of nicotine applied to the heart of Limulus took ninety-four minutes to stop rhythmic activity in the ganglion, 265 minutes to destroy irritability and conductivity in the nerve plexus, and 1140 minutes to destroy irritability and contractility in the muscle.

That in the heart of Limulus the pace-making impulses come only from the large unipolar ganglion cells found in certain parts of the nerve cord and not from the small multipolar cells or from the axone fibers is now strongly indicated by the work of Heinbecker. The evidence presented in the two papers by Heinbecker and Heinbecker and Bishop suggests, then, that nicotine puts a stop to the rhythmic impulses which arise in the big pace-making ganglion cells.

In the case of the bowel of mammals the assumed synapse at the end of the vagal fibers is sensitive to small doses and extremely resistant to large doses of nicotine (Kuntz and others (47)); the synapses in Auerbach's plexus seem to be highly susceptible, as shown by the usual prompt stoppage of rush waves; and the ganglion cells, much perhaps as in the heart of Limulus, are apparently fairly susceptible, granting that one can assume this from the fact that nicotine suppresses the rhythmic action currents of the gut while it leaves the muscle beating regularly at a slower rate (Berkson, Puestow (7, 8, 9, 10, 11)). It is conceivable, of course, that in the bowel the suppression of the rhythmic currents is due to injury to synapses in an oscillating nervous circuit such as that conceived by Lorente de Nó.

According to Himwich and Fazikas, nicotine probably interferes with the metabolism of nervous tissue by blocking the dehydrogenation of lactic and succinic acids. According to Ing, nicotine, like curarine, is a chemical antagonist to acetylcholine, which may account for its ability to block conduction in some synapses. Curiously, physostigmine is able to restore the function of vagal synapses in the heart after they have been blocked by nicotine or barbiturates (Linegar, Dille and Koppanyi).

Efforts have been made to throw light on the point of attack of nicotine by comparing its actions on normal bowel and on bowel from which Auerbach's plexus has been stripped with the help of a dissecting needle. Thus, Magnus concluded that "plexus-free" strips of intestinal muscle would not respond to nicotine, but van Esveld and Gasser observed depression with large doses; it was only the stimulating effect that could not be obtained.

Unfortunately, definitely plexus-free muscle can probably never be secured by dissection. One can get muscle free from either Auerbach's or Meissner's plexus, but one cannot remove the fine intramuscular plexus of fibrils which some observers say are related to connective tissue and others feel sure are nervous in origin (van Esveld, Tiegs (76, 77), Schabadasch). As Bayliss once said, however, it does not seem probable that such fibers or the occasional ganglion cells that can be found on blood vessels can serve to originate the regular rhythmic contractions of the muscle. The recent observations of Heinbecker, already quoted, make this assumption still more doubtful, but still it cannot be dismissed.

So far as the action of nicotine on the bowel is concerned, the classic experiment is the one in which the drug was shown to block the effect of stimulating the preganglionic but not the postganglionic fibers (Langley and Anderson, Langley (48), Bunch). From this it was assumed that the preganglionic fibers which enter the bowel are connected by synapses to neurones in Auerbach's plexus, while the postganglionic fibers run directly to the muscle. Much confirmation of this idea has been published by Nolf and others, but in recent years a number of observers besides myself have found that large doses of nicotine can block the effect of stimulating the postganglionic fibers (Thomas and Kuntz (47, 75), Hendricks and Thienes).

In the face of the many contradictions to be found in the literature on nicotine, and the many puzzling observations which will be recorded in this paper, it would seem unwise to theorize much about the results of experiments done with this drug. This is particularly true at a time when our conceptions of function at nerve endings is changing rapidly, and the actual chemical intermediaries between nerve and muscle are becoming known.

TECHNIC

The technic used in the studies here reported has been described elsewhere (1). Briefly, rabbits were anesthetized with urethane, the spinal cord was pithed distal to the fourth thoracic segment, and the abdomen was opened under a bath of warm Locke's solution. Records were obtained with the help of apparatus described elsewhere (2).

There were two main ways open for studying the effects of nicotine on the gut. The first method, in which the drug was injected intravenously or intramuscularly, had the disadvantage that it usually put a stop to the peristaltic rushes which I wished to study. The second method consisted of connecting a segment of gut to light recording levers, bathing it for a few minutes in a solution of the drug, dropping it back into the tank, and then studying the behavior of rushes that reached or passed through it.

As was to be expected, the concentration of nicotine necessary to injure synapses in the bowel had a decided effect on some of the functions of the brain. Thus, in a medium-sized rabbit, 0.05 c.c. of a 1 per cent solution, or 0.5 mg., injected into the ear vein usually produced some change in the rate and depth of the respiratory movements; occasionally it produced convulsions, and sometimes if the animals were not helped to breathe, it promptly killed. Usually the peristaltic rushes were stopped. With twice the dose, or 0.1 c.c., peristaltic rushes usually stopped and the animal died unless respiration was maintained artificially.

When the drug was injected intramuscularly, at least 0.02 c.c. of the undiluted substance was needed to get results. When an animal survived such a dose it was often possible, a few minutes later, to give larger doses, and sometimes, with respiration maintained artificially, the animal would live on after huge doses of the poison had been given.

Dosage of nicotine used. Because varying dosage can greatly modify the effects obtained, it might be well to review briefly the concentrations of the drug used by a number of investigators. To abolish the effects of vagal stimulation on the bowel Bayliss and Starling used 0.3 c.c. of a 1 per cent solution. Mulinos used from 1 to 10 mg. per kilogram of body weight. Raventos (69) blocked conduction in the vagus nerve with a solution of 0.5 to 1 per cent. Thomas and Kuntz used from 1 to 20 mg. per kilogram to paralyze vagus endings and from 25 to 50 mg. to restore them to activity. From 2000 to 3000 mg. per kilogram were then required to stop them again. Mulinos restored the vagus effect with from 20 to 60 mg. To "denervate" the excised bowel Thomas and Kuntz used a 0.2 per cent solution. Rhythmic contractions were abolished with the help of a 0.5 per cent solution. Heinbecker and Bishop used a 0.5 per cent solution on the heart of Limulus.

Hendricks and Thienes abolished the effects of stimulating postganglionic sympathetic fibers with a 1:1000 solution. Nolf used from 1:10,000 to 1:1,000,000 on the bowel of the chicken, the latter strength being apparently sufficient for the blocking of synapses. Bunch used 1 mg. per kilogram to abolish the effects on the intestine of stimulating the extrinsic nerves. Langley (49) usually used a 1 per cent solution. Bayliss and Starling stopped the rhythmic contractions of the bowel by injecting 2 or 3 c.c. of a 1 per cent solution into a fairly large dog. They blocked vagus nerve endings with 0.3 c.c. of a 1 per cent solution. Franke and Thomas (28) lost several dogs after giving doses of from 2 to 4 mg. per kilogram. Macht paralyzed the ureter with a 1 per cent solution. My impression is that if one hopes to study the effect of the drug on synapses or ganglion cells one should use the smallest dose that will stop function in these structures; with larger doses the drug is likely to act as a general protoplasmic poison.

Effects of altered nicotine. From the start of my work I had difficulty in obtaining the results I had been led to expect with nicotine, but as months passed I ran into an even worse trouble, namely, I could not duplicate the results of experiments performed earlier in the year. The nicotine I was using looked and smelled all right, and when injected into animals caused death in the usual way; there was the usual beady appearance of the gut, and the usual slowing and strengthening of the rhythmic contractions, but no longer could I be sure that even a large dose given by vein would stop the peristaltic rushes. Curiously, the drug still interfered with the rushes when, well diluted, it was applied directly to segments of gut. In one animal, killed by repeated injections of a large dose, a fairly normal rush was seen just before death, and shortly after, two good rushes were elicited by an intravenous injection of epinephrine.

Finally, it occurred to me that I was using nicotine from a bottle which had been around the laboratory for some time. Although this bottle was made of dark amber glass I still feared that light might have af-

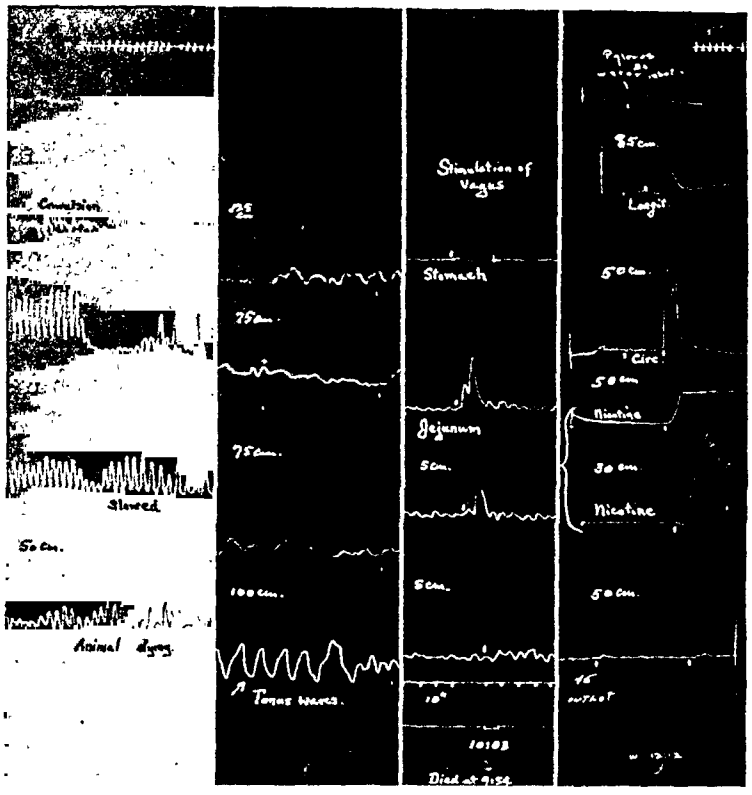

Fig. 1*a*. Inhibition of rhythmic movements and slowing of the rate of rhythmic contraction in an animal dying of nicotine poisoning; *b*, tonus waves in an animal severely poisoned with nicotine; *c*, responses to stimulation of a vagus nerve in an animal that had died nine minutes before from an overdose of nicotine, and *d*, defective emptying in a segment poisoned with nicotine.

fected the contents. Accordingly I opened a new bottle, and immediately found that its contents would almost always stop peristaltic rushes. It may be of interest in this connection that Pacini and McGuigan and Wakeham and Tracy found marked changes in the toxicity of nicotine exposed to ultraviolet radiation.

My experiments revealed, then, a curious change in nicotine which left it as toxic as ever to the central nervous system but without some of its usual paralyzing effect on the mechanism that produces peristaltic rush. It would be helpful if someone could penetrate the secret here concealed. Certain it is that hereafter any physiologist who wishes to study the effects of nicotine on the bowel must first make sure that his supply of the drug is fresh and capable of stopping peristaltic rushes.

EFFECTS OF NICOTINE HERE REPORTED

Appearance of the nicotinized bowel. The nicotinized bowel commonly took on a beaded appearance which suggested either an incoördination of the activity of the muscle bundles or a peculiar form of local stimulation. The appearance of this beadiness was helpful in that it served to show the experimenter when enough nicotine had been given to produce an effect. It probably was not due to failure of conduction along nerve fibers because sometimes it disappeared after a few minutes, at a time when the nervous mechanism that facilitates the passage of rushes was still out of order. Furthermore, such beadiness is not typical of bowel which has lost its power to conduct through long continued anoxemia. I think, therefore, that the beadiness is due at least in part to the well-known stimulating effect of nicotine on nervous tissue. On one occasion a slow rush was seen to pass through a beady bowel, which suggested that if rushes are dependent on the integrity of synapses, then beadiness cannot be depended on as a sign of injury to these structures.

Effect on rhythmic contractions. I found, as others have done, that the rhythmic contractions are usually slowed, are often made more regular, and the amplitude is commonly increased (Fig. 1, *a*). The greater amplitude shows that there is no impairment of conduction in the fibrils which presumably enable many muscle fibers to contract as a unit. As Bayliss and Starling and Trendelenburg noted years ago, the fact that the rhythmic activity is improved at a time when the peristaltic rushes are stopped, and the animal is perhaps dying, indicates that nerve cells are not important in producing the phenomenon. Their argument is even stronger now that Heinbecker and Heinbecker and Bishop have presented evidence indicating that nicotine does put a stop to the activity of pacemaking ganglion cells.

A slowing of the rhythmic contractions similar to that observed with nicotine is seen immediately after the death of the animal or after the removal of the

bowel to a tank of oxygenated Locke's solution, or after degenerative section of the vagus or the splanchnic nerves. This suggests that although the muscle alone is capable of rhythmic contraction, the rate at which this contraction is maintained is normally elevated by some stimulus or chemical substance which arrives by way of the extrinsic nerves of the bowel.

The situation may be similar to that in the heart of Limulus where nerve impulses alter the rhythmic activity of the muscle without imposing their rhythm on it (Heinbecker and Bishop). As Hoagland pointed out, rhythms can be altered by chemical substances that simply change the rate of the metabolic processes in the nerve cells.

van Esveld concluded from his work that the rate of rhythmic contractions in "plexus-free" intestinal muscle is not affected by nerve poisons, but Figure 3 in Gasser's article would indicate that it can be slowed by nicotine. Thomas and Kuntz (75) concluded that when nicotine slows the rate of rhythmic contractions it is a sign that the drug has thoroughly denervated the bowel.

Curiously, Elliott found that although nicotine did not stop the rhythmic movements of the cat's bladder, denervation produced by picking off the ganglion cells with the help of fine forceps and a dissecting microscope, did stop them.

When, as sometimes happens with massive doses, the rhythmic movements of the bowel are stopped by nicotine, the effect is probably a toxic one on the muscle. Puzzles remain, however. Thus, in one of my experiments, an initial dose of 0.05 c.c. of nicotine given intramuscularly almost killed the animal and almost stopped the rhythmic contractions. Later, when after a dose of 0.45 c.c., respiration was almost stopped and death was imminent, the rhythmic activity of the bowel returned to normal.

Strangely, in a number of the animals killed by nicotine, the rhythmic activity of the bowel was good up to the moment of death, and then the contractions stopped just as they commonly do when a normal rabbit dies (Fig. 1, *a*). Such stoppage in normal animals is not due to anoxemia alone, because when the bowel is cut away from the mesentery, contractions return, and they can then be maintained for hours. There are reasons for believing that the pause is due to chemicals formed in the blood at the time of death.

Effect on short nervous tracts in the bowel. In rabbits the contraction produced by an interrupted electric stimulus spreads out for from 5 to 20 cm. along the bowel. This type of conduction, which seems to be mediated by nerves (Alvarez and Hosoi, Elliott, Eugling, Henderson) was interfered with by nicotine only when the dose of the drug was so large as probably to injure the muscle and to destroy its ability to contract. From this and other experiments to be described later, I conclude that nicotine, in doses sufficient to stop peristaltic rush, leaves the intestinal nerve fibers and nerve endings in good working order. About the only evidence against this view is that of Fleisch who thought that the short-distance conduction observed in the guinea-pig's bowel was blocked by nicotine. He may perhaps have used a dose that injured the muscle.

Effects on stomach and colon. It is interesting to note here that Cannon (15) found that the giving of nicotine or the making of several parallel cuts through the muscular coats of the stomach was without effect on the gastric waves (see also Thomas and Kuntz (75)). Similarly, nicotine had no effect on colonic reverse paristalsis (Elliott and Barclay-Smith, Cannon (15, 16)). These facts fit in with others, all of which indicate that the conducting mechanisms in the stomach and colon are different from those in the small intestine.

Effects on tonus waves. The tonus waves of the bowel were sometimes abolished by nicotine, at least for a time, which perhaps fits with the conviction of Gross and Clark that these waves are neurogenic in origin. Kuntz and Thomas (47) also noticed a loss of tonus waves after giving nicotine. I found them, however, well marked in records made from heavily nicotinized bowel, so the subject is still open to debate (Fig. 1, *b*).

Effect on irritability. The irritability of the bowel to faradic stimulation was not lowered until large doses of nicotine were used, and even then it was not always affected adversely. I have obtained excellent responses to faradic stimulation in bowel just removed from animals killed by an overdose of nicotine.

Effect on the vagal synapse. I confirmed the statements of Thomas and Kuntz, Mulinos, and Henderson to the effect that nicotine in large doses does not block the effect on the bowel of vagal stimulation. Actually, I obtained records showing definite response to such stimulation in the intestine of animals which, a few minutes before, had succumbed to a large dose of nicotine (Fig. 1, *c*). In one animal these responses continued for twenty minutes after death, or until the moment when one would expect anoxemia alone to put an end to function in the synapse.

I assume that such a synapse exists partly because it has been seen by histologists (Hill, Irwin). Another argument in favor of its existence is the old one of Langley (50) who pointed out that there are not enough nerve fibers in the vagus bundles to connect with the millions of muscle cells in the bowel. He thought there must be intermediary nerves in Auerbach's plexus, but now that we have the new humoral explanation of nerve action, and now that Bunting, Meek and Maaske, Finkleman, and Dale and Feldberg have demonstrated what looks like a chemical transmission of nervous effects to the smooth muscle of the intestine, Langley's reasoning is not so impressive. Formerly I might have argued in favor of the synapse idea from Klee's and my observations that the latent period of stimulation through the vagus is much longer than that after direct stimulation of the bowel, and that the bowel suddenly fails to respond to stimulation of the vagus nerves after the circulation has been shut off for approximately twenty minutes, but now it is possible to explain such things on the basis of the new ideas of acetylcholine formation.

If one assumes the presence of a "synapse" at the end of the vagal fiber, one must conclude that nicotine interferes with its function in small doses but not in large. Thomas and Kuntz concluded that the blocking effect of small doses is probably due to some form of inhibition. At first glance one would expect a vagal synapse in the bowel to be blocked by atropine, but Bayliss and Starling could not obtain any blocking either with this drug or with curare.

Effect on peristaltic rush. Bayliss and Starling early reported that nicotine stops traveling waves and

disrupts the myenteric reflex, and later these observations were confirmed by Langley and Magnus, Cannon and Trendelenburg.

When I began my work I, too, found that a dose of nicotine sufficient to alter respiration and to modify the appearance of the bowel usually put a stop to peristaltic rushes so that they could no longer be elicited in the usual way by squirting fluid into the duodenum. Often there would be one or two rushes during the stage of apparent stimulation due to the arrival of the drug in the tissues, and then there would be no more. There were, however, puzzling exceptions to the rule, and sometimes the rushes did not stop until several doses had been given.

Obviously, just one *normal* rush seen in an animal dying from an overdose of nicotine freshly obtained from a reliable drug house should be enough to upset all deductions drawn from many experiments in which rushes could not be obtained. The difficulty comes in telling whether or not the rushes seen in nicotinized animals are normal. It would seem as if a careful study of the graphic records should have settled this point, but it did not always do so for reasons that I have given elsewhere and which I will repeat further along in this paper.

Another difficulty seems to arise from the fact that many of the rabbits one buys are full of parasites and perhaps sickly. At any rate, the bowel in many of the animals seems to be so sluggish and unresponsive that any little extra handicap puts a stop to all peristalsis. After working with such animals for a while one may think that certain results have been obtained often enough to settle a point, and then along comes an animal, perhaps unusually healthy and vigorous but at any rate with rushes so powerful that they keep running in spite of severe poisoning by nicotine or anoxemia, and then the investigator does not know what to conclude.

In several experiments in which the effect of a moderate dose of nicotine wore off in half an hour or so, normal rushes reappeared, showing that the injury done was not irreversible. Prompt recovery was the rule when segments of bowel were soaked in a solution of nicotine.

Sometimes, for a minute or two following the injection of nicotine, widespread intestinal contractions were seen which suggested the passage of a rush, but each time the record showed that a number of contractions had appeared simultaneously in several parts of the bowel and had each traveled caudad a short distance. In some cases these contractions were probably produced by the action of the irritant drug directly on the muscle as it reached all parts of the gut about the same time.

Occasionally, after giving nicotine, I observed short reverse rushes appearing at one time in several parts of the small bowel, and in some animals, short rushes caudad were associated with short rushes orad. Similar observations were made by Bayliss and Starling, Thomas and Kuntz (75), and Trendelenburg, all suggesting that the drug sometimes flattens the gradient. Other observations, however, indicate that usually this gradient is not much altered.

Incidentally, bathing segments of bowel in strong solutions of atropine had no demonstrable effect on the way in which peristaltic rushes went through.

Effects on the myenteric reflex. I cannot comment on the effect of nicotine on the myenteric reflex, because I have not been able to demonstrate this reflex in the rabbit.

Effect on afferent nerves. The application of pure nicotine to the bowel usually caused the (anesthetized) animal to struggle, indicating that afferent nerves were being stimulated powerfully.

Effects observed in segments of bowel soaked in solutions of nicotine. In a large series of experiments a loop of jejunum or ileum, from 25 to 150 cm. long, was lifted above the level of the fluid in the large tank and dropped into a shallow dish containing a solution of nicotine. Ordinarily I used a dilution of 1:250,000. Nolf concluded that a solution of 1:1,000,000 can be counted on to interrupt synapses in the myenteric plexus of excised gut, but I had to allow for dilution and the washing out of the drug, not only by the circulating blood but by the fluid in the tank. At any rate, with the dosage I used, the affected segment always showed signs of poisoning, often with the rosary-like appearance and sometimes with a temporary weakening of the rhythmic movements. After a segment of bowel had been soaked for two or three minutes, it was dropped back into the tank, recording levers were quickly attached, and water was squirted into the duodenum so that rushes would start there and run down to the region being studied.

It will be remembered that a peristaltic rush consists of a powerful wave of contraction which involves perhaps 15 cm. of bowel. This wave carries ahead of it a column of fluid, a column that can be pushed for long distances through dead bowel procured from another animal or even through lengths of rubber or glass tubing. Knowing this, I was not surprised to find that when rushes approached the poisoned segment of bowel the column of fluid entered at the upper end, and if the segment was not too long or too severely paralyzed, emerged at the lower end. There the fluid stimulated the bowel in such a way that a wave of contraction appeared and went on caudad as a normal rush.

As the rushes traversed a segment of poisoned bowel, there was usually failure of the muscle there to contract, and as a result, much of the column of fluid which would normally have been carried onward was left in the segment. This failure of the muscle to contract in a coördinated way could be seen with the unaided eye, and sometimes it was evident in the records. In normal bowel, the passage of a rush produced a marked rise in the record, with a sharp, steeple-like peak, but when a segment was poisoned, the writing tips of the levers attached to that region were likely to be slow in returning to the base line (Fig. 1, *d*).

As I remarked before, the effect of nicotine on the soaked segments was evanescent, and in many cases, rushes were going through normally again after an interval of from seven to ten minutes. When the local rhythmic contractions were stopped by large doses of the drug they generally reappeared in less than five minutes. The effect of intravenous injections also tended to wear off if the dose was not too large.

Sometimes rushes would continue to seep through the injured segment after one or two soakings in the solution of nicotine, but they could not get through after several soakings, which apparently had had a cumulative effect. Similarly, rushes might get through after the segment had been poisoned with a solution of 1:250,000, but not after it had been in a solution of

1:60,000. Curiously, also, when a small dose of nicotine was injected intravenously, rushes sometimes could still be elicited in the normal bowel, but they would not go normally through a segment which, some time before, had been soaked in a solution of nicotine and had then apparently recovered.

As one would expect, the length of the poisoned segment had something to do with determining whether a rush would get through or fade out. With loops 70 cm. long, some rushes faded out and others did not. In one experiment rushes got through a segment 130 cm. long, and in another they traversed 150 cm. of poisoned bowel. As I said before, if they got through, it was apparently because fluid ran onward, helped probably by a tonic contraction of the distended muscle.

When the soaked segment was severely poisoned, the contraction ring of a rush coming down from above would not enter, and records made of the activity of the segment failed to show any sign of contraction. So far as the unaided eye could detect, the injured bowel was first distended, and then the muscle gradually regained enough tonus to force out some of the fluid that had entered.

Puzzling results ascribable to poor recording apparatus. During the first months of this work I was puzzled to find in most of the records obtained with threads fastened by small wire serrefines to the bowel, signs indicating the passage of a more or less normal wave of contraction. As I have described elsewhere, I finally learned that this was due to defects in the methods of recording, and better apparatus was devised. With the help of a new "distention recorder," the visual observations were shown to be correct, and that in the thoroughly nicotinized bowel there was seldom any wave of contraction following the wave of distention. When a column of fluid entered the upper end of the poisoned segment it was kept going partly by the force applied by the normal bowel orad to the segment, and partly, perhaps, by those contractions of the muscle in the segment which were produced by the stimulus of local distention. Not infrequently the recorders would show what the observer could not see, namely, that a shallow wave of some kind had gone through the nicotinized segment.

It seems certain, then, that nicotine injures some coördinating mechanism which normally causes the intestinal muscle to contract vigorously in the wake of a traveling column of fluid. One can think of its interfering not only with some hook-up of neurones strung along the length of the gut, but also with connections between the mucous membrane and the overlying muscle. Perhaps in favor of this view are the observations of Borchardt, Garry, Raiford and Mulinos (65, 66), and Never, that the application of cocaine or procaine to the mucous membrane of the bowel abolished the usual responses to local distention and tended to interfere with peristalsis. Somewhat against this view is the work of King and Arnold who could not see any sign to indicate that nicotine affects the connections in Meissner's plexus.

I tried to differentiate rushes in normal and in nicotinized bowel by measuring in the graphic records the rate of travel of the wave, but I could not find any characteristic difference.

Painting a segment with nicotine. Painting a segment with nicotine did not work as well as soaking it in the solution. In one instance, the painting of a short segment with a 1:250 solution of the drug almost paralzyed the whole gut. Either a large amount of the poison had passed into the blood stream or else there was a powerful reflex inhibition.

Effect of nicotine on long nervous tracts and nerve endings. What I call "long-distance nervous conduction," which correlates activities in all parts of the bowel, was not impaired even by lethal doses of nicotine. By cutting away the mesentery from a heavily nicotinized segment of bowel and stimulating at a point orad, I could show that long-distance conduction can take place through such a badly poisoned loop. I found also that a stimulus coming from a distant part of the gut could affect the muscle in a poisoned segment, showing that not only the nerve fibers but also the endings in the muscle must be highly resistant to the action of the poison.

In one remarkable experiment in which a rush occurred while the animal was severely poisoned by an intramuscular injection of nicotine from a freshly opened bottle, the wave was unable to enter a segment which had previously been soaked several times in a dilute solution of the drug, and yet, as the rush swept down the upper part of the bowel, the muscle in the poisoned segment showed a decided anticipatory increase in tonus such as is characteristic of the approach of a big wave in normal bowel.

What looked like the result of a persistence of function in the long conducting tracts and in the nerve endings connected with these tracts was observed in several rabbits in which, after severe poisoning of the whole animal, there appeared simultaneously throughout the bowel a series of powerful contractions. According to Dixon such synchronous contractions of the whole bowel have been observed in men poisoned by nicotine. Perhaps it is this type of spasm with superimposed traveling waves which produces the diarrhea seen in some patients poisoned with nicotine. Theoretically, if peristaltic rushes are abolished by the drug, in man as in animals, there should not be any diarrhea. Perhaps, however, the colon is stimulated to contract more or less as a whole and thus to empty itself.

A gradient of susceptibility along the bowel. In a number of animals, injected with large doses of nicotine, it was noted that the rhythmic activity ceased at the oral end of the bowel when it was still present at the caudal end. As recovery took place, the rhythmic contractions appeared first at the caudal end and slowly spread orad. In one experiment it was an hour before the returning rhythmic contractions reached the duodenum.

Rate of travel of peristaltic rushes in nicotinized bowel. As I have already said, I could seldom see any deviation from normal in the rate and regularity of progress of the rushes which could sometimes be elicited after the giving of nicotine, but sometimes they were unusually fast.

COMMENT

Nicotine, even in moderate concentrations, seems usually to paralyze some part of the nervous mechanism of the bowel, probably a synapse. It seems also to put a stop to the rhythmic functions of certain ganglion cells. In massive doses it is probably a general protoplasmic poison which can injure the muscle fiber. Strangely, in such large doses it does not block conduction in the nerve fibers, or in the

nerve endings in the muscle, or in the synapses between extrinsic nerves of the bowel and the myenteric plexus.

As I have said, the discovery by Berkson (7, 8, 9, 10, 11), and later Puestow, that nicotine stops the "action current" while it tends to leave the rhythmic contractions with a slower rate and a larger amplitude, suggests that, much as in the heart of Limulus, so in the bowel, impulses originating in ganglion cells modify the rhythm of the muscle. Curare had much the same effect as nicotine on the electro-enterogram, and ephedrine had a deleterious effect on both the electrical and the mechanical record (Berkson (8)). Epinephrine stopped the muscular activity but left the "action currents" (Alvarez and Mahoney, Berkson (7), Puestow, Castleton).

Although it seems probable that peristaltic rush is largely dependent on a synaptic nervous mechanism, many of my observations do not fit perfectly with this view. Too often what appeared to be normal rushes ran through a bowel severely poisoned by either nicotine or long continued anoxemia. As I have pointed out in an article on anoxemia, the easiest way out of this difficulty would be to assume that the puzzling waves were all abnormal, but I cannot do this because, in so many instances, I could not see anything wrong either with the unaided eyes or with the help of graphic records. Unfortunately for the experimenter, there are several mechanisms which can serve to keep rushes going, and some can produce a normal-looking wave.

In a number of most interesting and thought-stimulating articles, Nolf has reported studies with nicotine which indicate that in the chicken, Auerbach's plexus consists primarily of a chain of neurones running the length of the bowel and connected with valve-like synapses which permit conduction and peristalsis only in the caudad direction. Experiments indicate that the vagal and the preganglionic sympathetic fibers are connected by synapses with this primary chain of neurones, while the postganglionic sympathetic fibers go directly to the muscle. There are reasons for believing also that in the chicken there is a second group of neurones interposed between those of the longitudinal conducting chain and the muscle fibers of the gut. So far as my experiments go they do not suggest the presence of similar neurones in the myenteric plexus of the rabbit, but I have not yet had the opportunity to repeat Nolf's experiments exactly as he performed them.

SUMMARY

An attempt was made through the use of nicotine to learn something about the structure and functions of Auerbach's plexus and about the mechanisms underlying peristaltic rush. Unfortunately there still are doubts as to the exact way in which the drug affects the nervous system. The effects obtained vary somewhat with the dosage used.

Most susceptible of all structures seem to be certain synapses in Auerbach's plexus, and the ganglion cells. The immunity of the vagal nerve endings to large doses of nicotine was confirmed. Almost insusceptible to nicotine were the nerve fibers and their endings in the muscle.

Conduction over long stretches of bowel seemed actually to be improved, so that the gut sometimes contracted as a unit.

Nicotine improved the amplitude of the rhythmic contractions of the intestinal muscle; it made them more regular, and usually slowed their rate. Only in the largest doses did it temporarily stop them. The irritability of the muscle was almost unaffected even by the largest doses of nicotine. The nicotinized bowel commonly presented a beaded appearance.

The tendency of nicotine to interfere with peristaltic rush was confirmed, but this effect could not always be demonstrated. The difficulty may have been due at least in part to the fact that there are several mechanisms by which a rush can be forwarded. A segment of bowel poisoned by nicotine did not empty itself caudad as well as did normal segments. Nicotine seemed to interfere with the mechanism which connects the muscle to the underlying mucosa. The effects of nicotine wore off quickly.

There were indications of a gradient of susceptibility to nicotine along the small bowel, with the oral end more susceptible to injury than the caudal end.

Nicotine did not seem to interfere with peristalsis in the stomach or colon.

It was found that nicotine can so decompose that, while retaining most of its characteristic toxic effects, it loses much of its ability to interfere with peristaltic rushes.

The Management of Strangulated Hemorrhoids*

By

EMOR L. CARTWRIGHT, M.D., F.A.C.S.

FORT WAYNE, INDIANA

THIS controversial subject is still the cause of much debate, after these many years. Whether to operate early or to delay until the active inflammation has subsided is still as undecided, in some quarters, as it was in William Allingham's time. The remark of N. J. Kilbourne (1) when discussing prolapsed, strangulated, gangrenous hemorrhoids that "Such cases are not usually operated on by competent proctologists in this stage" serves to show the attitude of some physicians. That such a view is not correct I

*Read in extended form before the meeting of the American Proctologic Society, Atlantic City, June 7, 1937.
Submitted May 28, 1937.

have been able to determine by interrogating the competent proctologists of the United States and Canada.

DEFINITION

The term hemorrhoid means, of course, varicosities in the lower rectum, and not perianal hematomas. The various descriptive terms, such as prolapsed, thrombosed, strangulated, and gangrenous hemorrhoids refer merely to pathological changes and to changes in position of the lesion. The condition may or may not be accompanied by perianal hematomas, and anal edema may be much or little. There is one common finding in strangulated hemorrhoids and that is thrombosis of the arteries, veins and capillaries making up the hemorrhoid.

ETIOLOGY AND PATHOLOGY

It was formerly thought that thrombosed, prolapsing hemorrhoids were due to strangulation, produced by the sphincter muscles, but this idea is gradually giving way to the more tenable theory that the resulting pathology is one of trauma. The extrusion of a hard stool, or perhaps severe diarrhea, prolapses the hemorrhoids breaking the intima, and thrombosis results. The natural sequence then is edema, cellular infiltration, inflammation, ulceration and frequently gangrene. Strangulation does not enter into the picture at all, as noted by F. C. Smith (2). Inserting the finger into the rectum of one of these cases shows that the sphincters themselves offer no resistance.

With this pathology in mind, it would appear to me that it is just as essential to excise this tissue at the earliest possible moment, as it is to excise a perianal hematoma at once, which latter procedure is universally accepted, I believe. Delay in instituting surgery serves to prolong the pain unnecessarily and increases the likelihood of sepsis.

FEAR OF EMBOLISM

The danger of embolism is often mentioned, and this is no doubt a real danger when a crushing clamp is used, or when the anesthesia consists of local infiltration. In the fatal cases I have investigated the clamp and cautery or local infiltration was used. Clean surgery by prompt excision of the masses, under a block anesthetic, either spinal or caudal, or, if required, a general anesthetic, helps to avoid this danger and is a safe procedure to be followed in thrombosed hemorrhoids. Some vessels will require ligation, but this is easily accomplished when the hemorrhoids have been removed.

An embolic death may follow a simple hemorrhoidectomy as well as after an operation on thrombosed piles, and the menace is not confined to proctology, as orthopedists and gynecologists will testify.

FEAR OF LIVER ABSCESS

Another danger that is given considerable thought is the likelihood of liver abscess, or a general blood stream infection, following surgery on thrombosed or gangrenous hemorrhoids. W. B. Gabriel (3) in his book has this to say, "Septic internal piles should be treated on palliative and antiseptic lines. When the piles are perfectly clean, a decision can be made as to what further treatment, if any, is required." Yet on page 30 of this same book, we find this sentence. "The process is almost invariably well localized, and in spite of the theoretical dangers of septic pylephlebitis and portal pyaemia, I can recall only one death from a sloughing haemorrhoid." This death in a patient who was not operated upon shows us that liver abscess may occur in the absence of hemorrhoidal surgery as well as following such surgery. Necrosis, therefore, is no contra-indication to the removal of these hemorrhoids, provided it is done without clamps and without local infiltration. Lockhart-Mummery (4), with whom Gabriel was associated as an assistant for some time, writes in his most recent book, as follows: "I have always made it a practice to operate at once upon sloughing and strangulated piles, unless some other contra-indication existed. The result in all cases has been an immediate relief of pain; and as a rule the patient has been quite well again in a fortnight or three weeks, and at the same time cured of his piles. If one waits until all sloughing and inflammation have subsided before doing the radical operation, the total time before the patient is well is nearer five or six weeks." "I have never seen any ill-effects follow immediate operation upon sloughing piles, and, on the other hand, I am sure that the patient is saved much trouble and pain by immediate operation."

FEAR OF STENOSIS

Still another reason given for delayed operation is the inability to judge the amount of tissue it is necessary to remove. It is a bit disconcerting to be confronted with a patient having large clumps of thrombosed hemorrhoids protruding from the anal canal. My experience in these cases has been very satisfactory. The convalescent period has frequently been shorter than following an uncomplicated case. Experience, of course, is the guide one needs to reach a decision as to what sort of a plastic or repair operation is required in the case at hand.

CASE REPORT

A typical case report follows: F. R. S., male, 51 years old, a packing house employee, was brought to the hospital by his doctor, with this history: Rectal bleeding and protrusion for at least twenty years. For the past few days piles have been out and he is unable to replace them. When the piles were first protruded, one was bleeding quite badly, and his doctor ligated it with black silk. I saw the patient at the hospital and found a lobulated mass as large as a small orange prolapsed from the rectum. The ligated pile was gangrenous and gave off the characteristic odor. The patient was suffering intense pain. He was sent to surgery immediately and under spinal anesthesia all thrombotic and gangrenous piles were excised. No clamps were used at any time. The bleeding vessels were ligated when necessary. He entered the hospital August 5, 1935, dismissd from the hospital August 9 and discharged from my care August 23. He had the largest collection of prolapsed, thrombosed hemorrhoids I have ever seen.

I have recently obtained the views of the surgeons of the American Proctologic Society concerning this vexatious problem. Of 116 replies to my questionnaire 76 operate promptly upon acute strangulated hemorrhoids while 38 do not, and two follow no predetermined plan.

It is interesting to note the trend away from the clamp and cautery, as shown by the choice of operation from the 76 operating early. Only eight chose the clamp and cautery, while 65 use some form of a modified ligature operation, and three had no preference. It would appear that if there ever was a time when the clamp and cautery was especially dangerous it would be in the presence of thrombosis. Quite a

number of the surgeons volunteered the information that they *never* use the clamp and cautery.

The choice of anesthesia assumes as great importance, from the standpoint of safety, as does the type of operation. There are 18 who use local infiltration, the big majority use block anesthesia, and a few general. If the infiltration is made at a considerable distance away from the thrombosed area it may be a fairly safe method. If not away from the area the procedure may be extremely dangerous. This view is held by a big majority of the surgeons as shown by their choice of block anesthesia.

A few replies to the questionnaire follow: Dr. Louis J. Hirschman prefers the ligature operation with caudal anesthesia. He says: "Knowing that a blood clot forms an excellent medium for the culture of pyogenic organisms in this region thrombosis is an indication for immediate removal."

"Knowing that strangulation means necrosis and even when hemorrhoid is reduced means recurrence, immediate removal is also mandatory."

Dr. Curtice Rosser uses the ligature operation, always under a block (spinal or caudal) or general anesthesia, never under infiltration. He says: "I find that it is always possible to discover normal tissue at the *base* of the strangulated pile and if local injection of chemicals and trauma to the pathologic tissue is avoided at operation, I believe there is *less* danger in the removal of the pathology than in awaiting further extension. I used the clamp and cautery for some years in this situation, but decided there was some danger of trauma with the clamp."

Dr. Frank C. Yeomans uses the clamp and cautery operation and uses low spinal anesthesia with a small dose. He says: "My results in several such cases have been very satisfactory." In his book (5) we find the following: "When the sphincter is tight and the protrusion not replaced, thrombosis of the vessels and gangrene frequently ensue. Sloughing then occurs and spontaneous relief may be obtained, but at the expense of several weeks of needless pain, suffering and disability. Prolonged ulceration, abscess, or a fistula may be sequelae. Under these circumstances, when the situation is fully explained to the patient and there is no other contra-indication to operation, he will usually accept immediate operation, which is the proper procedure for strangulated, sloughing piles. Relief is immediate, the hemorrhoids are cured, and no complications, other than those encountered in a simple hemorrhoidectomy, ensue. To limit the possibility of infection, the clamp and cautery is the operation of choice."

The 38 surgeons advising delay before instituting surgery in strangulated hemorrhoids gave as their reasons; fear of embolism, blood stream infection or liver abscess, and fear of stenosis if too much tissue is removed. They advocated various methods of palliation, chiefly rest and hot moist compresses.

One of the most interesting discussions that I read on this subject was that of N. L. Blumental (6), Director, Surgical Division of Trekhgorny Hospital, Moscow, U.S.S.R.

He recounted the dangers of the conservative treatment of strangulated piles, and emphasized the likelihood of the condition not remaining localized, with embolism and pyemia imminent. He then decided to break away from the generations-old attitude of merely standing by while the nurse recorded exquisitely painful as well as dangerous defecations, the while applying hot water compresses. In a series of cases operated upon by excision, without clamps and without anal dilatation, under general anesthesia, his results were so good that he recorded them in a paper which should be read in its entirety.

The important thing to remember is that we all want to get our patients well. However we should not close our minds to any advances in surgical therapy which tend to hasten this end. A procedure which brings about a worth-while reduction in human suffering, while at the same time eliminating the hazards of watchful expectancy, should be utilized.

SUMMARY

An attempt is made to bring order out of chaos in the therapy of strangulated hemorrhoids. Following a description of the condition, the etiology and pathology are taken up in turn. The alleged dangers of early operation are cited, and the reasons for these dangers are given. Quotations are taken from well-known text books on proctology. A questionnaire was devised and submitted to members of the American Proctologic Society for their opinions on this vexing problem. These questionnaires were tabulated, and quotations made therefrom. One case history is given.

CONCLUSIONS

Strangulated, thrombosed, sloughing, and gangrenous hemorrhoids should be operated upon promptly.

The danger of embolism or liver abscess is greater in those cases not operated upon, than it is in those cases operated upon under block anesthesia, without clamps, and without anal dilatation.

The preponderance of opinion among the surgeons of the American Proctologic Society favors this procedure.

A Collapsible Indwelling Nasogastric Tube

By

EDWARD E. WOLDMAN, M.D.
CLEVELAND, OHIO

A METHOD has been devised for using a collapsible thin rubber tube for the instillation of medication and food into the stomach through the nose. A need for such a tube was encountered in the treatment of peptic ulcer by the continuous administration of colloidal aluminum hydroxide (1). The Levin nasal catheter which, in this treatment, must be left in for several days, presented a number of difficulties. When the larger sized catheters were used, many patients complained of irritation and soreness of the nose and throat caused by the stiff rubber tube. Even when the smallest tube was used, there was still considerable irritation in some instances, and also the colloidal aluminum hydroxide, even in diluted form, tended to collect in the narrow lumen, causing obstruction of the flow into the stomach.

These difficulties were overcome by using a thin rubber tubing (Penrose Latex) one-fourth inch in diameter and 30 inches long, of the type used for cigarette drains in surgical cases. This tube is not sufficiently rigid to pass through the nose into the stomach, so an obturator has to be used. This is made from silk-worm gut suture by tying two 15-inch lengths together with a piece of thread. Other rigid suture material might also be used. The suture gives the tube just enough rigidity to allow it to be forced through the nostril and into the esophagus. A small loop is made at the distal end of the silk-worm gut suture and tied with thread, so that the sharp end can not injure the mucous membrane. The suture is inserted into the lumen of the tube as an obturator, which stops about one inch from the distal end. This free end of the soft tubing is folded on itself to prevent protrusion of the suture material while the tube is being passed. After the tube reaches the stomach, the free end of the tube straightens out again.

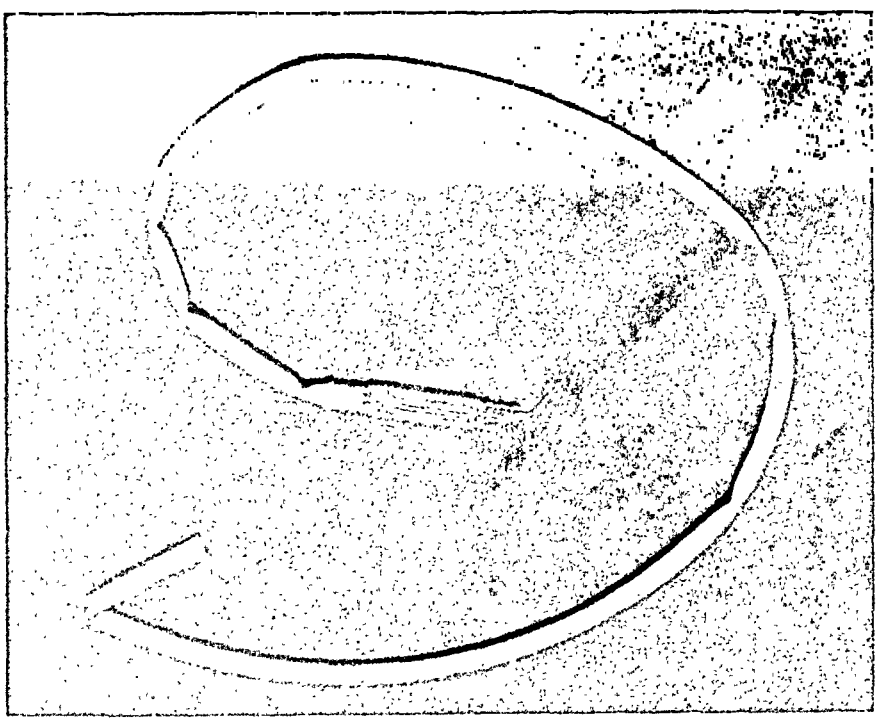

Fig. 1. The thin-walled nasogastric tube with silk-worm gut suture obturator in place. Note that the obturator prevents sharp kinking of the tube.

The technic of passing the tube is as follows: The outside of the cigarette drain is first lubricated by dipping the length to be passed in mineral oil. The tube must be grasped tightly so that the tube and the obturator are passed together through one of the nostrils until the pharynx is reached. The patient is asked to drink water through a straw while the remainder of the tube is pushed down slowly through

Submitted May 13, 1937.

the esophagus into the stomach. The obturator is left in the lumen to prevent sharp kinking of the thin-walled tube.

The proximal end of the thin tube is connected to another rubber tube by a glass connection. The obturator at this end is permitted to extend into the glass connecting tube a short distance to preclude any kinking at the junction of the glass tube and the cigarette drain. A small strip of adhesive holds the tube against the upper lip to keep it from slipping out.

This type of tube can not be used for siphonage because any suction causes it to collapse. This has proved an additional advantage in the continuous instillation of aluminum hydroxide into the stomach. With the Levin tube, whenever the level of the patient's stomach is elevated, as when he sits up, there is suction of the stomach contents into the air-tight gravity bottle. The collapsing of the thin tube under such circumstances allows fluid to flow into the stomach but does not permit a back flow or suction. Hence this thin tube has a definite sphere of usefulness in the instillation of food or any other material into the stomach when siphonage of stomach contents is undesirable. The lumen of this tube, which is much larger than that of the ordinary thick-walled gastric tube, allows a free flow of any thick material.

This tube has been used on many patients and not one of them has complained of discomfort or irritation while the tube was in place for ten days or more. There is no interference with eating or drinking, and, in most instances, the patient is scarcely conscious of its presence. In one patient with an old fracture of the nose this collapsible tube was especially useful. His nasal passages were too small to permit passage of the smallest Levin tube, but admitted the thin-walled tube with no difficulty.

The advantages of a thin-walled tube in the instillation of material into the stomach are (1) irritation of the nose and throat or esophagus is prevented, (2) the tube is so soft that there is no danger of any injury to any lesion of the stomach, (3) there is no possibility of back flow or suction of stomach contents and (4) because of its large lumen there is no obstruction by particles of food.

This method of instillation of medication or food into the stomach is convenient and immediately available for use, because it simply consists of a new adaptation and use of materials already at hand. In addition to its service in the treatment of peptic ulcer, it is also useful in cardiospasm and in carcinoma of the esophagus to allay superimposed irritation. It is of value in any case in which prolonged intubation is necessary, for it has a distinct advantage over other types of tubing in protecting the tissues of the body from irritation and trauma.

The Incidence and Permanence of Unexplained Gastric Anacidity in the Rhesus Monkey After Histamine and Mecholyl, with Hemotologic Studies*

By

J. G. SCHNEDORF, M.S., M.D.

and

A. C. IVY, Ph.D., M.D.

CHICAGO, ILLINOIS

A STUDY of the incidence and permanence of gastric anacidity in the monkey is of significance because of the close relationship of this animal to man.

Polland (1) using histamine and Vanzant (1) using a test meal found a similar percentage of incidence of anacidity in the human. The percentage of frequency of anacidity in the human varied with the age and sex. In their series the percentage incidence of anacidity between the ages of 20-39 years was male 3.2, female 6.4; 40-59 years male 12.2, female 18.9; over sixty years male 30.6, female 23.3. The average incidence of the entire series was 14%; male, 12.0%; female, 16.2%. Dietrick and Shelby (2) found free acid in response to histamine in every case in a series of 14 children (ages 4-14 years). Polland and Bloomfield (3) determined the pepsin concentration of the gastric juice from 8 patients with complete anacidity after histamine. In only one case was there no trace of pepsin, another showed an increased concentration of pepsin while the other six all showed low concentrations of pepsin. Bloomfield and Polland (4) in their experience have found that true anacidity is permanent and are of the opinion that the observations on the return of normal acidity, after long periods of absence, must be looked on with some skepticism, because they are based upon test meals, and not upon the results of histamine stimulation.

METHODS

Forty-five healthy Rhesus monkeys (macaca mulatta) (23 males, 22 females) varying from one to six years of age were employed in this study. The monkeys have been divided into three age groups, youthful, adolescent and mature, according to their size, weight and sexual development. All the monkeys have been in our laboratory for from eight months to six years. They have been maintained in a state of good nutrition upon a varied diet consisting of milk,

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago, Ill.

Submitted May 15, 1937.

potatoes (raw and boiled) bread, carrots, lettuce, bananas, oranges, apples and peanuts.

Gastric analysis was performed upon monkeys fasted for 24 hours. A Rehfuss tube (minus the olive) was passed into the stomach and the fasting contents were removed; the stomach was washed with distilled water and emptied. The monkeys then each received 0.5 mg. histamine (ergamine acid phosphate) subcutaneously. If free acid failed to appear in the gastric samples, the dosage of histamine was increased to 1.0 mg. Gastric samples were taken at 30, 45 and 60 minute intervals after each injection and analyzed for free acid (p-dimethylaminoazobenzene) and bile (naked eye).

Eight to ten gastric analysis were made over a period of eight months upon those monkeys which did not respond to dosages of histamine up to 1.0 mg. A qualitative assay for pepsin (Mett tubes) and rennin (milk coagulation) was made on the gastric juice of the anacid monkeys. Erythrocyte, hemoglobin (Newcomer) and hematocrit determinations were made upon all of the monkeys.

RESULTS

The viscid, mucoid fasting contents of the stomach were scanty, never contained free acid and but little total acid.

Table I shows that 8 of the 45 monkeys (17.7%) did not have free acid in the gastric samples taken at 30, 45 and 60 minute intervals after subcutaneous injections of 0.5 mg. and 1.0 mg. of histamine. In our entire series anacidity in the male was 13.0%; female, 22.7%.

TABLE I

Incidence of gastric anacidity after histamine in the normal Rhesus monkey

Age	Weight lbs.	Sex	No. Animals	Gastric Anacidity Histamine 0.2 mg. No.	0.5 mg. 1.0 mg. %

Total			45	8	17.7

Table II shows that the anacidity persisted in the eight monkeys for from one to five months. Gastric pepsin and rennin however were present in all cases. Regurgitation of bile and intestinal contents did not occur.

On February 8, 1937, free acid was secreted by four of the eight anacid monkeys after 0.3 mg. of Mecholyl (acetyl B. Methyl choline chloride) given in three subcutaneous injections (0.1 mg. each, 15 minutes apart). This dose of Mecholyl, given in the manner indicated, stimulates gastric secretion in dogs (4). On February 10, 1937, six of the anacid monkeys secreted free acid in response to 1.0 mg. of histamine also given in three injections (0.33 mg.) at 15 minute intervals. On March 20, 1937, all the anacid monkeys except No. 35 secreted free acid following one injec-

41	Adolescent control	Female	+	+	+	+	+	+	+	+	+	+	+	+	+

tion of 0.5 mg. of histamine. In three subsequent gastric analysis at 2 week intervals, all of the anacid monkeys secreted free acid following single subcutaneous injections of 0.5 mg. histamine and of 0.15 mg. mecholyl.

Blood studies showed that none of the above anacid monkeys were anemic at the time that the analysis were made.

One of our monkeys (No. 7) had an anacidity and only 9.05 gm. % hemoglobin. After the hemoglobin was brought up to 12.50 gm. % by the oral administration of iron salts, free acid was found in the gastric samples in response to histamine.

Because our series of 45 monkeys is considerably larger than any upon which hematologic studies have been reported and because of our correlation of the blood picture with the age and sex of the monkey, we shall include our hematologic findings in this paper. The largest series occurring in the review of the literature by Hall (5) is that of Krumbhaar and Musser, who in 14 monkeys found average values of 5.985 million erythrocytes and 85.15% hemoglobin. The average ranges of erythrocytes of the various authors varied from 4.648 to 6.252 million and the hemoglobin from 60 to 85.45%. In a series of 11 normal Rhesus monkeys Bussabarger and Ivy (6) found a mean erythrocyte value of 6.200 million and a mean hemoglobin value of 12.86 gm. %, the mean hematocrit value being 47.64.

TABLE III

Blood picture of normal macacus Rhesus monkeys

Age	Weight	Sex	No. Animals	No. Determinations	R.B.C.	Hb per 100 c.c.	Hematocrit
Youthful	3.5-4.5	Male	8	16	5.270	11.84	47.2
(12-24 mos.)		Female	6	12	5.169	12.42	45.9
	Average		14	28	5.193	12.07	45.6
Adolescent	4.5-6.1	Male	3	6	5.456	12.25	45.8
(24-57 mos.)		Female	5	10	5.219	11.56	41.2
	Average		17	34	5.300	11.79	43.5
Mature	6.5-12.5	Male	13	26	5.378	12.73	42.8
(57-72 mos.)		Female	7	14	5.333	11.97	40.4
	Average		20	40	5.511	12.35	41.9

*Newcomer method.

Table III shows that a sex difference in the blood picture was not found and that the values fall within the same range in youthful, adolescent and mature Rhesus monkeys. The average values and ranges of the determinations are shown in Table IV. It is interesting to note that the average values given by different authors upon smaller series fall within our range.

TABLE IV

Average blood picture for 45 normal macacus Rhesus monkeys

Determination	No. of Determinations	Average	Range
Red Blood Count	99	5.410	(4.756-6.064)
Hemoglobin (Newcomer)	99	12.27	(9.64-16.32)
Hematocrit	99	47.8	(31.0-59.5)

DISCUSSION

In spite of our small series it is interesting to note the close comparison of the percentage incidence of anacidity in monkeys, 17.7% (male 13.0%, female 22.7%), with the percentage incidence of anacidity of the entire series of Polland and of Vanzant, 14% (male 12.0%, female 16.2%). The correspondence is striking.

The presence of gastric enzymes (pepsin and rennin) in anacid monkeys confirms the observations of Polland and Bloomfield on the human.

Our results on the monkey do not agree with their observation that true anacidity is permanent because our monkeys showed a true unexplained anacidity to histamine upon repeated gastric analysis over a period of five months and then within a period of five days six of the anacid monkeys secreted free acid after the administration of mecholyl, a drug which from the available evidence is a powerful parasympathetic stimulant. Thereafter all of the eight anacid monkeys secreted free acid in response to histamine and to mecholyl over a period of three months. A recurrence of anacidity occurred in one monkey (No. 35) on one occasion only (March 20, 1937).

Since all of our anacid monkeys were in good health and were not anemic, the anacidity was not due to anemia as has been brought out by Apperly (7). We did have one monkey in which the anacidity disappeared after the anemia was corrected.

The abruptness of the appearance of free acid following the administration of mecholyl in all of our monkeys, formerly anacid to histamine, leads us to believe that this powerful parasympathetic stimulant may have awakened a latent or dormant acid secretory mechanism. This suggests that anacid human subjects should be injected with the small doses of mecholyl to ascertain if responsiveness to histamine will appear. However, our studies do not rule out the possibility of a seasonal variation, which is important, if true.

CONCLUSIONS

1. The incidence of gastric anacidity after hista-

mine in a series of 45 healthy Rhesus monkeys was 17.7% and was higher in the female (22.2%) than in the male (13.0%).

2. Gastric pepsin and rennin was present in the gastric contents of all of the anacid monkeys.

3. The unexplained gastric anacidity after histamine lasted for from two to five months and disappeared suddenly following administration of mecholyl.

4. Subcutaneous injections of mecholyl caused the secretion of free acid in normal monkeys and in eight monkeys which have been anacid to histamine for five months.

5. Hematologic studies revealed no age or sex difference in the blood picture of our monkeys.

6. These observations in monkeys indicate that the effects of mecholyl in anacid human subjects should be studied.

A Method of Determining and Recording Human Intestinal Motility*

By

ROY KEGERREIS, M.D.

CHICAGO, ILLINOIS

IT is generally admitted that we do not as yet possess a valid and acceptable method for assaying cathartics. The attempts thus far made have been largely directed in noting the consistency of the stools, in weighing them, or in counting their number in animals or in human beings after the taking of the drug. It may well be doubted whether this method of study will lead to conclusions of marked therapeutic value. The term "constipation" has no scientific meaning and should give place to the term "colon stasis," and the relief of this stasis should be the aim of therapy, rather than the production of a greater number of bowel movements. Even numerous and liquid evacuations may not affect the actual seat of

Gastro-intestinal X-ray series - on same patient showing that 0.30 gm. Phenolphthalein accelerated evacuation somewhat and that 0.60 gm Phenolphthalein greatly accelerated evacuation time For graph of same observations see Fig 2

Fig. 1. *Typical X-ray Gastro-Intestinal Series*, Secured from One Individual: First row: Control Series; Second row: After 0.30 Gm. Phenolphthalein Series; Third row: After 0.60 Gm. Phenolphthalein Series. It will be seen that while the 0.30 Gm. dose lessened the cecal evacuation time, it did not very markedly lessen the total evacuation time. The 0.60 Gm. dose caused great acceleration in total evacuation time.

the colon stasis or relieve the patient of the symptoms thereof.

It must be remembered that the colon is a large complicated organ which may roughly be divided into several functional departments:

(1) The cecum and ascending colon, the chief func-

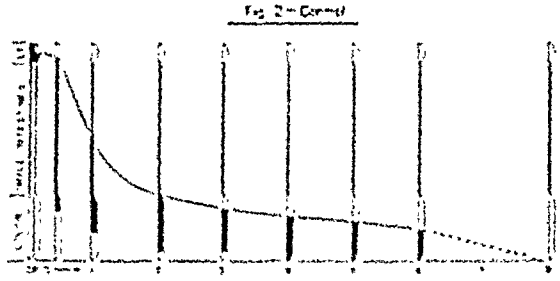

Fig. 2. *Control Series.* Curve secured in interpretation of the X-ray gastrointestinal series shown in Fig. 1

tion of which is to retain the digesting material thrown into it from the small intestine until much of the fluid has become absorbed from its contents. That the consequent reduction of the bulk of the contents is an important function of this part of the intestine is evident from the fact that the cecum holds approximately four times the volume contained in an equal length of any other colon segment. It is the most distal portion of the actual digestive apparatus. Retention occurs normally; and abnormal retention, or stasis, is very common. It is likely to be detrimental to health when it occurs to a marked degree.

(2) The transverse colon is that part in which the inspissation of the contents is completed and the formation of fecal material begun.

(3) The descending colon finishes the formation of feces and becomes completely emptied with a "peristaltic bowel movement." It might be considered the colon "shipping department."

(4) The sigmoid colon, which is equal in length to any one of the other portions of the colon, with the rectum, retains the feces until evacuation.

(5) The rectum should normally be practically

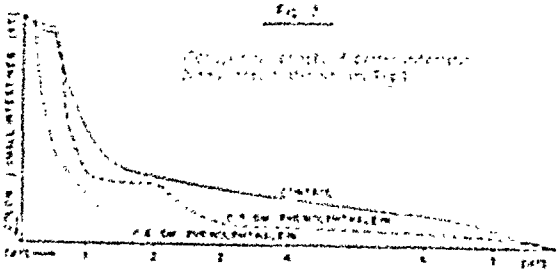

Fig. 3. Comparison of curves representing tail end of column in the roentgenintestinal X-ray series shown in Fig. 1: A, Control series, B, 0.30 Gm. phenolphthalein series, C, 0.60 Gm. phenolphthalein series.

empty excepting just before a bowel movement, as the presence of a considerable amount of material in it should excite the act of defecation.

Though admitting that it is *merely schematic*, it is believed this interpretation of the functions of the anatomic divisions of the colon has didactic value. It is, of course, admitted that the proximal colon is a functional unit which extends to the junction of the right and middle third of the transverse colon. It is

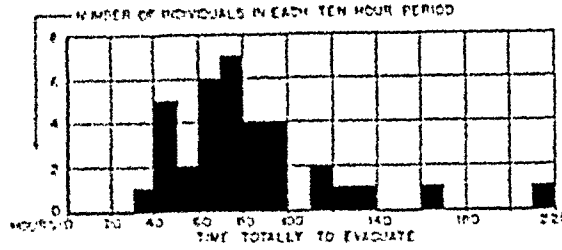

Fig. 4. *Control Cases.* Frequency distribution graph of the time required totally to evacuate the gut, using the average of the two control observations on any one individual.

also admitted that the various segments of the colon have compensatory relations to each other.

THE PROBLEM

Cathartics must be studied from the standpoint of determining where in the colon their action is chiefly exerted and patients suffering from constipation must be examined to determine in what portion of the colon the stasis occurs, so that the patient may be fitted with the cathartic he really requires; that is, the one which will best correct the functional abnormality.

In spite of the fact that humanity has been using cathartics from time immemorial, it may seem remarkable that the scientific study of the action of cathartics in health and in disease has barely been commenced. The chief reason for this is that an efficient means—the roentgen-ray—by which such study may be accomplished, has been put into our hands but a few decades ago. Thus far, roentgenologists have been largely concerned with the study of anatomic rather than functional abnormalities. The

Fig. 5. Control Cases.

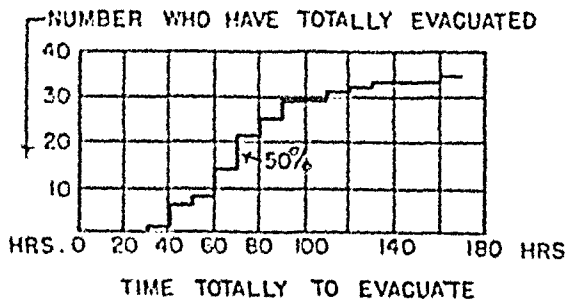

Fig. 5. *Control Cases.* Summated data for same group of tests shown in Fig. 4, showing that the most probable (50%) time for total evacuation of gut is about 70 hours.

great expense of such a study is, no doubt, an additional impeding factor.

At least four steps must be taken to remedy our deplorable ignorance of the nature and the treatment of colon stasis.

First, there is a crying need of a large and comprehensive series of control observations in normal individuals. These observations should include at least two gastro-intestinal X-ray series upon each person,

Fig. 6. Control Cases.

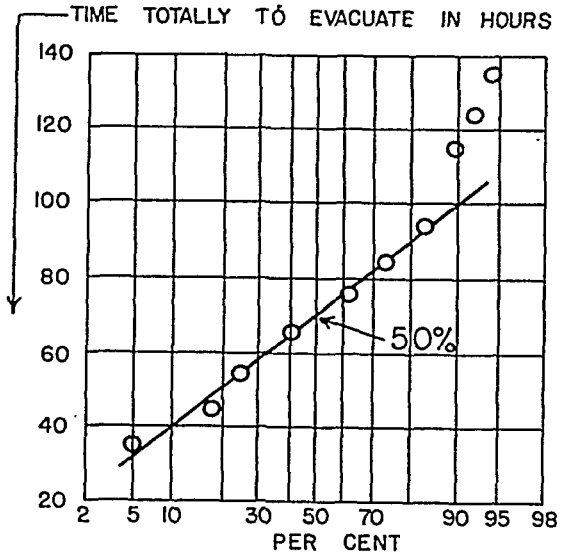

Fig. 6. *Control Cases.* Same data as shown on Fig. 4 and Fig. 5, plotted on "probability paper" after the number of cases has been reduced to percentages. The 50% ordinate intersects the time abscissae at about 70 hours.

in order to obviate errors due to the normal variations encountered in the individual. The cases might have to be differentiated under such headings as:

Colonic Motor Function:

(a) in individuals with and without visceroptosis

(b) in persons of sedentary habit and in those doing manual labor

(c) in habitual consumers of residue-high diet and of residue-low diet

Fig. 7. Phenolphthalein 0.30 Gm. Cases.

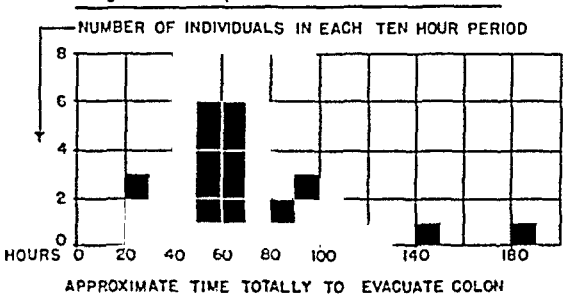

Fig. 7. *Phenolphthalein 0.30 Gm. Cases.* Gut evacuation time shown on frequency distribution graph.

(d) in the phlegmatic and the emotional, etc.

Secondly, once such a control study is available, it could be decided when abnormal retention of colon contents, or colon stasis proper, can be said to exist. It would then—and only then—be possible to study the clinical significance of the different types of colon stasis encountered in patients.

Thirdly, all the important cathartics should be studied as to their effect upon "normal" individuals, and then upon the several classes of diseased individuals to which they are to be applied.

Fig. 8. Phenolphthalein 0.30 Gm. Cases.

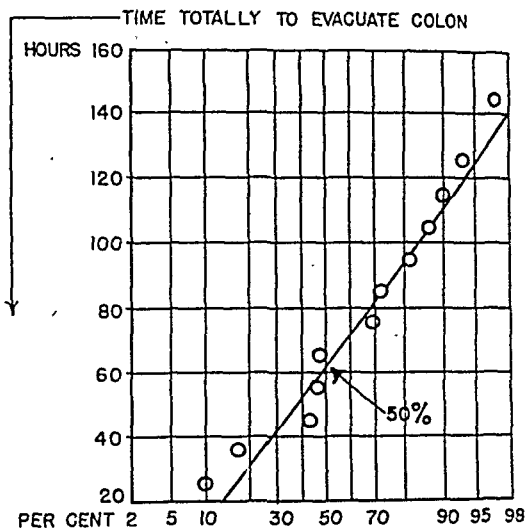

Fig. 8. *Phenolphthalein 0.30 Gm. Cases.* Gut evacuation time plotted on probability paper, showing that the most probable mean is at 62 hours.

Fourthly, when a certain form of harmful colon stasis has been encountered, it should be scientifically fitted with the proper evacuant procedure, be this a regimen depending on diet or drug, exercise, or enema, physical therapy or surgery.

Finally, having roentgenographically identified the nature of the harmful colon stasis, there should be no cessation in treatment until a subsequent X-ray examination shows that the abnormality has been corrected by the treatment chosen.

Fig. 9. Phenolphthalein 0.60 Gm. Cases.

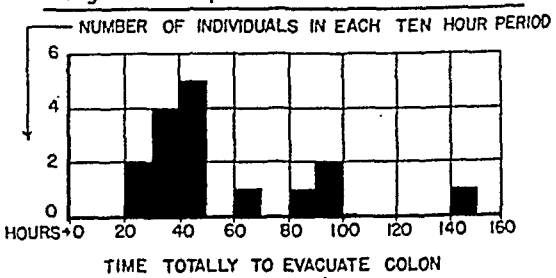

Fig. 9. *Phenolphthalein 0.60 Gm. Cases.* Gut evacuation time frequency graph in subjects "resistant" to the *0.30 Gm. dose.*

We have made only a small start in the attack upon this stupendous task by an attempt in the direction of demonstrating the use of a method that might pos-

sibly serve as a means of such study. It is submitted for criticism and, if such a scheme of analysis be found useful, it is hoped that it may be adopted for

Fig. 10. Phenolphthalein 0.60 Gm. Cases.

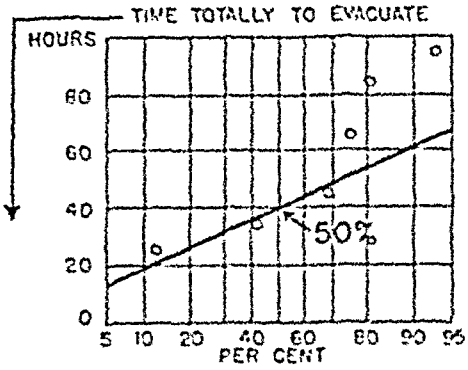

Fig. 10. *Phenolphthalein 0.60 Gm. Cases.* Gut evacuation time incidence plotted as percentages on probability paper. The most probable mean value lies at 40 hours.

cooperative study by possibly many groups of investigators.

THE METHOD

The observations which are here reported were conducted upon male inmates of the Chicago State Hospital for the Insane. Only men were examined who were mildly afflicted mentally, i.e. persons near enough to normal to be more or less fully employed at some useful work about the institution. It was hoped that a proper understanding of the bowel function might be of distinct advantage in the management of these patients. None of the subjects had physical defects that would unfit them for a moderate degree of physical labor. They were admittedly

Fig. 11. Comparison of Gut Evacuation Time in Controls and After 0.60 Gm. of Phenolphthalein.

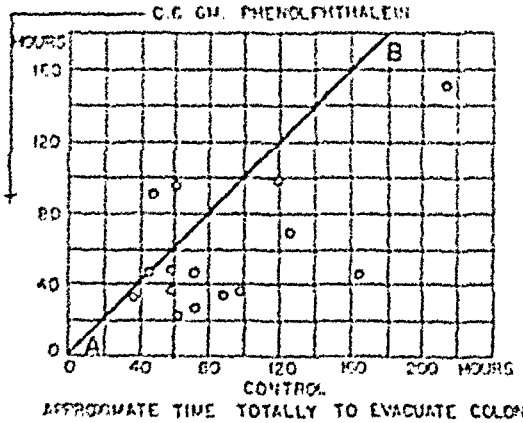

Fig. 11. Comparison of gut evacuation time in controls (abscissae) and after 0.60 Gm. of phenolphthalein (ordinates). While in most individuals the time was shortened, there were two in whom it was increased.

less active than a cross-section of normal healthy individuals. Nevertheless, the bodily activity of the persons studied was quite comparable to that of an ordinary office worker with the proviso that the "mental activity" of these subjects was on a distinctly lower level since at best the tasks which they performed were largely menial and of a routine nature.

It should be specifically noted that all the subjects were offered the same diet which for purposes of comparison is a very important consideration; though, it must be admitted that there was no check on the amount of each constituent or the total quantity actually consumed, a matter also of considerable importance.

The ages of the men ranged from 21 to 68 years with the average about 40. They were chosen at random, with no regard to their bowel function. Several of the subjects did complain of constipation, but no special attention was paid to this matter in the present study as method rather than therapeutically valid deductions was all that could

Fig. 12. Gut Evacuation Time Curves of Individuals Without (0) and With Phenolphthalein.

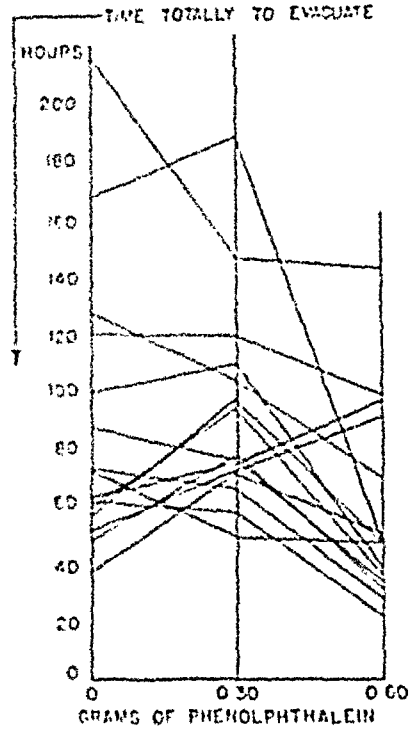

Fig. 12. Gut evacuation time curves in controls (0) and after 0.30 Gm. and 0.60 Gm. of phenolphthalein. Each line represents observations on one individual. Downward slope shows decrease in evacuation time; upward slope, increase in evacuation time.

be aimed at. This fact will also largely answer the objection which may be raised that the results secured from the study upon insane persons cannot be applicable for normal individuals. It may furthermore be emphasized that this study is not invalidated by the fact that it was carried on upon the insane for the following additional reasons:

(1) Controls were secured by taking a gastro-intestinal X-ray series before as well as after the giving of the cathartic.

(2) It will probably be difficult, excepting in prison populations, to find a group of individuals living under more nearly similar conditions of exercise and of diet.

(3) As has previously been stated, individuals physically normal were chosen.

Should subsequent investigation show that we have encountered great deviations from the average of physically similar individuals who are mentally normal, this study might serve as a beginning of the understanding of the intestinal functions of the insane.

Fig. 13. Control Cases.

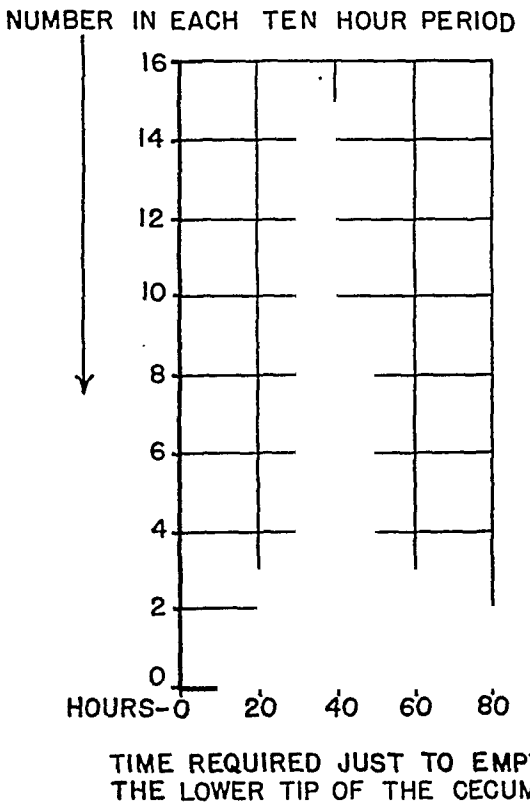

Fig. 13. *Control Cecal Tip Evacuation Time.* Frequency distribution graph.

TEST WITH CATHARTIC (PHENOLPHTHALEIN)

The tests to be reported include 61 control series on 36 individuals, 32 series after the giving of 0.30 Gm. of phenolphthalein to 32 individuals, chosen at random from the 36, and 16 series after the administration of 0.60 Gm. of phenolphthalein to 16 individuals, 15 of whom had been found to be more or less refractory to the 0.30 Gm. dose of phenolphthalein.

The tests were conducted in a uniform manner. They were always begun about one-half hour after the Sunday morning breakfast, the day when the men were least occupied. Each individual ingested 60 grams of barium sulfate suspended in water. When phenolphthalein was given a week or more later, it was mixed with the barium sulfate and the patients were entirely unaware of having received a cathartic and had no knowledge other than that the same examinations were being made each time. The influence of suggestion, therefore, was eliminated as a factor and played absolutely no part in the results.

Three radiographs were made the first day, one and one-half, three, and about ten hours after the ingestion of the opaque material, and then one on each succeeding day at 8:00 a. m. until total evacuation had occurred.

Size 14 x 17 inch pieces of photographically sensitized paper were used for making the radiographs, since the cost of this paper is only about one-half that of the ordinarily used X-ray film. The exposures were all made with the patient lying with the ventral surface down on a Potter-Bucky horizontal radiographic table, giving postero-anterior views of the abdomen and pelvis.

An effort was made to record all bowel movements from two days before the study was begun until at least a day after it was finished, but these data could not be utilized since a large percentage of the statements of the patients was obviously unreliable.

Reproductions of most of the radiographs of a typical test secured on one individual are presented in Figure 1.

The radiographs were carefully scrutinized and tabulations were made as to the times involved in the passage of the opaque meal through various parts of the digestive tract. Other less definite factors that might in any way have a bearing on the problem were also noted. While the radiographs revealed no evidence of the production of a generalized or localized spasticity as usually interpreted roentgenologically, the possibility of colon spasm having been produced is by no means eliminated as but few fluoroscopic examinations were made. The patterns were all of just about the appearance that would be encountered among normal individuals in the routine work of an X-ray laboratory. No types of greatly abnormal appearance were encountered.

The data from each series of radiographs were plotted, making what in reality constitutes a motility diagram of the gastro-intestinal tract under the particular conditions that prevailed during the test. The different regions of the gastro-intestinal tract were represented symbolically by appropriate lengths and the cross-sections by the separation between parallel lines. The parts of a normal adult digestive tract average in lengths as follows:

Stomach	three-fourths of a foot
Small intestine	20 feet
Colon	Five feet

These ratios were not reproduced exactly in the

Fig. 14. Control Cases.

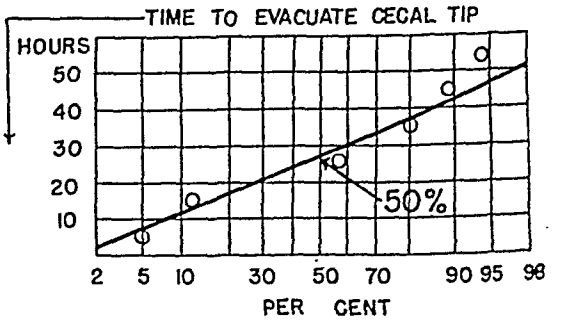

Fig. 14. *Control Cecal Tip Evacuation Time.* Number of cases expressed in percentages plotted on probability paper. Most probable mean value: 27 hours.

schematic diagrams. The abscissa scale represents time and the position of the opaque meal in each radiograph is indicated by shading. Each radiographic examination was shown pictorially by a sepa-

Fig. 15. Phenolphthalein 0.30 Gm. Cases.

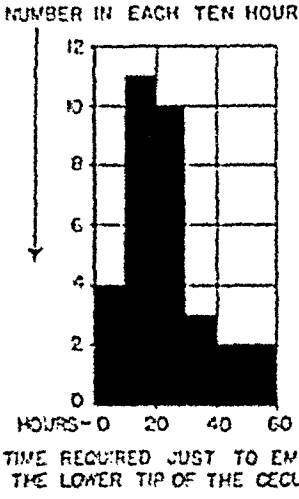

Fig. 15. Phenolphthalein 0.30 Gm. Cases. Cecal tip evacuation time. Frequency distribution graph.

rate sketch of the gut so placed as to indicate the time at which the radiograph was taken. Curves were constructed to show the location of the tail of the column of opaque material at the various times (Fig. 2). It was then possible to secure a direct comparison of these motility curves by superposing them (Fig. 3).

CONTROL STUDIES AS TO TOTAL EVACUATION TIME

Figure 4 shows the frequency distribution of the time required by controls for total evacuation, using the average evacuation time of the two control runs of each of the individuals studied. The summated data for the same group of tests are shown in Figure 5. The same data are shown on Figure 6 when plotted on "probability paper." These data show that the most probable mean time completely to evacuate ingested material is normally 70 hours.

PHENOLPHTHALEIN (0.30 GM.) TOTAL EVACUATION TIME

The frequency distribution of time totally to evacuate the opaque material when 0.30 Gm. of phenolphthalein is ingested is shown in Figure 7. The same data plotted on probability paper (Fig. 8) show that the most probable mean time completely to evacuate when 0.30 Gm. of phenolphthalein is ingested is 62 hours: a speeding up of just over 10%.

PHENOLPHTHALEIN (0.60 GM.) TOTAL EVACUATION TIME

The frequency distribution of time totally to evacuate is shown in Figure 9 for sixteen "resistant" subjects when they ingested 0.60 Gm. of phenolphthalein; and the same data plotted as percentages on probability paper are shown in Figure 10.

No direct comparison between this graph and that of the similar graphs for the other groups can be made since these subjects were selected resistant cases and not chosen at random as were those of the first group. The most probable mean value of the evacuation time for this group under these conditions is 40 hours (Fig. 9 and 10) which is less than two-thirds of the control value of 70 hours.

COMPARISON OF CONTROL AND OF PHENOLPHTHALEIN EVACUATION TIMES

Figure 11 shows the relation between times totally to evacuate. Each point on Figure 11 represents an individual, the abscissa being the time totally to evacuate for the average of two control tests and the ordinates being the time totally to evacuate when 0.60 Gm. of phenolphthalein was ingested. All points excepting two lie below the line A-B which shows that, while in most of the subjects 0.60 Gm. of phenolphthalein did shorten the evacuation time, in the case of two individuals there was an increase in the time required for the tail of the column to pass through the entire colon.

Figure 12 expresses the same facts in the form of curves. These curves would all descend if a purgative response to phenolphthalein were uniformly realized. The curves of the same two individuals, referred to above, have slopes consistently in the opposite direction, even after a 0.60 Gm. dose of phenolphthalein.

"CECAL TIP EVACUATION TIME"

Figure 13 shows the time required for the tail of the column just to leave the lower tip of the cecum in the control observations. This factor seems to hold promise as a quantity for comparative analysis since the values are bunched and a rather well formed curve results. Owing possibly to reverse peristalsis, it seems almost impossible to get consistent results from the use of other criteria.

Figure 14 shows that the most probable value of the cecal tip evacuation time was 27 hours. The same time relations after the ingestion of 0.30 Gm. of phenolphthalein are shown in Figures 15 and 16 which give 18 hours as the most probable value for cecal tip evacua-

Fig. 16. Phenolphthalein 0.30 Gm. Cases.

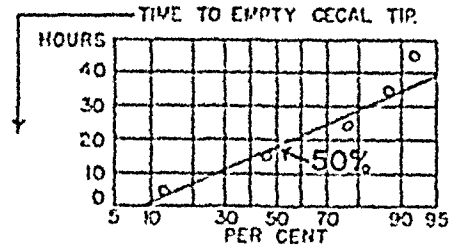

Fig. 16. Phenolphthalein 0.30 Gm. Cases. Cecal tip evacuation time. Number of cases expressed in percentages plotted on probability paper. Most probable mean value: 18 hours.

tion after the ingestion of 0.30 Gm. of phenolphthalein, a speeding up by one-third.

There are fewer individuals whose cecal tip evacuation time is not influenced by phenolphthalein than there are whose total evacuation time is not influenced. This indicates that *the chief evacuant effect of phenolphthalein is probably exerted in the cecum.* It might

also be stated that the total evacuation time in many cases was unduly prolonged by the retention of only a relatively small amount of opaque material of possibly questionable importance.

Detailed investigation of those exceptional individuals whose evacuation time was definitely increased by even 0.60 Gm. dosage of phenolphthalein might furnish valuable hints for the understanding of the mode of action of phenolphthalein and also help in the elaboration of more definite indications and contraindications for the use of phenolphthalein as a cathartic.

RECOMMENDATIONS

As the number of subjects investigated in this study was rather small, studies of a larger series would yield information of greater reliability.

More intelligent subjects would be highly desirable because they would cooperate more fully and give information as to frequency and condition of bowel movement which should be incorporated in data of this type.

Exhaustive studies of resistant subjects might yield very significant data.

CONCLUSIONS

1. A method is described for the graphic representation of the progress of an opaque meal through the alimentary tract and for deriving data of possible use in the evaluation of the motility of human alimentary tracts.

2. In the relatively small group studied, the most probable value of the total evacuation time was 70 hours and of the cecal tip evacuation time just under 27 hours.

3. The most probable time for the opaque meal to be evacuated completely when 0.30 Gm. of phenolphthalein had been ingested was 62 hours: a decrease of over ten per cent; and the cecal tip evacuation time just under 18 hours: a decrease of thirty-three per cent.

4. When subjects, who were "resistant" to 0.30 Gm. of phenolphthalein, ingested 0.60 Gm. of phenolphthalein, the most probable time totally to evacuate was 40 hours, which is significantly below the control time and of the 0.30 Gm. of phenolphthalein evacuation time of the entire group. There were, however, exceptional individuals whose evacuation time was definitely increased by both 0.30 Gm. and 0.60 Gm. doses of phenolphthalein.

5. It seems that the time required totally to evacuate, and possibly also the time required just to empty the lower tip of the cecum, might be useful criteria for judging the action of cathartics.

Host Susceptibility to Common Colds*

By

IRWIN G. SPIESMAN, M.D.

and

LLOYD ARNOLD, M.D.

CHICAGO, ILLINOIS

A CAUSATIVE agent of disease in man must enter the body by passing through some surface covering layer, skin or mucous membrane. Some of the agents causing disease gain entrance through abrasions of these surfaces and belong to the wound infecting group. Most of the diseases however are produced by viruses, bacteria and parasites that invade the body by passing through an intact mucosa, the upper respiratory or digestive mucous membrane. The normal defensive power of the body against such invaders resides in the ability of these membranes to prevent the invasion after contact.

Man must adapt himself to his environment in order to maintain health. Environment can be subdivided into various factors, such as: (1) Meteorological or climatic, (2) nutritional, (3) mental and (4) parasitic. This article will present our experimental and clinical observations upon common colds considered from the standpoint of maladjustment to these environmental factors.

The mucosa of the upper respiratory tract is an unusual body surface covering layer. Embryologically it is closely related to the skin. The mucosa of the nose has several physiological functions in addition to those of a limiting integument or covering for this body surface.

Hill and Muecke (1913) showed that the mucosa of the nose becomes "flushed and swells" when a normal subject is placed in a warm moist atmosphere (80° F.). The lumen is narrowed and even choked. When the subject passed to a cold atmosphere the mucosa quickly became pale owing to constriction of the blood vessels, but still remained thickened or swollen. Mudd and Grant (1919), Mudd, Goldman and Grant (1921), Mudd, Grant and Goldman (1921) were the first to study the relationship between the chilling of the skin and the temperature of the mucosa of the nose and throat. Azzi (1920, 1921, 1921) in Italy carried on similar experiments at the same time. Azzi extended the respiratory mucous membrane surface to include the trachea in man. He had the opportunity of using some tracheotomized subjects for this study. Winslow and Greenburg (1932) extended the observations of the vasomotor reactions of the nasal mucous membrane to cold stimuli applied to the skin. Schmidt and Kairies (1932) in Germany and Undritz and Sassosow (1933) in Russia, carried out some extensive work at the same time in this field. The technical methods used by all of these observers were in general the same.

*From the Department of Bacteriology and Public Health and Ear, Nose and Throat, College of Medicine, University of Illinois and the Research Laboratories of the State Department of Public Health of Illinois, Chicago, Illinois.

Submitted May 20, 1937.

These workers differed in their procedure of applying the skin stimuli, such as stripping subject and using cold wind current on back, immersing foot or hand in cold water, applying cold, wet towel to back, chest or other body surface.

Townsend (1924) showed that epidemics of common colds occurred from the Pacific to the Atlantic coast at approximately the same time in each locality. Van Leghem (1928) studied the incidence of common colds in Holland and found the same thing. He found that the attack rate in small and large family groups was the same and concluded that "This joint result tells against the contagiousness of colds in the period of observation." Bibb (1924) analyzed the incidence of common colds in a military population and concluded that communicability played a minor role. Many more such observations could be cited. Kerr and Lapen (1931) could not transmit common colds to healthy human volunteers in air conditioned rooms held at "effective temperatures." During the early stages of the disease, common cold sufferers lived with volunteers in this room. The volunteers were inoculated in their conjunctival sac with secretions from the coryza patients' nares.

Several observers have emphasized the influence of meteorological environment upon the incidence of common colds, which presumably has a relationship to external temperature. Selado (1919), Van Leghem (1928) and Bibb (1924) and others have developed the thought that disturbances in the heat regulatory function of man due to climatic changes are the basis for increased susceptibility of the host to common colds.

Smiley (1929) showed that the winter or spring epidemic of cold among college students was mostly limited to the cold-susceptible group. Only one-fourth of the student population was responsible for the increased incidence of cold at these seasons. He concluded that if this group were made resistant to common colds, the winter and spring epidemics would disappear.

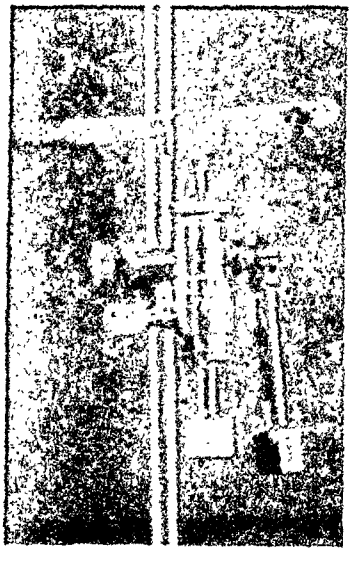

Fig. 1

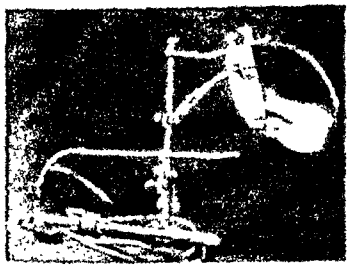
Galafer (1932) could find no decrease in the incidence of colds when some 300 subjects slept in rooms with open windows and took out-of-door exercise.

For an understanding of the reactions of the respiratory tract to external influences, it is well perhaps



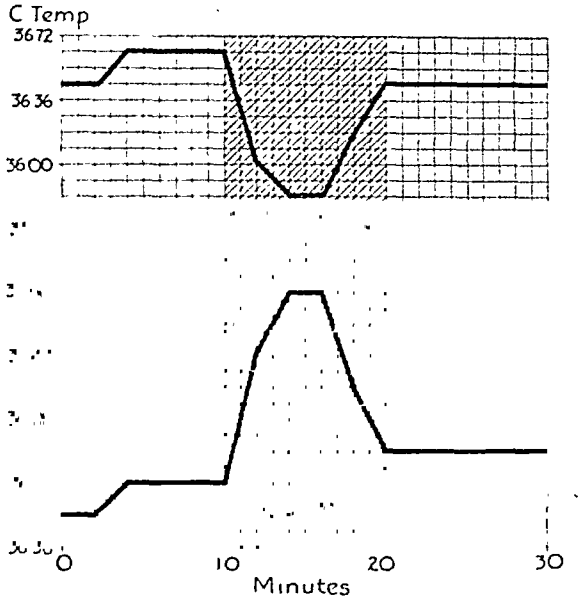


Fig. 2

at this time to review the physiology of the nose. One of the primary functions of the nasal mucous membrane is its ability to supply moisture to the inspired air. This moisture is supplied through the physiologic reactions occurring in the erectile tissue of the turbinates. Closely associated with the process of moistening or humidifying is the heating of the inspired air. This function is accomplished by the large and numerous blood vessel spaces in the deeper layers of the mucous membrane of the turbinates. Another important function of the nose is its ability to filter the inspired air. Coarse particles in the air are filtered out by vibrissae within the vestibule of the nostrils. The turbinates break up the column of inspired air, producing eddies, so that most of the air comes in contact with some part of the surface covering mucous membrane. This facilitates the deposit of foreign particles on membrane. Wright and Smith (1914) state that thin sheets of air in passing over these surfaces deposit at least three-fourths of their bacterial content on the mucosa. The dust and foreign particles including bacteria thus deposited on the mucous membrane are disposed of, in part at least, by the action of cilia with the protective layer of mucus. Goodale (1895) was the first to show that air taken in through the nose and exhaled from the mouth gave the greatest increase in temperature and relative humidity. He also demonstrated that while the nose nearly saturates the air, it contributes only about two-thirds of the total amount of moisture evaporated by the respiratory tract.

The vasomotor mechanism of the nose involves the physiologic activity of two sets of antagonistic sympathetic nerves, the vasoconstrictors and the vasodilators. The constrictor fibres consist of preganglionic fibres arising from the central nervous system and postganglionic fibres from the cells of the sympathetic ganglions. The vasoconstrictor fibres arise chiefly from the cervical sympathetic ganglia. The vasodilators are not as powerful as the vasoconstrictors. Not much is known regarding the vasodilator fibres. They arise from the cervical sympathetic and from the ganglia and connecting sympathetic of the seventh and ninth cervical nerves.

Hilding (1931, 1932, 1932, 1932) states that the film of secretion covering the membrane of the respiratory tract extends like a continuous membrane over the surface of the nose, the paranasal sinuses,

pharynx and the trachea. This film of mucus is in continuous motion throughout this entire extent of surface. The general direction of flow is toward the nasopharynx. The mucinous covering is kept in motion by direct ciliary activity. Lucas and Douglas (1934) showed that the mucous sheet which covers the cilia is composed of two layers, an outer stratum of mucus which rests on the top of the cilia and an inner fluid layer of low visocosity which forms a suitable medium for the vibrating cilia. They emphasized the possible importance of the fluid layer as a mechanism of dissemination of bacteria and viruses. Phillips (1926) and Gordonoff and Mauderli (1936) showed that ciliary action was sluggish and delayed after an acute

Common Cold Resistant Type

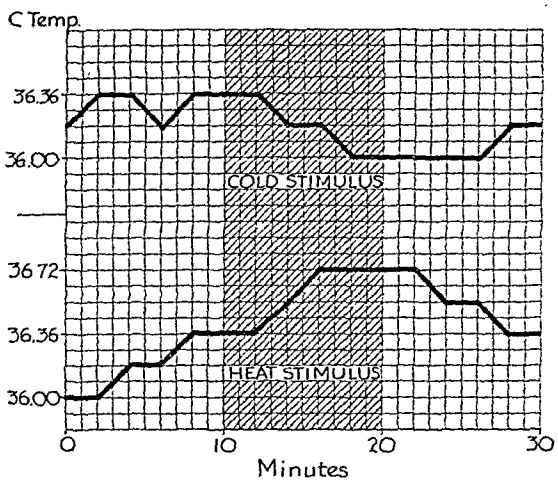
Graph III. Upper line represents nasal mucosa temperature changing after cold stimulus is applied to skin of back. Lower line represents the same after application of heat.

upper respiratory infection, and that healthy ciliated epithelium is a most important factor in maintaining a normal sinus condition.

That filtration, humidification, temperature regulation of the inspired air play an important part in the protection of the nose. (Heetderks, 1927) paranasal sinuses and the lower respiratory tract against deleterious influences is now accepted without question. Ciliary action and mucous secretion also play an important part in the protection of the underlying mucosa against the deleterious effects of foreign agents, especially bacteria. The vibrissae of the nasal vestibule play some part in filtering out gross particles from the inspired air which under ordinary conditions contains few pathogenic organisms. It has long been suspected that some antibacterial substance in the secretions is a contributing factor. Hilding (1930) points out that the protective coat of mucus and ciliary activity are important factors in removing bacteria from the nose and sinuses. Fleming (1929) found lysozyme present in a large number of tissues and secretions from the human body. Considerable quantities were found in nasal sinuses and in saliva. The properties of lysozyme have been studied by Ridley (1927) who concluded that the action of lysozyme on bacteria causes them to swell, lose their outlines and disappear.

Kisskalt (1903) and some of his students (Maugeri (1933), Krishnamurthy (1935) and Margaritis (1936)) have studied the fate of bacteria in the respiratory tract in animals. They ascribe a phagocytic function to the epithelial cells. Ropes (1929) found the ciliated cells in the trachea and bronchii of rabbits phagocytized carbon particles. This function may play a role in the upper part of this tract and may be a factor in defense against bacterial invasion.

The whole problem of resistance of the mucosa of the upper respiratory tract to infection has been recently reviewed in considerable detail by Linton (1933).



The susceptibility to the common cold has been approached from numerous angles. Dietary inadequacies, particularly of vitamins, have been suspected as being in the background of susceptibility. Numerous investigations have concerned themselves with the specific immunity of the individual to bacterial antigens; a number have dealt with the role of vasomotor phenomena in susceptibility to upper respiratory infection. Spiesman (1935, 1936) reported his observations upon the vasomotor response of the nasal mucosa to thermal stimuli applied to various areas of the skin. These reports dealt more with the physiology of the mechanism of the relationship of skin stimuli and nasal mucosal capillary response. The previous reports dealt largely with the situation in normal individuals and only brief reference was made to the findings in subjects with head colds. The primary object of this investigation was to provide a means of study of altered function in the subjects with head colds.

Thirty-nine patients were included in this investigation, excluding the twenty-four normal subjects whose findings have already been reported. In the 39 cases "colds" of various variety were studied. Thirty-four of this number were adults, five were children; twenty-three were males and sixteen females; the age distribution of this group varied from six to fifty-four years. Twenty-one of this group were classified as the chronic cold group because these subjects had had more than three colds a year, as distinguished from the already mentioned twenty-four cases, or cold resistant group which had not more than one "cold" per year.

All of the thirty-nine cases were selected from the outdoor clinic patients applying for relief after having had a long history of various types of treatment previously received but who nevertheless came to the clinic presumably because their symptoms continued in spite of previous treatment. A complete history was taken on each patient and a general physical examination made including X-ray of the sinuses and chest. The patients finally chosen for this study presented no detectable pathology as determined by the above methods of examination. It was advisable to eliminate those who suffered from repeated head colds and who showed sinus pathology since an infected or inflammed sinus would in itself predispose the patient to repeated infections.

The vasomotor reflex mechanisms were investigated by the following method. A three element thermopile made of No. 30 German silver wire and No. 25 copper

wire mounted in a Bakelite block, as indicated in Figure 1, was placed lightly on the mucosa of the inferior turbinate. The pressure was adjusted with a micrometer screw arrangement attached to the headgear as shown in Figure 2. The constant temperature

Chronic Infectious Common Cold Type

Graph IV. Upper line represents nasal mucosa temperature changing after cold stimulus is applied to skin of back. Lower line represents the same after application of heat.

junctions of the thermocouple were placed in the thermos jar filled with chipped ice. A type K potentiometer and a sensitive galvanometer were used to measure the voltage differences corresponding to the temperature differences in the two thermocouples. In the system as used 2 x 10-5 power volts equals 0.018° C.

APPEARANCE OF NASAL MUCOSA

The appearance of the nasal mucosa of the young healthy subjects studied was pinkish in color. When a cold stimulus was applied to the skin over a small portion of the upper back no noticeable change in the appearance of the nasal mucosa was seen. Changes in appearance of nasal mucosa (ischemia) were definitely seen when larger skin areas were stimulated, as for instance, when applying cold water to the skin of the entire back or immersing the lower limbs in cold water. The presence of ischemia was dependent on the amount of skin area stimulated.

SITE OF THE NASAL ELECTRODE

At first the nasal thermopile electrode was applied to various areas of the nasal mucosa to determine which area was most practical for our experiments. The following areas were studied; inferior turbinate, middle meatus, middle turbinate, superior meatus, and septum. Except for the septum, the results were alike in all the areas mentioned. However, for all practical purposes, we found that the anterior half of the inferior turbinate was most accessible because in this area the electrode could be applied without causing any irritation to the surrounding mucosa. When applying the electrode to the nasal mucosa great care had to be exercised, since any irritation of the mucosa created by the electrode produced congestion with increased temperature and excess mucous formation.

The electrode after being applied to the nasal mucosa was held in place by an adjustable clamp attached to a head gear. The nasal clamp had a micrometer adjustment for making desired pressure upon the electrode tip on the mucosa. By previous experiments we found that too light pressure allowed the respiratory air to circulate around the tip of the electrode thereby preventing correct temperature measurements. Very firm pressure of the electrode to the nasal mucosa brought about local irritation. Moderate pressure gave the desired results, however, and the micrometer adjustment made possible the application of the desired pressure to the mucosa.

PREPARATION OF THE SUBJECT

The subject was brought into the experimental laboratory; a room about 8 feet square in which the temperature did not vary and drafts were minimized. He stripped to the waist and remained at ease in sitting posture until the experiment was begun. A record was made of the condition of his nasal mucosa before the experiments. At the end of the half hour, the electrode was applied and the control temperature record was made of the nasal mucosa, a reading every 2 minutes for five readings. The experimental subject arrived at the laboratory usually one hour after breakfast. Readings were made five mornings each week: Monday, Tuesday, Thursday, Friday and Saturday. The same subject was studied weekly from four to six months during the winter. Several subjects remained for study throughout the summer and weekly records were made of their nasal mucous membrane temperatures. The experiments were all conducted before noon, usually between 9:00 and 12:00. The skin area stimulated by choice was that of the upper back; the duration of the experiment was thirty minutes, as follows: ten minutes for control temperature, ten minutes to record changes due to application of the cold stimulus followed by another ten minutes for a control record.

Each subject was studied as described above for a period of three to five weeks to determine the average nasal mucosal response to a cold stimulus applied to the skin of the upper back. Various treatments were then prescribed and observations continued at weekly intervals for several months.

Spiesman (1936) has outlined in detail various methods of applying thermal stimuli to skin surfaces while recording the temperature changes of the nasal mucosa. The reports we are including in this paper were made with the use of a uniform technic as follows:

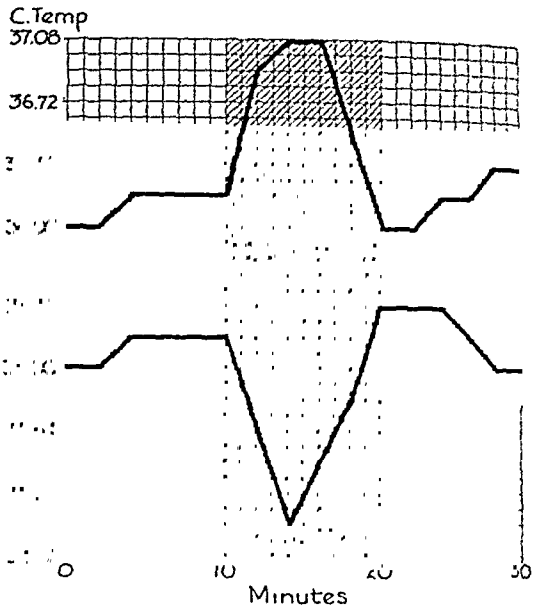
Aluminum cups, varying in diameter from four to nineteen centimeters filled with chipped ice were used as cold stimuli. The ice-filled cups gave a surface skin temperature of 12.6° C. within a minute. Aluminum cups filled with hot water were used as heat stimuli. The hot water ranged from 42.5 to 43.5° C. The subject's back was bare of clothing when the thermal stimulus was applied. There was a ten minutes' period of observation before the thermal stimulus was put on the skin. This was to obtain a normal curve of the temperature and to record the influence of the local irritating factor of the electrode applied to the nasal mucosa.

Graph III illustrates the average of several hundred observations made on normal subjects. The upper line records the temperature of the nasal mucosa for thirty minutes period of time. The first ten minutes is the control period, the next or middle ten minutes is the duration of the time the cold stimulus was applied to the skin of the back. The last ten minutes period records the temperature of the nasal mucosa after the cold stimulus was removed from the back.

Attention should be called to the prompt lowering of the temperature of the nasal mucosa immediately after the cold stimulus is applied to the skin and the gradual recovery or return to approximate normal temperature level even while the stimulus is still being applied. Recovery of the nasal vasomotor reaction is complete during the ten minutes time of ap-

plication. There is no change in the temperature of the nasal mucosa after this equilibrium is reached. This is characteristic of the normal person.

The lower line on Graph III records the temperature changes of the nasal mucosa as a result of applying a hot stimulus to the skin of the back. This is characteristic of the normal person. The same general statements can be made for this warm stimulus as have been made for the cold stimulus.



THE CHRONIC OR FREQUENT COMMON COLD SUFFERER

Graph IV records the temperature changes of the mucosa of the nose before, during and after application of thermal stimuli to the skin of the back. The control or the ten minutes period before application of the stimulus shows deviations from the normal. The initial temperature is usually lower, and the mechanical stimulus of the electrode gives variable responses. The nasal mucosal response to cold skin stimuli is delayed and never varies greatly in magnitude. Recovery is delayed and extends for fifteen to twenty minutes or more in time as compared to prompt and quick recovery of vasomotor equilibrium in the normal (Graph III). There are considerable variations in the response of different subjects and even in the same subject on different days. The pattern of vasomotor response of the nasal mucosa to cold and hot stimuli applied to the skin is regular in the normal individual, but manifests considerable variations in the chronic, repeated or frequent sufferer from common colds. These experiments were carried out on these subjects at the times they were free of colds or between their attacks.

THE HYPERSENSITIVE CASES

At first all of our cases were received as patients with frequent head colds. After studying these persons we immediately had on hand two classes of patients: (1), the chronic group of head colds, and (2), the non-infectious or hypersensitive group. This latter group was classed as hypersensitive because the subjects presented a syndrome, during an attack, which was characterized by sneezing, itching, nasal obstruction, nasal discharge and loss of the sense of smell associated mostly with a pale discoloration of the nasal mucous membrane. Anyone or more of these symptoms dominated the clinical picture. The frequency, duration and degree of these symptoms varied a great deal in individual cases. Although all of this group was given skin tests to determine the particular sensitivity, their skin reactions to various allergens was negative. It is generally admitted that from the standpoint of symptoms as described above that these cases of hypersensitive rhinitis are of allergic origin in spite of negative skin tests and that in these particular cases the nasal mucous membrane is hypersensitive, although the skin tests were negative.

Graph V illustrates the average temperature response of the nasal mucosa of the hypersensitive or allergic group to thermal stimuli applied to the skin of the upper back. The control or the ten minutes' period of temperature observation does not deviate from the normal person. The vasomotor response of the nasal mucosa is just the opposite to that of the normal; an increased temperature when cold stimulus is applied to the skin and a decreased nasal mucosal temperature when heat is applied to the skin. This has held true for all of the subjects in this group. The recovery period after removal of the thermal stimuli is not as uniform as in normal subjects. It requires a longer period of time before an equilibrium is

Allergic or Hypersensitive Cold Type

Graph V. Upper line represents nasal mucosa temperature changing after cold stimulus is applied to skin of back. Lower line represents the same after application of heat.

reached. The general pattern of this curve as shown in Graph V is typical for this group of subjects.

We have been able to classify the subjects we have studied into three groups:

(1) The normal or the individual who rarely has a common cold. (Graph III).

(2) The chronic or frequent common cold sufferer. (Graph IV).

(3) The hypersensitive or allergic type. (Graph V).

It became very apparent to us in the early part of this work that if one wished to apply any preventive methods it would be necessary to differentiate between these three groups. Preventive procedures applied to the normal group would not alter the usual physiological vasomotor response of the nasal mucosa to thermal stimuli applied to the skin.

Autogenous vaccines were administered to eighteen patients of the chronic common cold group. The vaccines were prepared from organisms cultured from the respiratory and digestive tracts, following only part of the suggestion made by Dorst and Morris (1930) to include intestinal strains. Sensitization tests were not made, however, in this group. The following bacteria were isolated in pure culture and vaccines prepared from each in the usual manner.

Respiratory Tract:

Streptococcus viridans and micrococcus catarrhalis. Streptococcus hemolyticus. Staphylococcus albus. Staphylococcus aureus. Staphylococcus hemolyticus.

Digestive Tract:

Streptococcus viridans (most frequently found and in the same strains as in the respiratory tract). Bacillus coli communis. Bacillus coli communior. Bacillus coli hemolyticus. Bacillus mucosus capsulatus. Bacillus fecalis alkaligines. Bacillus acidi lactici. Bacillus proteus. Bacillus cloacae.

From two to six bacterial antigens were included in a polyvalent vaccine. Injections were given subcutaneously every other day, beginning with one minim dose and increasing slowly to produce the local or focal reactions; maximal dose was one c.c. The total treatment lasted three months. The frequency of colds was not affected by this treatment, nor was there any effect produced upon the vasomotor responses of the subject in question. We devoted a year to the vaccine studies. Our results using the nasal vasomotor reflex and clinical observations coincide with the negative findings reported by Sholly and Park (1921), Ferguson, Davey and Topley (1927), Brown (1932), Dochez (1933), Hoyle (1933), Kneeland (1934) and many others, all of whom were unable to show any protection against colds after the use of vaccines.

Spiesman (1936) showed that if the skin was anesthetized the application of the thermal stimuli still produced the same vasomotor response in the nasal mucosa, pain was therefore not the factor in this mechanism. Lowered temperature was due to vasoconstriction and an elevation in temperature was caused by vasodilatation. In other words, pain was not a factor in this vasomotor reflex response.

It was, therefore, concluded to attempt to increase the efficiency of the vasomotor tonus mechanism of the nasal mucosa of the chronic cold and the hypersensitive types by hydrotherapy. These subjects were not hospitalized; our object was to apply simple methods applicable by anyone desiring to carry them out. Each subject received instructions to take a hot bath and cool or cold shower on arising each morning and repeat if possible each evening before dinner. The water was to be warm enough to be comfortable; followed immediately with cold water, applied first to the legs, thighs, abdomen, chest and then the back. The cold water was not to be applied to the extent of chilling the body. If the patient became chilled, which was frequent at first for the hypersensitive group, a warm shower should be taken immediately. Once each week a temperature reading was made of the nasal mucosa applying both heat and cold to the back.

The same hydrotherapy was carried out on the hypersensitive group. There was little improvement in the nasal vasomotor tonus, in many of these subjects. This group requires long study because of their unstable reactions before one can arrive at trustworthy end points. It was apparent that some few were markedly improved, but most of them showed little benefit, either in vasomotor response or clinically in a reduction in the incidence of their colds.

After six weeks of hydrotherapy, the hypersensitive group was placed upon an elimination or non-allergic diet as outlined by Rowe (1931). For the purpose of completion we are listing the diet used at this place:

Cereals — Rice, Corn, Tapioca; *Meats* — Lamb, Chicken, Bacon; *Vegetables* — Lettuce, Spinach, Carrot, Squash, Asparagus, Pea, Artichoke; *Fruits* — Lemon, Pear, Peach, Pineapple, Apricot, Prune; *Also* — Sugar, Karo Syrup, Maple Syrup, Mazola Oil, Olive Oil, Olives, Salt.

After the six weeks, if the patient showed sufficient improvement the following foods were added: beef, tomato, beet, string-bean, celery, grapefruit, Wesson oil. The hypersensitive group showed greater improvement on the combined non-allergic diet and the hydrotherapy than on hydrotherapy alone. During the three years, while these patients were under observation, the hypersensitive group was placed on the elimination diet alone, then on vasomotor massage (hydrotherapy) alone for a period of three months. The best results were obtained with the combined treatment of diet and vasomotor massage. A larger number returned to the normal vasomotor response and were free of upper respiratory disturbances. However, this group proved its vasomotor instability over and again by reverting to type after experiencing mental maladjustment. Apprehension and worry produced a complete recurrence of symptoms, and alterations in vasomotor responses. While in this state of apprehension, the same treatment produced no effect. All signs of recovery were removed until worry ceased to exist in the patient.

The non-allergic or elimination diet proved so advantageous a factor in assisting the hypersensitive type to gain a better vasomotor response of their nasal mucosa to thermal stimuli applied to the skin, as well as a better feeling of well being and freedom from colds, we thought a modification of this diet might help the chronic cold subject who had not gained vasomotor control by hydrotherapy alone. We had observed during our experience with the hypersensitive group that the ingestion of wheat and wheat products combined with a high carbohydrate content, were most likely to alter the nasal mucosal responses, as well as being associated with the onset of a cold.

Again for the purpose of making a complete and practical record of our experiences we give the diet we have used for this chronic common cold group:

Cereals — Rice, Corn, Rye; *Vegetables* — Lettuce, Tomato, Carrot, Spinach, Squash, Asparagus, Peas, Beet, Stringbean, Celery; *Meats* — Lamb, Chicken, Bacon; *Fruits* — Orange, Grapefruit, Lemon, Apple, Pear, Peach, Pineapple, Prune, Apricot, Plum; *Dairy Products* — Butter (much), Cream, Milk, Cottage Cheese, Egg Yolk; *Also* — Sugar (sparingly), Karo Syrup, Maple Syrup, Mazola Oil, Olive Oil, Olives, Salt.

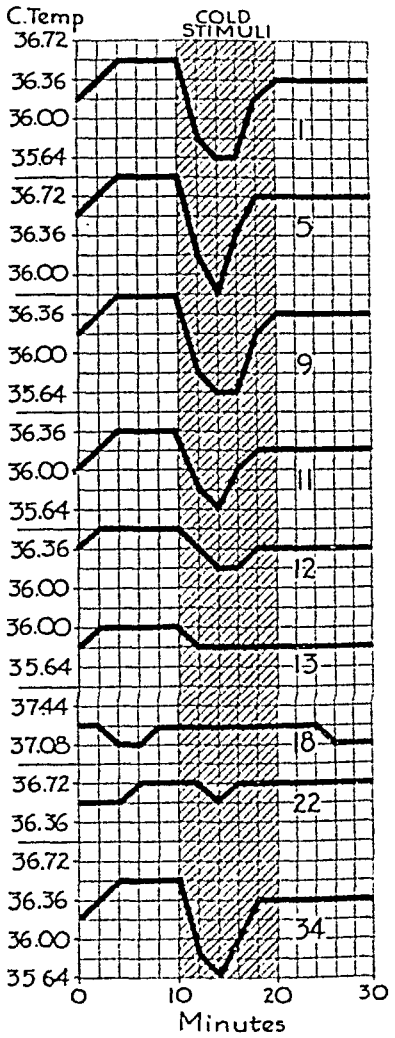
All products made from wheat, i.e. white flour breads, pastries, pies, cookies, etc., were eliminated from the diet. The patients in this group were requested to abstain from the use of tea, coffee or alcoholic beverages, and to smoke sparingly. They were instructed to eat two large vegetable portions, or a vegetable and fruit salad each day, and to make the salad the main course of the meal. They were also asked to eat as much fresh fruit as they could daily—six ounces of orange juice and six ounces of tomato juice per adult per day. Eight glasses of water were prescribed a day. Fried foods were prohibited. No condiments. Butter was to be added very freely to all cooked vegetables and eaten generally very freely; two to four egg yolks for each adult and one to two for a child per day. The patient was not to hurry while eating, nor be tired or worried. He was to take a short rest after every meal. The day's menu for a patient of the chronic infectious group read:

Breakfast: A glassful of orange juice (adult). One or two additional fruits, fresh or cooked (sugared

sparingly), in good quantity. Cooked cereal of rice or corn meal with milk or cream in moderate portion, or Bacon with buttered toast made from rye, corn or rice flour. Glass of milk if desired.

Lunch: A large portion of vegetable or vegetable and fruit salad. Bread made of special cereal, rice, rye and corn meal with much butter. Milk. Cottage cheese, if desired. Fruit, good portion. Water.

Dinner: Large vegetable salad. Meat, small portion. Two cooked vegetables (non-starchy.) Fruit. One glass of milk. Water.



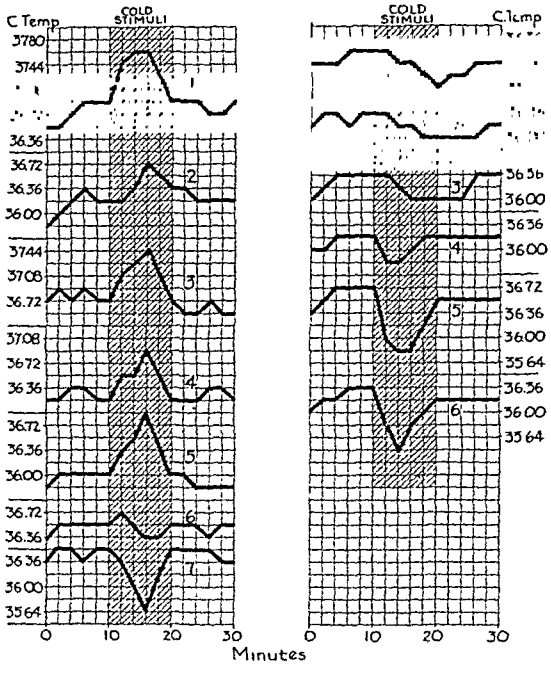
The patients on this regime improved clinically and also in their vasomotor response. During the three year period, the group placed on the diet alone improved much better than on hydrotherapy alone, but best of all on the combined treatment of diet and hydrotherapy. We found, in our experience with dieting of these patients, that an overindulgence of carbohydrates, especially of the wheat-cereal variety, was most to be guarded against. Time and again we observed, after excellent results were obtained, that a return of the patient to an excess carbohydrate diet caused a recurrence of symptoms.

The increased vitamin content, the larger amount of roughage, and other factors are apparent in this diet. These do not, however, explain to our satisfaction the results we obtained. We are now studying this problem. Paton (1933) calls attention to the high ingestion of carbohydrates and the incidence of "catarrhal illnesses." Orr and Gilks (1931) also incriminate a high cereal diet as a factor in mortality from respiratory diseases in their studies of some East African tribes.

After the combined treatment of diet and hydrotherapy the results in both the infectious and non-infectious cases were very satisfactory. However, in some instances, even after careful treatment of diet and hydrotherapy, in both of these groups, individual patients did not produce satisfactory results. That is, the patient under the combined treatment, who had been in good health for some time and free from head colds, infectious or non-infectious, would have, for apparently no reason, a complete relapse with recurrent symptoms and altered vasomotor response. This relapsed state occurred more frequently in the hypersensitive group. Careful observation was then made of these patients and it was found that apprehension and worry were real factors in their condition. Apprehension and worry produced a complete recurrence of symptoms — head colds, and alterations in vasomotor responses. While in this state of apprehension, the same treatment produced no effect. All signs of recovery were absent until worry ceased to exist in the patient.

That apprehension and worry, and unusual emotional activity can produce irregular vasomotor reactions was observed in normals and reported in a previous paper, Spiesman (1936). In hypersensitive cases, where a very irritable and easily altered vasomotor mechanism already exists, continuous good results from the therapy outlined above, is in our experience, maintainable only if the patient's mental attitude is not allowed to change by severe worry or unusual emotional stress. Re-education along the line of mental hygiene is needed therapy for such patients.

One of the normal subjects studied five times per week for several consecutive months in order to determine the daily variations of the nasal vasomotor response, developed a cold during the period of observation. This subject was a healthy young adult male. He had not had a cold for two years. Graph VI shows a few of some eighty-five observations we have made upon this subject. Curve 1, 5 and 9 show



Common Cold Resistant Type

Graph VI. Followed through an attack of acute common cold. Lines 1—11 are normal responses of nasal mucosa temperature to cold stimulus applied to the back. Line 12 represents the incubation period. Lines 13—22 are during the attack of common cold. Line 34 represents the return to normal nasal mucosal response.

averages of the nasal mucosal temperatures observed before, during and after application of cold stimulus to the skin of the back. The last curve (9) was made on a Saturday morning. This subject visited his married sister in her home Sunday afternoon and evening. Two adults and two children in this home were suffering from common colds at the time of his visit.

Curve 11 was made Monday morning; the subject did not complain but felt tired and spoke of having eaten and smoked too much the day before. Curve 12 was his nasal temperature response on Tuesday morning. He complained of headache, backache, etc., but con-

Hypersensitive Type — Chronic Infectious Common Cold Type

Graph VII. Each line represents an average of weekly readings of nasal mucosa response to cold stimulus applied to the back. A gradual return to the normal is shown as a result of hydrotherapy, corrective diet and mental hygiene.

junctiva and nasal mucosa were not altered in general appearance. There was, however, a loss of vasomotor tonus of the nasal mucosa. The next day, Wednesday, (Curve 13) the patient had a typical acute coryza, a conjunctiva injected, continuous aqueous nasal discharge, etc. This subject was then hospitalized. We wished to study his vasomotor reactions daily and did not desire him to be exposed during transit to and from the laboratory. A few of the nasal temperature records are shown on Graph VI. Curves 13, 18 and 22 represent the number of days in consecutive order. Ten days (Curve 22) after the beginning of the infection (Curve 12) the nasal discharge had disappeared. It was, however, twelve days later (Curve 34) before the normal vasomotor tonus returned. Daily observations were made. This illustrates the alterations in the vasomotor tonus of the nasal mucosa of a healthy, cold-resistant person, who has been subjected to a massive exposure of the virus or causative agent and was followed from the incubation through the disease until recovery.

Graph VII represents a few of the nasal temperature records made upon two cases, one a hypersensitive type, the other a chronic or frequent head cold subject. The hydrotherapy, diet and mental hygiene outlined above were carried out by these subjects. The curves are typical averages of weekly readings of nasal temperature after cold stimulus was applied to the back. The hypersensitive case did not show improvement with the sixth week of observation, but after the seventh week he had a normal nasal vasomotor response which has been maintained for over two years. This patient has been checked-up with nasal temperature tests each week during this time.

The other series of curves on Graph VII is from a chronic cold type. It required four weeks after beginning hydrotherapy, combined with certain dietary restrictions and mental hygiene, before this person showed an altered nasal temperature response to a cold skin stimulus. After the fifth week he had a normal nasal vasomotor reaction. This subject has been under observation three and a half years. He has been free of colds during this time.

The mental factor in this readjustment of the nasal vasomotor response cannot be overemphasized. We have frequently and repeatedly observed subjects as indicated in Graph VII change from the normal response, as indicated in the lower curves, back to the abnormal response as shown at the top of each series of curves, as a result of mental maladjustment. Many specific instances could be cited; loss of position, bankruptcy, illness or death of a relative; in fact worry and mental strain of various kinds; all tend to offset the advantages derived from hydrotherapy and diet.

The best preventive measures, as well as the most lasting therapy, for these two groups may be summarized as follows:

1. Vasomotor massage or hydrotherapy given continuously, with the patient made to feel that this is an essential health measure and important to a state of well-being.
2. Diet prescribed not merely as a therapeutic measure, but as a daily measure of intelligent eating for a better state of health.
3. Change of mental state through mental hygiene with the express purpose of producing a more wholesome attitude of the patient to himself and his environment.
4. Physical exercise as an important adjunct of the daily regime. Twenty minutes of setting up exercises, in the nude in a cool room, prior to taking a hot and cold shower. A brisk walk for one hour a day, either in divided time or for the whole hour, walking, never hurrying, breathing deeply and thinking soundly.
5. Rest, even if only for a short period after each meal.

DISCUSSION

The individual suffering from repeated colds between October and April has an altered vasomotor reaction of the upper respiratory mucosa to thermal stimuli applied to the skin. When the skin is chilled, there is a slow, gradual vasoconstriction of the capillaries in the mucosa of the upper respiratory tract which persists for several minutes to two hours. This represents a maladjustment of the peripheral capillary response to climatic or meteorological environment. So long as this abnormal reaction exists the host is susceptible to the common cold virus and the bacterial flora residing in his upper respiratory tract. Such a person becomes a reservoir for the causative agent. We could not alter the vasomotor

response nor reduce the incidence of common colds in this group by vaccine therapy. We have been able to do both by hydrotherapy and certain simple alterations in the diet. The best results were obtained by a combination of both methods of prevention. The mental factor also plays a role, but not to the same extent as was found in the hypersensitive group. We have records showing a normal nasal vasomotor response to thermal stimuli of the skin and a freedom from colds for two years in subjects giving a history of four to six colds each winter for several years. Some few of these subjects due to various reasons, such as loss of their positions, bankruptcy of their business, sudden death of a member of the family, etc., promptly developed a head cold. In two or three instances we were able to demonstrate a change in the vasomotor response of the nasal mucosa for several days preceding the onset of the cold. The mental factor in adaptation of the vasomotor equilibrium of the upper respiratory tract cannot be overemphasized in those persons showing abnormalities in their capillary controlling mechanism.

The hypersensitive or allergic type of cold is more difficult to control and to prevent than the chronic, frequent and severe head cold type. But we have been unable in our experience to trace secondary head colds from anyone of these hypersensitive types. Office, factory, laboratory or class-room contacts closely associated with this type of cold subject have never developed colds. We have, at least up to the present, no evidence that these allergic vasomotor nasal reactions are associated with the infective virus of common colds. Although many interesting problems are presented as a result of our study of these hypersensitive cases, we feel they are not a reservoir for the common head cold virus and their control hence becomes less urgent than that of the chronic infectious head cold group.

The nutritional factor in susceptibility to common colds has been frequently observed by us during this study. It seems that the mucosa of the nose is more sensitive to allergens ingested by mouth than the skin. All of our subjects were studied in the Allergy Clinic and only those showing negative skin tests to various antigens were studied by us. The non-allergic diet helped the hypersensitive group to readjust its vasomotor responses. We have no explanation to offer for the beneficial results obtained in the frequent infectious head cold group following the elimination of wheat breads, pastries, pies, cookies and such rich carbohydrate foods. Our experience convinces us that these foods increase the susceptibility of the chronic cold sufferer to repeated attacks and exercises a detrimental influence upon the nasal vasomotor response to thermal skin stimuli.

The reservoir for the causative agent of common colds is, in the main, confined to the chronic, frequent and repeated head cold subjects. The restriction of the distribution of this virus can best be approached by increasing the resistance of these people to autoinfection. Minor alterations in their environment, meteorological, nutritional or mental, causes a common cold. We have found this group responds to preventive and hygienic procedures better than the hypersensitive group. The hypersensitive type of upper respiratory disturbance is not communicable and from a public health standpoint is not a source of contagious material. We have observed common colds of the infectious type in some of the hypersensitive group, but the clinical picture is different, the nasal discharge and course of the disease are the same as in the other groups.

The hypersensitive type of long standing develops pathology of the mucosa and tends to develop or superimpose upon these altered tissues a chronic infectious cold type. These subjects then become chronic carriers and are therefore a combination of the allergic and chronic infectious type of cold. As stated before, we eliminated these pathological cases before we began our observations.

Massive exposure of the normal resistant person to the causative agent can be followed by infection. The resistance enjoyed, by proper adaptation to the environmental factors discussed, is only relative. The parasitic environment is most important to this resistant type, in as much as these subjects are adjusted to their meterological, nutritional and mental environmental factors.

The repeated or chronic common cold type is out of adjustment to his or her environmental factors and hence requires some corrective measures to assist in adaptation, such as vasomotor stimulation (hydrotherapy), certain dietary restrictions, better mental hygienic control, etc. While in a state of maladjustment this portion of the population acts as reservoirs for the cold virus. Smiley (1929) called attention to this when he stated that less than a fourth of the population, who are the chronic type, are responsible for the winter or spring epidemics.

There are many reports in literature of transmission of common colds by nasal instillation. The results of these experiments vary widely, from success to complete failure. It may well be that the results were to some extent dependent upon the susceptibility of the volunteers used for the experiment. The recent work by Dochez (1936) who has used cultures of the virus may be due to the massive dosage of the virus. The choice of volunteers based upon their vasomotor reflex reactions might lead to newer knowledge upon susceptibility.

We have studied sixty-three subjects over a period of three years. There were some two hundred and fifty subjects examined and observed for varying periods of time, but only sixty-three were under continuous observation. These can be divided into three groups:

1. The resistant or normal type.
2. The chronic, frequent and infectious type.
3. The hypersensitive, non-infectious type.

Vaccines, vitamins, drugs and any other specific prophylactic measure for preventing colds should take into consideration these three groupings of the population. The results obtained in the resistant or normal group will be good for any preventive measure that is physiological and hygienic. Specific prophylactic procedures should be tried on the chronic infectious common cold types.

The extent or magnitude of the maladjustment of chronic or frequent cold sufferers differs in individual cases. Some will find that retaining the vasomotor reflex response by hydrotherapy will be sufficient to prevent colds. Some will find the nutritional factor most important. Others will find the mental factor to be of major importance. Some cases will experience little difficulty in maintaining a cold resistant state of

health; others will need to give more attention to one or more factors associated with readjustment to maintain the same state of health. We are unable at this time to evaluate these separate factors. We have suggested the hydrotherapy first; then the diet control and have found most cases are benefited. The nasal vasomotor response returns to the normal pattern. There is an absence of head colds and what is of equal importance, the subjects enjoy a better state of well being and continue these hygienic practices for this reason. Recurrences of colds, in the absence of undue exposure, indicate a lack of proper adjustment and require investigation. The mental factor frequently is found important in such instances.

Functional Disorders of the Gastro-Intestinal Tract: the "Gastro-Intestinal Neuroses"*

By

WILLIAM C. MENNINGER, M.D.

TOPEKA, KANSAS

IT is indeed presumptuous to attempt to discuss a subject so broad as the functional disturbances of the gastro-intestinal tract in a brief presentation. It is probably literally true that one could present the field of surgery of the abdomen in the same period of time and do more justice to the subject. At least, with that topic one could omit the lips, teeth, tongue, mouth, pharynx and esophagus from consideration. Of necessity, I shall limit the discussion in this paper to certain generalities concerning the entire gastro-intestinal tract, and then attempt to deal only with

*Read before the Third Annual Post-Graduate Course in Neuropsychiatry, The Menninger Clinic, April 24, 1937, and before the Kansas Section of the American College of Physicians, May 20, 1937.

Submitted May 31, 1937.

three specific syndromes: namely, gastric disturbances, constipation, and diarrhea.

Indefiniteness of concept "Functional" applied to this group: In contrast to certain other uses of the term "functional," for instance, as applied to the heart or even to mental illness, the group of disorders of the gastro-intestinal tract can rarely be regarded as entirely "functional." Very often we find physiological disturbances such as the changes in the peristaltic activity of the stomach and the intestines; likewise, often there is disturbance in the chemical balance, referring particularly to the presence or absence of hydrochloric acid, as well as other gastro-intestinal secretions; and there are found even some relative anatomic changes in the position and size of the stomach, the location and convolutions of the intestines. There is probably no other organ system which shows such fine intergradations between "functional" and organic changes as those reflected by the gastro-intestinal tract. Probably more often than in any other set of organs in the body, do longstanding, so-called "chronic functional" illnesses result in structural changes in the tissues, as seen for instance, in the ulceration of the stomach, the duodenum, or the colon.

The prevalence: If for no other reason than the length of the gastro-intestinal tract, its functional disorders probably constitute the largest single group of organ misfunctioning in medicine. Next to the skin, the gastro-intestinal system has more contact with the outside world than any part of the personality. It receives more direct demands for adjustment and accommodation, more insults and abuses, and a greater variety of opportunities for gratification than any other set of organs suffers or enjoys. Such disturbances occur in every one of us, in some of us all too frequently. A large proportion of our patients come to us complaining chiefly of some disturbance of this portion of their anatomy. Most gastro-enterologists will agree that at least 50 per cent of the cases they see fall into the so-called "functional" group.

Attitude towards etiology: It seems almost paradoxical in the face of the prevalence of these disorders, that the layman should be so ignorant of the emotional factors producing them, and should have developed so many erroneous ideas about the supposedly normal functioning of the gastro-intestinal system. Among the most popular quacks are the naturopaths with their dietary fads, those who focus their attention on the distal three feet: the "colon specialists," and the "pile doctors." Perhaps it is even more paradoxical that the practitioners of medicine should give evidence of considerable confusion and uncertainty both as to the cause and the management of these illnesses.

There is an increasing recognition on the part of physicians that a "functional" difficulty in the gastro-intestinal tract is only an expression of a disorder in the personality. While recognizing this commendable trend, we must also face the fact that not very many physicians make practical use of such an understanding. A British doctor, Crookshank (1), has adequately expressed this apparent paradox in the medical attitude by stating, "It always seems to me odd in the extreme that doctors, who when students suffered with frequency of micturition before an oral examination, or who when in France had actual experiences of the bowel looseness that occurred before action, should persistently refuse to seek a psychological correlative —not to say an etiological factor—when confronted with a case of functional enuresis or mucus colitis. I often wonder that some hard-boiled and orthodox clinician does not describe emotional weeping as a 'new disease,' calling it paroxysmal lacrymation, and suggesting treatment by belladonna, astringent, local applications, avoidance of sexual excess, tea, tobacco, and alcohol, and a salt-free diet with restriction of fluid intake; proceeding, in the event of failure, to early removal of the tear glands. Of course, this sounds ludicrous. But a good deal of contemporary medicine and surgery seems to me to be on much the same level."

The confusion regarding the etiology is well expressed in the various causes ascribed to the "functional disorders" of the gastro-intestinal tract. I hasten to add that in part, some of these are probably correct, and certainly we are not justified in saying that they are entirely wrong. Referring, for instance, to only one disorder, the so-called "unstable colon" has been described variously as being due to avitaminosis, allergy, intercurrent infections, mental strain, spasmophilic diathesis, autonomic imbalance, nervous strain, endocrine disturbances, dietary deficiencies, or constitutional factors, as well as to a whole series of anatomical anomalies of the gut. Regarding the latter a prominent gastro-enterologist, Palmer (2), has expressed this opinion, "Much has been written of the redundances and loopings, of mobile and immobile cecums, of high-lying cecums, or low-lying cecums, of autonomic imbalance, of visceroptosis, etc. It is necessary to maintain a critical and somewhat skeptical attitude towards all this innovation."

I may interject that the progressive attitude of the gastro-enterologist is shown in Palmer's further opinion of regarding such individuals as having a "barometric abdomen," which is only an indication of the total personality, and that "attention should be directed not to the bowel alone but to the total personality of the patient."

If the attitude towards the etiology as evidenced by the causative factors ascribed to these conditions is confusing, the terminology is quite hopeless. Considering the stomach alone we can find classifications of the sensory, motor, and secretory disturbances, all of which fall under the more general categories of "reflex dyspepsia," or "nervous dyspepsia." In standard textbooks (3, 4) I have found included under the sensory disturbances such diagnostic groupings as "gastric hyperesthesia," "gastralgia," "mental anorexia," "anorexia nervosa," "bulemia," "gastric obsession," "pseudogastropathy," "dilatation of the stomach," "sitophobia." Under the so-called "motor neuroses" are included "nervous eructations," "nervous vomiting," "rumination," "pylorospasm," "hyperkinesis," "aerophagia." Under the "secretory neuroses" are included "hyperacidity" and "hyperchlorhydria," along with "hypersecretion," "hypoacidity," and "gastromyxorrhea." If one wished to review the many terms that are used and have been used in the past for intestinal difficulties one could literally find hundreds. Sullivan (5) reported in his extensive survey of mucus colitis that 35 different terms have been applied to this one particular syndrome.

What can one conclude from these formidable lists, were they completed, of etiological factors and terminology? Only that we are forced to use unsatisfac-

tory descriptive terms of a local condition which at most is only one very small part of a total personality disturbance.

The theory of psychogenic etiology has received widespread recognition. Even in our everyday language there are many phrases which indicate a relationship between the personality traits and various parts of the gastro-intestinal tract. Thus, we speak of a "sucker" as the man who "bites" on something and is fooled; we designate certain persons as "leeches" because of their hanging-on propensities. We speak of a person "sinking his teeth" into a job; we speak of not being able to "stomach" something, of "guts" and "intestinal fortitude." Everyone is familiar with the phrases of having a "belly full" and of "biting off more than one can chew." There are a great many vulgar words and phrases for feces which are used colloquially to indicate depreciation or disparagement or hate. In all of this language the layman recognizes a definite relationship, even though intuitively and unconsciously, of the significance of the gastro-intestinal tract to the development of the personality.

The general practitioners, the internists, and particularly the gastro-enterologists almost unanimously accept the existence of some such relationship. In general, there are three classes of reactions shown by these groups. First, there is a group of "die-hards" who take the attitude that the chronic intestinal ulceration causes the personality change; they are prone to get into arguments as to whether the hen or the egg came first. There is a second group, a large number of physicians (6, 7, 8, 9, 10, 11), who concede the psychogenicity of the "functional" disorders of the gastro-intestinal tract, but who use vague terms to refer to the psychological components, such as "emotional disorder" or "worries," or "anxiety"—and assume that these explain the problem. An example from one of our leading textbooks serves as an illustration. A brief discussion on "nervous dyspepsia" ends with the remark, "Practically all of these cases are psychogenic and the treatment is psychotherapy." The next paragraph takes up a new subject. To the critical psychiatrist this is equivalent to saying that "the disease is hematogenic and the treatment is hemotherapy." Thus, an excellent gastro-enterologist like Alvarez (12) in his justly popular treatise "Nervous Indigestion," divides the functional diseases of the digestive tract into "fatigue neurosis," "temperamental indigestion," "anxiety neurosis," "mental infelicity," "nervous vomiting," and "psychopathy." Such terms are just as vague to the psychiatrist as "stomach trouble" or "bowel disorder," and the psychiatrist who employed gastro-intestinal terms of comparable age and inexactness in a paper would receive little mercy at the hands of a reviewing internist, and rightly so.

There is a third group of physicians, small in number, who have made it a special point to study the personalities of patients with these difficulties. Outstanding in this group is Draper (13) who has made a detailed evaluation of the personality reactions in individuals with gastric ulcer. Similarly, Sullivan (5, 14) has approached the problem of ulcerative colitis with excellent therapeutic results. With perhaps a little less detail in the personality evaluation, studies have been carried out by Oppenheimer (15), Underwood (16), Diamond (17), Palmer (18), and probably others.

WHAT CONTRIBUTION HAS PSYCHIATRY MADE?

Unfortunately, except as gastro-intestinal disturbances occur in his neurotic and psychotic patients, the psychiatrist has had little opportunity in the past to study this group of problems. Of some fifty papers written in the past few years on this subject by internists and gastro-enterologists, I did not find a one in which it was recommended that the aid of a psychiatrist was necessary, even though the great majority specified agreement that the illness was psychogenic. In Alvarez' book "Nervous Indigestion," referred to above, there is not a single reference to a psychiatrist, and in the reading list given there are no psychiatric writings included. Why does this lack of cooperation exist? It is not the purpose of this paper to find the reason. It may be that the majority of internists are not aware that they might obtain any help from the psychiatrist, and on the other hand, this may be in part the psychiatrist's fault because for so long he had confined his interest and the subjects of his papers to the "insane."

There have been some contributions by psychiatrists (19, 20, 21, 22) which are of much interest to the general practitioner and to the internist. The most detailed study and the most helpful understanding of a limited number of these functional disorders of the gastro-intestinal tract has come from the Institute for Psychoanalysis in Chicago (23), under the direction of Franz Alexander. Two years ago they published the first results of their study, and a brief summary of their approach and the findings indicates the contribution that may be expected in gastro-enterology from psychiatry, and particularly from psychoanalysis.

In this research problem at the Institute for Psychoanalysis the gastro-enterology department of the University of Chicago cooperated by referring certain well authenticated cases of gastric disorder, particularly ulcer, diarrhea, and constipation, for psychoanalytic study and treatment. Some of the cases were given psychoanalytic treatment but a larger number received only psychoanalytic study. Early in their study these workers were impressed with the constancy and similarity between the nature of the psychological conflict and the type of gastro-intestinal disorder. It was possible to describe the patient's emotional trend in terms of the three elemental tendencies applicable to both the psychological conflict and the gastro-intestinal symptoms, of first, the wish to receive or take as related to stomach disorders, second, the wish to give or eliminate as applying to the diarrhea cases, and third, the wish to retain as applied to the constipation cases.

Gastric disturbances: In the psychological development of the infant, it is apparent that his first interest and aim in life is concerned with the taking in of nourishment. The infantile wish to receive, to be taken care of, to be loved, to depend upon someone else, is most ideally gratified in the parasitic situation of the sucking infant. Thus, these emotional qualities of receptivity—the wish to be loved and taken care of—become closely associated in an early period of life with the physiologic functions of nutrition. Being fed is thus equivalent to being loved. The character attributes of the adult individuals with gastric dis-

order were found to be ambition and aggressiveness, and such persons often had effected considerable accomplishment. They consistently displayed a striving to be independent, active, and efficient. An investigation of the unconscious desires of these individuals, however, showed without doubt that this marked desire for independence, ambition, great self-assertiveness was an over-compensation. That is, the individual had to lean over backwards consciously, to completely repress or deny his unconscious wish to be dependent, to be loved, to be fed. This mechanism of over-compensation can be seen in many instances in life when the individual must consciously stress one point of view or desire, to neutralize an unconscious opposite point of view or desire. Such reversals are frequently seen in the personalities of individuals with psychoses, who in their normal life are exceedingly thoughtful, kind, pleasant and clean, but in their psychoses are extremely impolite, hostile, dirty. In the individuals with gastric neuroses it was thus apparent that this unconscious desire to be loved and to be dependent was in the primitive mind directly associated with the child's first form of love, namely food and nourishment. The gastric symptoms are thus presumably caused through these unconscious tendencies which serve as chronic psychic stimuli of the stomach, independent of the process of nutrition. Consequently, a peptic ulcer *per se* has no psychological significance, representing only the end results. On the other hand, the chronic hypersecretion and hypermotility which may lead to the ulcer are produced by the continuous unconscious desire to be fed.

Colitis Studies: In the group of cases showing diarrhea studied at the Institute for Psychoanalysis, the general conscious attitude expressed by these individuals was verbalized about as follows: "I have the right to take and demand because I give sufficiently. I do not need to feel inferior or guilty on account of my receptive and grasping wishes because I am giving something in exchange for them." In this conscious attitude there is apparent again the parallelism between the nature of the disorder, namely, diarrhea and the person's attitude toward life, particularly as it is reflected in his relations with other people, in that the diarrhea was found to be a substitute for giving something of real value, for making real efforts, and being actually active. It was also found to be a method that the individual could use to express hate. This hate or aggressiveness was mentioned above as being recognized even by the layman as exemplified in the colloquial expressions, using the vulgar terms for feces. In the individual with colitis it was thus found that the content of the unconscious psychic stimuli which caused the dysfunction were in some instances giving as a method of restitution for taking or receiving, and in other instances, aggressive elimination.

Constipation Studies: In the cases studied with constipation, the individual's emotional attitude to his environment could again be expressed in terms that applied equally well to his psychological problem—namely, to retain or to hold on. The conscious attitude as discovered in these individuals included a pessimism towards receiving help from others or depending upon them. They seemingly do not expect anything from anyone in contrast to the optimistic attitude of the gastric type. At the same time, however, there is a more or less conscious, very extreme sense of obligation to give, of which the patient tries to rid himself by renouncing all conscious tendencies to receive. Thus the conscious attitude is summarized as, "I do not take or receive and therefore I do not need to give."

The unconscious dynamic background of the symptom seems to be based on the rejection of the obligation to give on account of a fear of loss, but on the other hand, if he is forced to give, his gifts are of no value. The result of these two stimuli serve as a chronic inhibition of the intestinal peristalsis and result in the constipation.

In all of these types of cases—namely, the gastric, the colitis, and the constipation—these research workers have not claimed any finality about their findings. They believe that the dynamic relation of the individual to his environment cannot necessarily be reduced to these three groups of alimentary tendencies. Their findings, however, are highly significant in showing the specificity of the unconscious demands of the individual and the very likely possibility that the gastro-intestinal tract is affected by these chronic stimuli. They stress the fact that an adequate knowledge of the causative factors, namely, the unconscious desires, can be obtained only during psychoanalytic treatment of patients and by no other method. Furthermore, the patient's immediate life situation has usually only a precipitating influence on the disturbance, and his conscious attitude plays a subordinate role in the causation of the symptom. From their study it is the repressed tendencies, the unconscious desires, that serve as a constant stimulation and thus cause chronic dysfunction of the organs.

THE MANAGEMENT OF FUNCTIONAL GASTRO-INTESTINAL DISTURBANCES

Again, it is probably presumptuous to attempt a discussion of the treatment methods to be used in such a wide variety of manifestations of personality disorder. Perhaps in view of the fact that the psychiatrist rarely sees these cases, that is, that the general practitioner and internist rarely refer them, it indicates that the latter group can handle the majority of such instances in an adequate fashion. On the other hand, as judged by the reports of internists and gastro-enterologists in the literature and in textbooks, one gets the impression that their conception of dynamic principles of psychiatry is somewhat limited. Furthermore, from the long list of diagnoses and the long list of etiological factors, one may conclude that much confusion exists. For these reasons perhaps it is justifiable that occasionally a psychiatrist "speak his piece" about the treatment of such illnesses.

Regardless of what particular methods or procedures one is going to use, it is essential that he start with the premise that the physician is going to treat the individual and not the organ. If this axiom be kept in mind, the entire contact with the patient will be materially influenced, including the anamnestic interviews, the examination, and the subsequent management. At no time can we become so interested in the stomach mucosa or in the position of the colon that we lose sight of the fact that the patient himself is our primary interest and that his symptoms are only the mirrored expression of his maladjustment.

Psychotherapy: I have already complained that the textbooks are too prone to recommend psychotherapy without giving either explanation or direction, with

apparently the tacit assumption that the physician knows just what this is and how to apply it. Even in some of our most carefully reported studies, such as Sullivan's (14) on the psychogenic factors in ulcerative colitis, there is reference to psychotherapy as *the* method of treatment, but there is no explanation as to what form of psychotherapy was used, whether it was counselling, whether it was merely gaining confidence, whether interpretations were given, whether the unconscious motives were made conscious or what. Sullivan inferred that his patients, in many instances, were relieved entirely of their symptoms in the course of two or three months, but he did not state whether the psychotherapist saw the patient daily or weekly, or for five minutes or for an hour. This is not to be construed as a criticism because obviously the import of his paper was to point out etiology and not treatment, though it would be helpful to know in more detail about the methods of a man who has apparently been so successful in the treatment of such conditions.

Perhaps the particular type of psychotherapy (i e., whether it is expressive or suppressive, whether it is brought about through suggestion or persuasion or command) is not very important since every physician is largely guided by his own personality makeup in the administration of such treatment. It may perhaps be helpful to point out certain pertinent facts in the management of the psychotherapy of these particular kinds of difficulties that can be used by the average physician.

The Anamnestic Interviews: Previously I have attempted to point out the great importance of the initial contact of the physician with the nervous patient. These individuals as a group take themselves seriously, and particularly their illnesses, and consequently the anamnestic interviews are of tremendous importance. They are important because if the physician will give sufficient time and permit the patient to tell his story he gains two objectives: first, the cathartic value to the patient of reciting his difficulties (a procedure which previous physicians may have inferred was unimportant by a manifestation of impatience or busyness); and second, the establishment of confidence in the patient by giving this evidence of his sincere interest. During these interviews it is unwise for the physician to attempt to explain or give advice; his chief function is to listen.

Likewise, it is important that the physician should use care and patience to make a thorough, detailed physical examination, even if he is convinced in his own mind that the difficulty is entirely functional. By so doing he will impress the patient with the fact that he knows his status, and what he (the physician) may say later will have much more weight and consequently more influence with the patient.

However, to obtain a careful history of the patient's past physical health and the development of his present illness, and to make a careful physical examination, rarely puts the physician in a position to evaluate the psychological component in the illness. His own experience may tell him that this psychological element is there, but what it may mean in the life of the patient cannot be determined from such data. Only as the physician gains the patient's confidence can he learn of the past struggle, what the conscious anxieties may be, of the patient's life situation with regard to family, friends, and business. One can be sure that the patient with such complaints "suffers" far more than the individual with physical illness. It is probable that he suffers from discouragement or fatigue, or from weakness, fogginess, or fears.

The physician may rightfully ask, Why doesn't the patient tell me this in the first place? Why does he spend all his time talking about his abdominal complaints? Alvarez (24) has answered this question bluntly. "I can offer several excuses for him. One is that he soon finds that the average physician will not listen patiently to accounts of psychological troubles or vaguely described sensations. Often he is uninterested, incredulous, and without understanding or sympathy; often he scolds; he gives the patient the impression that he believes that he is imagining it all; he gives a prescription for a sedative and terminates the interview. Soon the victim learns to keep quiet about the psychic distresses and even to conceal them. Instead he talks about the one thing that he has found will interest the doctor, that is the abdominal discomforts. Unfortunately, he ends by overdoing it and soon he enters the hospital to get the first of a set of linear scars on the abdomen."

Once the physician has gained the patient's confidence, has learned what the vague sensations may be, what the fears or doubts or the troubles are that exist in his life (apparently quite independent of the physical complaints), then, and only then, is he in a position to make any suggestions relative to environmental changes or alterations in the relationships in the home or the business. Always in such instances must the physician be the counsellor in regard to the patient's life situation, and not merely the doctor for his "guts."

The psychotherapy may well include a certain amount of education—education in the sense of enlightenment about the gastro-intestinal life, the ways in which the gastro-intestinal tract can reflect the experiences and relationships and emotions of the individual. Furthermore, the physician is never in a position to evaluate the entire significance of such problems as these until he knows of the patient's sexual life. In a surprising number of instances there is a direct relation between the sexual practices, or, in some instances, the desires, inhibitions, and fears, and the gastro-intestinal symptoms. Again, in many instances, simple education may change the entire picture for the patient.

The obtaining of the anamnestic interviews, the evaluation of the psychological component in the patient's life situation, and the educational procedures are all forms and applications of psychotherapy. Such a procedure is not a matter of an hour but can certainly be expected to take many hours. One cannot set a definite time limit for these interviews, since in some instances the patient may respond in the course of two or three interviews, and in another instance, may not respond over a period of weeks or even months.

Perhaps it is this latter group with which one needs expert help, namely, the help of the psychiatrist. As far as the application of psychoanalysis is concerned, each case must of necessity be judged by its own merits as to whether this form of treatment would be helpful. From the psychoanalyst's point of view he is glad for an opportunity to study such patients, and a fortunate corollary is the therapeutic success in a high percentage of cases. But the application of

psychoanalysis is limited not only by the nature of the illness but by the fact that it is a long, often difficult, procedure which presents the economic problems of time and expense for the patient.

TREATMENT OTHER THAN PSYCHOTHERAPY

It is not to be inferred that the psychiatrist would assume for a minute that psychotherapy was the only treatment to be used in the functional disorders of the gastro-intestinal tract. So long as we follow the principle that we are treating the patient and not his particular organ, any method may be used to further this aim. As a consequence, various procedures and drugs may be used which in themselves are to be regarded as a kind of psychotherapy, and so long as they are used from this point of view they can be helpful. There is nothing contradictory to the use of psychotherapy along with the prescription of a regime or drug or physiotherapy or dietary recommendations, so long as these measures do not lead the patient to affirm his belief in his sick organ or a structural defect in his system. On the other hand, when they do lead the patient to such conclusions they are detrimental and become antagonistic to the principle that the patient is sick and not his organs.

The psychiatrist occasionally sees cases in which attention to the general physical condition is in order before psychotherapy is given. I am referring particularly to that type of nervous dyspepsia in which the individual loses weight rapidly and extensively. We recently had a patient who over a period of a year had lost in weight from 130 pounds to 68 pounds. She was so weak and emaciated that she could not lift herself from the bed. Drastic measures are always in order in such instances and psychotherapy follows. The prescription of all accessory methods of "psychotherapy," if we are to regard drugs and diet as such, however, cannot replace the desirability of determining the psychological component in the illness.

1. *Prescription of a Regime:* A regime of exercise, relaxation and rest if too rigid or over-emphasized may do harm. It does harm because it adds to the patient's illusion. It leads him to believe that his difficulty occurred because he has failed to take exercise, or because he doesn't get enough rest, or because he doesn't know how to relax. In part, these may be true, but the danger lies in letting the patient find a temporary escape in such corrective measures to the exclusion of the recognition of his mismanaged emotions. It is probably always safe to help the patient see that he doesn't get sufficient rest or exercise and in a great majority of instances the intelligent individual can be led to such conclusions without the physician's command being necessary.

2. *The Prescription of Drugs* in functional disorders of the gastro-intestinal tract is a temptation fraught with much danger. If a physician expects to treat the personality of his patient he cannot rely on the pharmacological action or the magic suggestion of the drug to make any very radical changes in the personality. Any drug should probably be used incidentally, and at most temporarily, depending upon the intelligence of the patient and the physician's judgment as to how much he can understand. It is perhaps often practical to "debunk" the patient regarding the magic of the drug, to explain specifically what it is, the temporary relief to be gained, the rationale for its momentary usage. Always should medication be interpreted as a temporary crutch, and if the patient has such an understanding the physician is justified in prescribing sedatives such as triple bromides or barbital for insomnia; likewise, carminatives for flatulence, intravenous glucose for vomiting, or insulin for anorexia. But he must use these guardedly, knowing that the patient's tendency will always be to capitalize on them and thus avoid solving his major problem of emotional disharmony.

3. *Dietary Recommendations:* In his dietary recommendations to the individual with gastric disorder or colonic difficulty, the physician is always in the predicament that if he stresses the necessity of a particular diet, he is likely to apparently deny the psychologic nature of the gastro-intestinal disturbance in the patient's mind. As a consequence, probably a majority of gastro-enterologists who direct their treatment in such cases to the total personality, suggest that as nearly a normal diet be prescribed as is possible. In other words, there is a fairly uniform condemnation of vegetarian or roughage diets. Here again, it seems practical for the physician to depend to a considerable extent on the patient's intelligence. If the patient is underweight and recognizes the fact, it is frequently possible to learn from him that he knows which are rich foods and which are likely to increase his weight. If he needs education about dietary matters the physician can give this chiefly as a matter of education and not of necessity specifically applying it to the patient. In other words, the more nearly the physician can help the patient to accept a normal diet and "debunk" fad diets and educate him in dietary facts, the more closely will treatment be in accord with our principle of treating the patient and not merely the gastro-intestinal tract.

4. *Physiotherapy:* Physiotherapy can be used ideally as a method of psychotherapy. The use of massage or ultra-violet ray can, if used along with suggestion, be directed in all instances to the general personality and not to the specific organ affected. Such an interpretation, however, does not hold true when applied to colonic irrigations, and there seems little to support the usage of this procedure, either for psychological therapy or physiologic benefit. Such treatment strikes a death blow to the physician's thesis that the symptoms are an expression of a personality disorder and not merely a colonic disease. Occasionally enemas are desirable, in fact necessary, but to make the habit into a daily ceremony is placing undue emphasis on a part to the detriment of the whole. The psychiatrist also recognizes that in some cases colonic irrigations and the enema habit have great significance in the unconscious. It is often apparent that some individuals, although complaining constantly, get obvious satisfaction from this prescribed and therefore approved "attack from the rear."

5. *Operations:* It is needless to say that operations are never indicated as a treatment for functional gastro-intestinal disorders. The subject is mentioned here not only to indicate that they are not good therapy, but particularly to call attention to the fact that a fair percentage of patients with these disorders demand operations. My brother, Karl A. Menninger, has dealt with the subject extensively under the title of *Polysurgery and Polysurgical Addiction (25)*. Alvarez (24) reflects a practical point of view on the problem. "All credit to physicians who try to talk these patients

out of the idea of an operation. You try to show them the truth but it takes so much time that it is usually hours; and often you are almost certain that all the patient will do is shop around until a compliant or a not overly-careful operator is found. Under such circumstances it is human to say to yourself, 'If the operation is going to be done anyway, perhaps it would be better that I do a good job and explore carefully than to let the patient run the risk of falling into the hands of some poorly trained man who will not explore or who may do great injury.' This is a dangerous reasoning and personally, I hate to yield to it. He who slips too easily along this path will end by losing his scientific soul." Further on, the same author states, "Often, the physician who doubts the wisdom of operating has attempted to console himself with the feeling that if he does permit the removal of the appendix at least he will do no harm. Would that this were always true. It may be true for a person with a normal mind and normal nerves but it is not true for many psychopathic and oversensitive persons. In them the harm done by needless operations is often terrible and irreparable; the abdomen never feels right again; new pains appear; some physician is found who rids himself quickly of a time-consuming patient by making a diagnosis of 'adhesions'; more operations are performed and finally we find the husband ruined financially and the wife lying on a couch, a hopeless invalid."

SUMMARY

An attempt has been made in this paper to present a psychiatric point of view regarding the functional disorders of the gastro-intestinal tract. That such disorders are primarily emotional in their causation is a fact granted by nearly everyone. The point is stressed, however, that such individuals should have the benefit of an accurate, penetrating, and detailed analysis of the psychological component in their illness, and that only as we understand the dynamic aspect of the personality disorder can we adequately treat the individual. Treatment in all cases must be directed towards the total personality and not towards the stomach or the intestine or the colon.

Studies on Autodigestion, VII. Is Digestion of the Living Tissues (Claude Bernard's Experiment) a Local Phenomenon?*

By

H. NECHELES, M.D., Ph.D.

and

F. NEUWELT, M.D.

CHICAGO, ILLINOIS

THE following work tries to answer the question whether the digestion of parts of a living animal as first demonstrated by Claude Bernard is a local phenomenon, or whether such changes occur in the blood of the animal that would tend to lower the resistance of its tissues to digestion. In previous papers the literature pertaining to and the theories about resistance of living matter to digestion have been reviewed (1-6), and will not be repeated here. During the course of this previous work the hindlegs of a number of anesthetized or pithed frogs were exposed to N/10 HCl or N/10 HCl with 2% pepsin 1:10,000† for 1-2 hours. In the first group no digestion occurred, in the second group either skin or skin and muscle were digested. While most animals of a control group (anesthetized only) survived, all frogs exposed to HCl or HCl pepsin, died within 12 hours. The rapidity of digestion was found to depend on the extent of surface

area exposed to acid pepsin (5). These two observations pointed to the possible occurrence of systemic rather than local changes and prompted the following experiments. Bullfrogs (rana catesbiana), albino rabbits and Belgium hares, and dogs were anesthetized (bullfrogs: urethane; rabbits: morphine + urethane; dogs: pentobarbital sodium) and both hind legs (hair being clipped first) exposed to pepsin HCl (N/10 HCl, 1% pepsin 1:10,000) only or alternately to alkaline trypsin (.25% Na_2CO_3, 2% 1/200 trypsin†) and acid pepsin. The digestive solutions were kept at 38° C. Blood was withdrawn from the carotid artery or, in the case of bullfrogs, from the aorta. Only such observations are reported in which at the termination of the experiment the animal was living and as viable as during the control period. Blood was withdrawn before exposure to the digestive fluid and after digestion had occurred. Some animals were anesthetized only and blood was withdrawn at intervals similar to those in digestion experiments. In case of the rabbits the volume of blood withdrawn was replaced by heparinized rabbits' blood.

The pH of the blood was determined with a glass electrode. Plasma CO_2, blood O_2 content and capacity, N.P.N. and total chlorides were estimated by the usual methods (7).

RESULTS

A. Bullfrogs: Six animals with an average weight of 660 grams each were anesthetized and exposed to pepsin HCl. Considerable digestion of skin and musculature occurred. Plasma CO_2 dropped from an average of 62 volumes % (56-68 vol. %) to an average of 44 volumes % (31-49 vol. %). In one control animal which was not exposed to pepsin HCl the same change of plasma CO_2 took place (from 65 to 44 vol. %). Changes in pH were small and inconstant.

B. Rabbits: Nine rabbits, weighing from 1.8 to 3.6 kg. were used (average weight 3 kg.). The rabbits exposed to HCl pepsin showed little or no digestion of their skin. Those exposed alternately to pepsin and trypsin solutions (1-2 hours in each) had considerable digestion of their skin and musculature and frequently bled abruptly and fatally from corroded arteries (Figure 1). Such lesions were multiple and no region of predilection could be detected. Changes in pH were inconstant. In 5 animals a decrease occurred (from 0.02 to 0.35, with an average of 0.1) and in 3 animals an increase of pH was found (from 0.02 to 0.1, with an average of 0.07). Blood CO_2 decreased in 8 animals (from an average of 48 to 38 vol. %). In one animal it rose from 44 to 52 vol. %. O_2 tension and capacity of the blood did not change materially in those animals which had no appreciable bleeding from corrosions. Total Cl and N.P.N. of the blood were done on 3 rabbits. The Cl rose slightly but insignificantly in all three instances—viz, from 524 mgm. % before digestion to 537 mgm. % after 13½ hours of digestion; the N.P.N. was variable, falling from 54 to 40 mgm. % after 10 hours of digestion in one experiment, whereas in another N.P.N. rose from an initial value of 50 mgm. % to 64 mgm. % after 13½ hours of digestion. Three rabbits were anesthetized only and showed similar changes of pH, CO_2, O_2, Cl and N.P.N. as in the case of the digested rabbits described above. Skin from digested areas was examined histologically, and localized ulceration, hemorrhages, hyalinization, and disintegration of the fibrous and adjacent muscular tissues observed; no thrombi were seen in blood vessels. Three rabbits were exposed alternately to HCl pepsin and alkali trypsin until small ulcers appeared in the skin, and then were put back into their cages; no untoward effects were noted, and the animals were well one week later.

C. Dogs: A four year old male dog of 6.5 kg. was anesthetized and the right hind leg was placed in acid pepsin solution for four hours on one day and for 7 hours on the next day without any signs of digestion nor any later untoward effects to the dog.

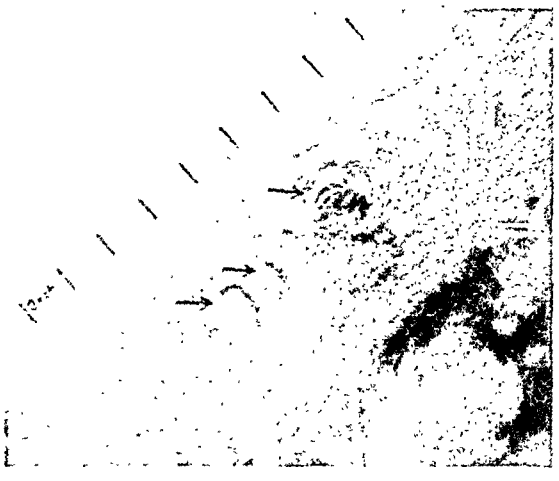

Fig. 1. Leg of 3.5 kg., female, albino rabbit after eleven hours of alternate exposure to pepsin and trypsin solutions. Exposed blood vessels in upper one of three ulcers.

DISCUSSION AND CONCLUSIONS

All such changes as occurred during digestion in pH, O_2, CO_2, Cl and N.P.N. of the blood were not specifically due to exposure to acid pepsin and alkali trypsin, but probably were due to the anesthetic and to prolonged exposure of the animals. While frogs died after such exposure, rabbits and a dog did not, and no after-effects were noted. No appreciable diffusion of H ions took place through blood or lymph vessels whose permeability might have been changed by the digestive media. It is unlikely that anoxemia was present in the limbs exposed to digestion. Erosions of small arteries and veins bled profusely, indicating no appreciable impairment of circulation in the legs. We conclude, therefore, that Claude Bernard's phenomenon of the digestion of the leg of a living animal is explainable as a local necrosis of tissues with subsequent digestion. This local necrosis can be performed by HCl alone without pepsin, and subsequent application of acid pepsin or of alkali trypsin will then produce digestion (6). Alternating acid pepsin and alkali trypsin was found to digest more rapidly and more intensely than acid pepsin alone, thus confirming previous work (6). Our above findings support those of Dragstedt and Vaughn (8) and our own (6), that the rate of digestion depends on the concentration of HCl in the HCl pepsin solution (in both reports the HCl concentration was within physiological limits). The above results do not explain why in frogs digestion is faster when more surface is exposed to acid pepsin solution. It seems however, that anesthesia and exposure damage the frog to a high degree. Dog

and rabbit survive anesthesia and exposure and even slight digestion of their skin without noticeable after-effects, and therefore results on these animals seem to be more fit for interpretation of the phenomenon than those on frogs. It seems to us that no inference can be drawn from the above experiments as to the genesis of gastro-duodenal ulcer. Unlike the skin, gastric and duodenal mucosa have a specific resistance against acid corrosion and decrease of viability seems to be the additional necessary factor leading to ulceration (9).

SUMMARY

In anesthetized bullfrogs, rabbits and a dog the effect of peptic and tryptic digestion of the hind legs on blood pH, CO_2, O_2, Cl and N.P.N. was observed. No constant significant change was found and the conclusion is drawn that Calude Bernard's phenomenon can be explained as slow acid corrosion and subsequent digestion of devitalized tissues. The results confirm the necessity of assuming an additional factor (devitalization) of tissues in the occurrence of gastro-duodenal ulcer. Alternation of peptic and trypic digestion greatly increased the rate of digestion.

Editorials

THE ATTITUDE OF THE ASSOCIATION TO NEW MEMBERS

INTEREST in gastro-enterology is rapidly increasing; the specialty as a sub-group of internal medicine has, in the last 20 years, made creditable advance both from a clinical and scientific standpoint.

Many of the younger men interested in this specialized field of medicine are ambitious in their efforts to attain membership in the American Gastro-Enterological Association. It is the desire of the Association to encourage and foster that ambition and to choose from aspiring candidates those who are best qualified to fill the occasional vacancies in the limited membership of the Association that arise as the result of deaths, transfers to Senior membership and advancements from Associate to Active Membership.

Candidates are judged on their scientific and clinical achievements, the position attained in their local community, hospital, school, their scientific publications, by their moral and ethical standards and their personal qualifications.

The Executive Council of the American Gastro-Enterological Association desires to encourage candidates for membership in the Association by announcing that the "American Journal of Digestive Diseases and Nutrition" will be glad to consider for publication contributions on clinical, laboratory, or scientific subjects dealing with gastro-enterology, metabolism, or nutrition.

Contributions of merit will be accepted for publication and, thereby, will assist the candidate in bringing to the attention of the members of the Association the type and character of the work he is doing. Contributions submitted for publication in the Journal should be sent to the Editor, Dr. Beaumont S. Cornell.

Burrill B. Crohn, New York, N. Y.

SOME DANGERS INVOLVED IN LEAVING ULCER PATIENTS TOO LONG ON A STRICT DIET

THE old injunction to physicians to cure safely and without doing harm needs still to be remembered today. When during one week a physician can see three patients who have been brought to the brink of serious disaster with pellagra or scurvy by the long continuance of an overly strict ulcer diet, it is time that gastro-enterologists did more to warn the medical practitioners of this country against this danger to their patients. Naturally, it is not always the practitioner who is at fault: he may never have intended the patient to stay for months on the strictest diet, but the man did not return to report, and so damage was done.

In many cases, however, when a patient with ulcer is doing badly, and especially when he has bled severely, it is natural that his physician should exhort him to be particularly strict with the diet. It is a natural reaction also on the part of some patients to conclude that if some deprivation in the matter of eating is good more should be better. If they get along fairly well they will not see the need for returning for a check-over, and in a year or so one is likely to find a pale sickly looking patient who is still living on a soft diet consisting largely of milk, cream and cereal. When, as sometimes happens, the milk has been boiled so as to destroy what little vitamin C it contains, it is hard to understand how the patient has escaped coming down with frank scurvy.

Unfortunately, also, for the patients who have bled badly and who need to build much hemoglobin, the probably needlessly strict but commonly used type of ulcer diet without meat does not contain much iron. Recently, the writer saw a woman with ulcer who had bled until her hemoglobin reading was around 50 per cent. Because she was so frightened she was glad to

stay on the strictest diet her physician would give her, and for months she lived on little besides milk, cream and cereal. Unfortunately her physician did not happen to remember that years ago Whipple and his assistants showed that one could produce a uniformly fatal anemia in dogs with just such a diet as this woman was on. As one would expect, then, she not only failed to regenerate the blood she had lost, but she continued to go on down hill. And as if her adherence to an almost iron-free diet were not bad enough, she was taking alkalies which, as has recently been shown, seem somehow to block the absorption or usage of whatever iron is being given by mouth.

Of late, Carlson and Rivers* have been studying a group of patients with hematemesis, with or without definite ulcer, from the point of view that in many cases the bleeding may be kept up or even brought on by the injury to mucosal cells and capillaries produced by the marked deprivation of vitamin C which goes with overly strict dieting. It may be that some of these patients are suffering from mild and unrecognized scurvy. Certainly in the case of one of the patients just seen by the writer the amount of vitamin C in the blood was only 0.25 mg. when it should have been at least 0.9 mg. In this case the patient, while on the diet, developed a severe gingivitis which resulted in the loss of most of his teeth, and one wonders now if this might not have been part of an unrecognized scurvy.

Another point which was brought out by Snell and Wilbur at the recent meeting of the American Medical Association is that even when a patient is given the minimum requirements of vitamins in the diet he may still get into trouble if he has a malfunctioning gastro-enteric stoma with jejunitis or some other condition which produces a too rapid progress of food through the upper part of the small bowel. Under these conditions he may be able to absorb only a small fraction of the stock of vitamins with which he is being supplied. It would seem then that in all cases in which digestion in the upper small bowel is handicapped, the supply of these small dietary essentials should be increased rather than diminished.

Some of the good results obtained by Meulengracht with a full diet in the case of persons with gastro-intestinal bleeding might be understandable now if a certain percentage of his patients should happen to be suffering with a mild form of scurvy such as can be relieved promptly by a full diet.

Incidentally, how certain can we be that in cases of ulcer, the adherence to a strict diet between attacks will help in the prevention of recurrences? Certainly the discouraging stories which the gastro-enterologist hears in his office every week are hardly designed to reassure him on this point. Time and again he will learn that pain or bleeding returned when the patient was still dieting carefully and taking food between meals, and the older and more experienced he gets the less disposed he will be to promise a patient immunity to recurrences as a reward for the strictest adherence to an ulcer regimen. Physicians who have ulcer themselves know this, and many will say that so far as they can see, it doesn't make much difference what they eat between their attacks. The really important factor in bringing a recurrence seems often to be nerve strain and worry.

Partly, then, because it does not seem to pay well to diet very strictly and partly because a man with ulcer should maintain a good state of nutrition, it would seem as if we physicians could afford to be fairly generous dietetically with all of those patients who have a tractable type of ulcer.

Many able gastro-enterologists are afraid of giving raw fruit juices, and some absolutely forbid their use, fearing that the acid will do harm. Others do not worry about this possibility because the organic acids in fruits are so weak and are present in such small amounts that it would seem they can have very little effect in the way of activating pepsin. Compared with the hydrochloric acid in the stomach they must represent but a drop in the bucket. In a recent article (this Journal, 2:242-243) Kugelmass showed that orange juice has a pH about 3.0 and tomato juice about 4, but they contain very little free acid. They are really buffer solutions consisting largely of mixtures of the primary and secondary salts.

Some studies should be made soon to determine once and for all if there is any difference in the results obtained by patients who are and are not given raw fruit juices. Certainly if it is not dangerous to give these juices they should be included in ulcer diets so as to protect the patient from slipping into a condition in which he will be predisposed to hemorrhage.

BACILLARY DYSENTERY

IN 1936, Dr. Arthur Hurst (1) of London, published in the Lancet, a paper in which he calls attention to the widespread distribution of bacillary dysentery in the British Isles and discusses the possible relationship of that disease to so-called non-specific ulcerative colitis. Dysentery of a specific bacillary nature exists in epidemic outbreaks in many localities of England; carriers surviving from the World War are numerous; in his opinion the etiological relationship of the two diseases is most often plausible if not often proven.

In this country, the United States Public Health Service is carrying on an investigation of this specific diarrhea. Particular attention is being given to New Mexico and Arizona. Preliminary observations suggest that the results will be interesting. These conditions are also being studied in Virginia. Some urban populations are also coming under close observation and examination.

If the relationship between acute outbreaks of infectious diarrhea, in camps, in institutions, on shipboard or in city communities is to be correlated with acute or chronic ulcerative colitis, if the scientific etiology and causal connection is ever to be clarified, it behooves every practitioner and specialist in medicine to study each colitis case for its possible infectious contacts, its exposure to other diarrheal cases, to possible carriers, and to centers and communities which may be harboring bacillary dysenteric endemics.

Even though stool cultures are individually negative, or serum agglutinations are inconclusive, the search must be constituted for possible contacts with carriers or distributing centers. In each family wherein a case of colitis occurs, a careful search for dysentery carriers should be instituted; members and

particularly the servants and food handlers should be questioned for their instances of contemporaneous diarrhea. One should diligently inquire regarding recent travels to possible states or countries where diarrhea is prevalent, to exposure to surface or unguarded drinking water, watered vegetables, shipboard diarrhea, or recent institutional sojourns. It is surprising how often it will be noted that some other member of the family, or one of the help, is also suffering from diarrhea, or how often significant grouping of other and similar cases suggests a locality infection. Most local Boards of Health will willingly cooperate in stool cultures of possible carriers or serum agglutination tests.

The problem of the association of colitis and bacillary dysentery is frankly before the profession for investigation and decision. There may be no relationship, or a relationship only in a small minority of cases, or there may be a significant connection. By wholehearted cooperation, by scientific willingness and alertness, an answer should be forthcoming or at least strongly suggested by this generation of clinicians, laboratory scientists, and public health authorities.

AMOEBIASIS AND THE NEW YORK CITY WORLD'S FAIR

THE recent appearance of the official report (1) of the Joint Committee which investigated the Chicago epidemic of amoebic dysentery in 1933 in connection with the Century of Progress Exposition calls to our attention the fact that plans are at present under way for a similar event in New York City scheduled to open in 1939. This report again focuses attention upon the possible public health dangers inherent in the massing together of enormous numbers of individuals in a restricted locale within a short period of time.

This report is of particular interest to the gastroenterologist due to his intense preoccupation with acute and chronic infections of the colon. In their clinical investigations the committee found that although the great majority of cases had an incubation period from one to four weeks, there were a significant number of instances in which this was less than one week and occasionally was as long as three to four months or longer. Especially striking were the difficulties and uncertainties in the diagnosis of amoebiasis due to the frequent occurrence of clinical features usually considered atypical. Among these was the frequent absence of diarrhea and the very real difficulty of finding E. histolytica in the stool. Another confusing feature and formerly considered an unusual event in amoebiasis was the presence of fever which was observed in many cases and which was relatively high at times even in uncomplicated cases. The frequent occurrence of local rectal symptoms associated with induration and ulcer formation led to the erroneous diagnosis of malignancy of the rectum in a large number of cases.

In their beautifully thorough and complete analysis of the accumulated data the Joint Committee found that the disease, acquired in Chicago, had been spread to at least 400 cities scattered through 43 states, Hawaii, Canada and two European countries. They were able to trace 1049 cases in an obviously incomplete reporting of cases. This would indicate the magnitude and importance of the problem.

The committee was fortunately able to trace the foci of origin of the epidemic to two hotels which were found to be the major but not the sole sources of spread of the disease. A complete investigation of these two hotels revealed several interesting and important facts. Thus they found an incidence of the carrier condition among food handlers in the two hotels amounted to 34.3% in the one and to 57.3% in the other. They found that vigorous measures directed to the prevention of the spread of infection by carriers among food handlers were ineffective. Elimination of carriers of cysts of E. histolytica from among the food handling staffs was unsuccessful in controling the outbreak.

As a result of their extensive clinical, epidemiological and engineering studies they reached the significant conclusion that the principle if not the sole means of spread in the epidemic studied was through water polluted within one of the hotels. As a contributing factor they noted a progressively increasing number of carriers of E. histolytica among the employees and probably also among the guests who remained for more than a few days. In this way any "pollution of the water with hotel sewage would become progressively more hazardous." The committee points out that "the measures required to prevent the recurrence of such an epidemic are: (a) Effective supervision of the installation of plumbing in new buildings and of changes in old ones; (b) reasonably frequent inspections of the water and sewage systems of buildings, especially of the older ones; (c) particular attention to the elimination of hazardous cross-connections, through preventing their installation and through detecting and removing existing ones."

The indictment of engineering defects in hotel construction implied in the above does not remove the responsibility for their tolerance from the hands of the medical profession and the public health authorities. An excellent opportunity is at present afforded to the medical profession and health authorities to avoid a duplication of the Chicago misfortune.

Abraham Penner.

PECTIN

A LITTLE over a hundred years ago a French investigator, Braconnot (1825) extracted some pectous material from plants; in as much as this material resembled a coagulum, he named it pectin.

Much work has been done on pectin since Braconnot's time. The water insoluble pectic substance is proto pectin, which is converted to water soluble pectin by enzymatic activity during the ripening of the fruit. If this hydrolysis goes still farther the methyl ester groups are split off and pectic acid appears as one of the substances associated with the decomposition of plant tissues.

It is generally agreed that these pectic substances are composed of a polymerization of galacturonic acid

anhydride as their basic unit and in addition there are arabinose, galactose, acetyl and methoxyl groups present. The latest work shows that unhydrolysed pectin contains an octagalacturonic acid nucleus.

It was customary to subdivide carbohydrates into those utilized and those not utilized; in other words, we have considered available and unavailable complex carbohydrate. The starches and sugars belong to the available, the hemicellulose, cellulose and pectic substances belong to the unavailable carbohydrates. The caloric value of the available carbohydrates is well known, but those not utilized are considered of little value except to form bulk or roughage.

The raw apple, the banana, and other fresh fruits have been administered with beneficial results to infants as well as adults with certain gastro-intestinal disturbances. The use of these fresh fruits has been more for therapeutic than for preventive purposes.

There are reports using apple and banana powder in place of the fresh fruit, with about the same, if not better results. Some authors have given pectin the credit for the improvement in the clinical picture in cases of diarrhea. Winters and Tompkins (*Amer. Jour. Dis. Child.*, 52:259, 1936) report better results with the use of a pectin-agar-dextrin-maltose formula than they obtained with the use of scraped raw apple in the treatment of infant diarrhea.

The galacturonic acid content of pectin has naturally been assumed to have a detoxifying action similar to glukoronic acid. Malyoth (*Klin. Wchnschr.*, 13:51, 1934), Riesser (*Schweiz. Med. Wchnschr.*, 16:1175, 1935), Manville, Bradway and McMinis (*Amer. Jour. Digest. Dis. and Nutrit.*, 3:570, 1936) and others considered this factor of importance in the action of pectin.

Imhaeusser (*Arch. f. exper. Path. u. Pharm.*, 167: 702, 1932) administered pectin to dogs and failed to find a rise in blood sugar. He also administered pectin to phloridzinized dogs and observed the same fatty changes in the liver as in the controls. This would indicate that no utilizable carbohydrates were derived from the pectin. There was, however, an antiketogenic action shown after pectin was fed to dogs, indicating that this substance was exerting some action and was not entirely unavailable, as had been assumed.

Banana and apple powder were used as carbohydrate source in the basal diet in some rodent experiments by Arnold (*Amer. Jour. of Pub. Health*, 24, No. 8:354, 1934). The control diets contained cornstarch or sucrose as their energy source. Rodents fed on the powdered fruit diets enjoyed a resistance to B. enteritidis administered by mouth as compared to the controls. The nature of this increased resistance to enteric infection was not determined. Such animals were very susceptible to the B. enteritidis when administered intraperitoneally or subcutaneously, but were resistant to oral feedings of these bacteria.

The so-called unavailable carbohydrates need more attention. The galacturonic acid component of pectin needs further study as to its detoxifying action.

The writer is convinced that pectin, as it is now available on the market, is not a uniform product. There is one very active carboxyl group attached to the pectin molecule. Most of the pectin on the market contains various positively charged elements attached to this carboxyl group, such as sodium, calcium, magnesium, etc., as well as arsenic acid and other insecticidal residues from sprayed fruits. The varying reports in literature may well be due to the use of various pectinates of this nature.

It is of interest to the gastro-enterologist to know that some of the so-called unavailable carbohydrates may, in part, be utilized in some way. The research workers in biology, chemistry, bacteriology and clinical medicine have new problems presented for their consideration.

Lloyd Arnold, Chicago, Ill.

Book Reviews

Medical writing. By J. H. Dempster, St. Paul, Minnesota, Bruce Publishing Company, 168 pages, 1937.

THIS is not just another handbook on medical writing, it is a delightful little volume which reflects on almost every page Dr. Dempster's rich culture, his wide experience as an editor, and his kindly philosophy and wit. It is the sort of book that one expects more from a cultured Regius Professor of Physics than from an American physician who commonly knows his medicine but seldom his Sir Thomas Browne, his Keats and his Charles Lamb.

As Dr. Dempster reminds us, writing makes an exact man. No other practice trains one in clear thinking to the same degree. Good writing is an art which a man can enjoy just as a painter enjoys a bit of painting, when at last he gets it just to suit him. As Lord Balfour once wrote, "What pleases me most is to write something quietly by myself—to touch it up and complete it with a feeling that one has really done one's best." How wonderful it would be if more American physicians were to get this thought about writing. Usually our main idea is to get a paper out of our system as quickly as possible, and later when some editor has to spend hours putting the manuscript into such shape that it can be printed and read, we become much annoyed over his efforts in our behalf.

As everyone knows who has ever tried to put his ideas across to others, easy reading means "damned hard writing." Dr. Dempster's comments about this remind the reviewer of the times when physicians have said to him, "If I could only dash things off as easily as you do I could get a lot of writing done." They didn't know that any paper that reads easily must always have been rewritten at least half a dozen times. Even the ablest and the most experienced writer can always find a better and clearer and shorter or a more vivid or musical way of saying a thing if he will spend some time trying.

Some of the chapters in Dr. Dempster's book which are not ordinarily found in works of this kind are those on the editorial functions, on preparing illustrations, on the use of the dictionary, on where to look for references, on Greek derivatives, on the history of medical journalism, and on copyright regulations. There is also a short list of books which can be read with profit.

The reviewer is particularly delighted to find Dr. Dempster approving of the occasional use of such things as a split infinitive. As he says, at times it is highly desirable that it be used. Unfortunately, an editor who sits all day correcting manuscripts tends to develop a number of reflexes which enable him or her to blue pencil certain grammatical constructions inevitably and without any cerebration. The experienced writer will follow no rule but will be guided always by his ear for good rhythm and accent in a sentence. If it does not *sound* right something is wrong and the arrangement of the words must be changed.

Dr. Dempster wisely quotes some unknown man who said that one good illustration is worth a thousand words of description. This holds true not only for drawings and photographs but also for verbal illustrations. One of the faults of medical writers is their tendency to write long sentences full of abstract statements the meaning of which may or may not be grasped after several careful readings. If the writer had only told a short interesting story about a patient or if he had briefly described one crucial experiment the reader might have gotten the meaning immediately and without the expenditure of much effort.

We physicians commonly make the same mistake in talking to patients. Too often we use long technical words, or worse yet, medical jargon about "flat plates" and B.M.R.'s, and the patient leaves with only the vaguest idea of what we were trying to tell him. More of us should practice talking to ignorant people in such simple speech that they can understand us. Wherever possible, we should teach as Christ did with the help of parables; we should use simple illustrations and similes, and should tell short stories of other patients with similar troubles whose experience taught them and the physician many things. Such stories will commonly interest and convince, and years later when the physician meets an old patient he may be surprised to find that some story that he told is still remembered together with the lesson that it taught. An abstract statement would probably not have been remembered for more than a few hours, if it was remembered at all. The same technic is useful also when one is talking to or writing for tired doctors. As a busy physician once said to the writer, "When I come home from my last call at night and slump down into my chair by the fire I would like to read my medical journals but often I am too tired to look at anything difficult. I just can't face a lot of long words and long sentences. But perhaps then my wife says: 'Here is a delightful article by Dr. John Stokes, which this afternoon I read and enjoyed and understood.' And then I read it, sitting up long after I should have gone to bed, because it flowed along so easily and interestingly, with here and there a delightful little story to make and hammer home a point. Some long-winded doctors tell me that such writing is not dignified, but all I say is, give me a lot more like it."

Surely physicians who would like to improve the appearance and the reading qualities of their papers would do well to buy this little book and to read it over and over again.

Walter C. Alvarez, Rochester, Minn.

Diagnosis and Non-operative Treatment of the Diseases of the Colon and Rectum. By Schwarz, Gottwald, Goldberger, Jacques and Crocker, Charles. New York, Paul B. Hoeber, Inc., Harper and Brothers, 540 pp., 1937.

THIS book has been written from the point of view that, in the case of proctology, the reader needs not only a good description of disease entities, with details as to symptoms, diagnosis and treatment, but also special instruction in the ways in which the roentgen ray and sigmoidoscope can be used to help in understanding the problem of the particular patient. An effort has been made by the three writers to bring together in this book information available in Austria, Germany and the United States.

The book is interestingly written and well illustrated. There are many colored representations of what can be seen through the sigmoidoscope. As usual with textbooks, the reviewer must feel that in many places the treatment of the subject is inadequate from the point of view of the specialist, but the answer would probably be that specialists never look to textbooks for information. Perhaps they would if writers who were really competent to teach would make their books adequate and up-to-date. Unfortunately they rarely do, and as a result the specialist who looks through a textbook is usually repelled by the number of statements he finds there which are antiquated, inadequate, or positively misleading. On the whole, however, this book will be of considerable assistance to students of proctology. Particularly helpful will be the fine bibliography.

Walter C. Alvarez, Rochester, Minn.

Handbook of Microscopical Technique. By C. E. McClung. New York, Paul B. Hoeber, Inc., Harper and Brothers, 698 pp., 1937.

ONE of the finest things that Paul Hoeber has done through the years is to produce in beautiful format, valuable handbooks on technics of various kinds, each chapter being written by an able specialist in the particular field. This work is a beautiful example of his craft. Dr. McClung has gathered together as contributors such men as Chambers, Cowdry, Downey, Mallory, Penfield and Florence Sabin. All those who work in laboratories are in their debt and will want this book.

Walter C. Alvarez, Rochester, Minn.

Gastroscopy. The Endoscopic Study of Gastric Pathology. By Dr. Rudolf Schindler, University of Chicago Press, Chicago, Illinois, 343 pp., June, 1937.

THE author states that "this book is based on the premise that the functional tests of the stomach used for the last sixty years have failed as methods of diagnosis and that only the morphological methods — X-ray and gastroscopy — are of direct diagnostic value."

The volume contains much information for the gastro-enterologist and particularly for the gastroscopist. No one making gastroscopic studies can afford to be without this book as it explains in detail the methods used by a pioneer in gastroscopy who has

contributed more than anyone to the development of gastroscopic methods. The text is very readable and the colored plates showing the gastroscopic views of various lesions are particularly instructive. Throughout the book the author emphasizes the necessity for roentgenoscopy in association with gastroscopy in the diagnosis of diseases of the stomach and shows that the one method must supplement the other in order to make the examination of the stomach complete. A considerable amount of space is devoted to the classification and diagnosis of gastritis, a lesion which is rarely detected by roentgenoscopy.

Porter P. Vinson, Richmond, Va.

ERRATUM

Apology is made to Dr. C. M. Wilhelmj and the readers for the erroneous inclusion of a chart with his editorial in the August issue. This ought to have been held for use with an article by Dr. Wilhelmj appearing in a later issue.

—Supervising Editor.

EDITOR'S NOTICE

The recent Supplement to the August issue of this Journal was sent out on my own responsibility and without consultation with the Board or Editorial Council. I make this statement for the purpose of completely freeing all editorial members of this Journal from any responsibility in the matter.

Abstracts

WILLHELMJ, ELLIS W.

Further Observations of the Histidine Treatment of Peptic Ulcer. Annals of Inter. Med., Vol. X, pp. 1365-1370, March, 1937.

Since January, 1935, 42 roentgen-ray proved cases of peptic ulcer have been treated with a series of 24 daily intramuscular injections of 5 c.c. of 4 per cent distidine monohydrochloride. Of these 42 cases, 28 have been followed closely and rechecked clinically and radiographically for at least one year following treatment. The patients were requested to carry on their usual activities of life, were given no medicine whatsoever and advised to eat a general diet. From this group 21 cases were selected as showing uncomplicated peptic ulcer and no other physical ailment.

Of the entire group of 28 cases carefully followed there were 17 males and 11 females, whose ages varied from 20 to 72 years, the average being 45.2 years. A history of typical ulcer symptoms, with intermittency, food and alkali relief and epigastric distress two to four hours after meals, was presented in about 90 per cent of the cases. Four of the patients had had previous hemorrhages. Two cases gave a history of perforation and three cases presented an entirely atypical symptomatology, the diagnosis being established entirely by roentgen-ray findings. The average duration of symptoms was 8.8 years.

Of the 28 cases in the series, 23 were duodenal and five were gastric ulcer. The roentgen-ray findings were rechecked every three months for one year and at the end of this time two cases of the duodenal ulcer group were considered cured. Sixteen of the duodenal cases and five of the gastric cases were unimproved roentgenologically. In percentage 75% of the cases showed no improvement radiographically, while 8.6 per cent were considered cured and 21.7 per cent improved.

The clinical results of the entire series show six cases, or 21.4 per cent received complete and total relief; eleven cases or 39.3 per cent received only partial or no relief; and eleven cases or 39.3 per cent received complete relief but relapsed in the first year following treatment.

In the group of 21 selected cases we find 28.6 per cent of the cases received permanent relief, 23.8 per cent were complete failures, and 47.6 per cent received complete immediate relief with relapse within the first year.

Ten of the patients from the selected group of 21 were given a second course of treatment four to six months after finishing the first course, regardless of whether or not they had relapsed within that period. Those patients who had previously relapsed all again developed symptoms following the second course of treatment.

Willhelmj concludes that this treatment will undoubtedly produce remissions in a fairly high percentage of uncomplicated ulcer patients, 76.2 per cent in the selected series, but the permanent relief is no greater than that derived by various other methods of ulcer treatment and the final results obtained do not justify the routine use of this procedure in the management of peptic ulcer patients.

JEGHERS, HAROLD.

"Night Blindness as a Criterion of Vitamin A Deficiency: Review of the Literature with Preliminary Observations of the Degree and Prevalence of Vitamin A Deficiency Among Adults in Both Health and Disease." Annals of Int. Med., Vol. X, pp. 1301-1331, March, 1937.

The purpose of this report is to give some observations concerning the degree and prevalence of vitamin A deficiency among a group of supposedly normal adults and also to give some preliminary results obtained by testing persons afflicted with various types of disease.

There is now abundant available evidence to show that in older children and adults, essential hemeralopia (night blindness) is usually the earliest and the most constant manifestation of avitaminosis A, and that it may exist for years without any other sign of the appearance of such a deficiency. This can be tested by at least four suitable methods, but for many years foreign investigators have been using various types of photometers to measure quantitatively minor to moderate degrees of night blindness. The Birch-Hirschfeld photometer was used in this study and the entire procedure for testing one patient takes less than twenty minutes. The author emphasizes that it is important to be sure that no intra-ocular condition is present which can cause night-blindness, before assigning the lowered photometer reading to vitamin A deficiency.

A total of 274 satisfactory photometer tests were performed. The subjects were divided into three groups as follows:

Group 1 consisted of 22 physicians who ate in the doctors' dining room at the Boston City Hospital.

Group 2 consisted of 149 subjects comprising W. P. A. employees, medical students, technicians and graduate nurses.

Group 3 consisted of 103 ambulatory patients. Tests in this group were usually made shortly before discharge.

Group 1 consisted of healthy males varying from 24 to 35 years of age and free of serious intra-ocular disease. This was considered the control group because of excellent cooperation, reliable dietary history and the uniform nature of their diet. The meals contained an abundant and varied supply of vitamin A and carotene. Butter, milk and cream in unlimited amounts were served at every meal; eggs five times a week; cheese once per week; liver once a week; whipped cream on desserts once a week; ice cream three times a week and pigmented (yellow or green) vegetables and fruit daily and often at each meal. With two exceptions the photometer reading of each person in this group fell into a narrow range which was considered normal, the exceptions were due in one instance

to attempted weight reduction and, in the second to many food dislikes.

Members of Group 2 were healthy in the sense that they worked daily and had no specific complaints of disease. Of 149 subjects tested 98 (65.8 per cent) fell into the normal group. Of the remainder, 42 (28.2 per cent) were mildly deficient in vitamin A; seven (4.6 per cent) were severely deficient. The reasons for the deficiencies could usually be assigned to some obvious dietary lack. This arose through the expense of the vitamin A containing foods or peculiarities in food habits (weight reduction, dislikes, etc.).

Group 3 comprised 103 ambulatory patients convalescing from the usual run of diseases which one finds in a general medical ward. No very sick or bedridden patients were tested because the subject had to be well enough to walk to the dark room.

Thirty-four (33 per cent) of those tested showed no deficiency.

Forty-three (41.7 per cent) were found to be mildly deficient in vitamin A; 18 (17.6 per cent) moderately deficient; and eight (7.7 per cent) severely deficient.

The cause of the high deficiency in this group is explained as follows: (1) Persons in this group belong for the most part to the lower economic level. (2) Many had diseases which cause anorexia, vomiting, diarrhea or otherwise hindered the proper ingestion and absorption of the vitamin. (3) Many were entirely ignorant of what constituted an adequate diet. (4) Some had fever, infection or other disturbances which increased the metabolic need for vitamin A. (5) Several had liver damage which prevented the proper storage of vitamin A or conversion of carotene to vitamin A.

Results of Therapy of Vitamin A Deficiency. In the present study 14 of the persons in Group 2, who showed low photometer readings, were treated with vitamin concentrates with no change in their diet. Each person received a daily carotene capsule containing 10,000 U.S.P. units of vitamin A activity. Each person was re-tested at the end of two, three and four weeks after the therapy, with one exception (where it took a month) the photometer reading returned to the normal range after either two or three weeks.

The author also extensively reviews the literature dealing with the physiology, biochemistry, pathology and clinical aspects of vitamin A deficiency.

SHAY, HARRY AND FIEMAN, PHILIP.

The Galactose Tolerance Test in Jaundice; a Consideration of the Evidence Permitting the Measurement of Galactose Utilization by Urinary Excretion; Some Sources for Error in Its Interpretation; and an Addition in Routine Technic. Annals of Inter- Med., Vol. 10, pp. 1297-1303, March, 1937.

In a study of the metabolism of galactose in the human subject, Shay, Schloss and Bell concluded that this hexose was best suited for testing the carbohydrate function of the liver. The urinary excretion of this sugar, orally administered, acts adequately as a measure of hepatic carbohydrate function because no renal threshold for galactose can be demonstrated, the utilization of galactose by tissues other than the liver is minimal or nil, and the urinary excretion after a standard dose of galactose may be taken as an invariable unit of measure.

The authors adopted the 3 gram level of urinary excretion of galactose as the upper limit of normal, five hours after a 40 gm. dose. They also claim that this test can have no value when applied as a general liver function test, but as an aid in the differential diagnosis of jaundice it is of incalculable value. It has its greatest value if applied early in the course of jaundice, and in the painless jaundice group of middle and later life.

Because of the possibility of some glucose excretion after the dose of galactose in some disturbed endocrine states (thyroid, adrenal, pituitary, potential or mild unrecognized diabetes, or in the case of impaired renal tubular absorption because of so-called low renal threshold) the authors feel that differential fermentation of the urine with properly prepared yeast should be made part of the routine technique in all cases in which the excretion of reducing substances in the five hour urine exceeds a grams.

FELSON, JOSEPH AND GORENBERG, HAROLD.

Chronic Dysentery, Distal Ileitis and Ulcerative Colitis. A Follow-up of the Jersey City Epidemic of Bacillary Dysentery. Amer. Jour. Med. Sci., Oct., 1936.

A nine to twelve months' follow-up study was made following the major Jersey City epidemic of 1934. Only hospitalized patients were included in the investigation. 122 cases were included. There were persistent or recurrent symptoms and signs in 46 (37.7%). Diarrhea with blood, mucus and pus, 8 (6.5%). Watery diarrhea without gross blood, 12 (9.8%). Bloody evacuations without diarrhea, 3 (2.4%). Miscellaneous intestinal symptoms, 23 (19.0%).

In Table 2 are included visible evidence of ulcerative colitis or ileitis. (a) Roentgenographic evidence of chronic ulcerative colitis, 8 (6.5%). (b) Additional cases with sigmoidoscopic evidence of chronic ulcerative colitis, 2 (1.7%). (c) Chronic distal ileitis (2 at operation, 1 at necropsy*) 3 (2.5%).

Discussion of Statistical Data and Their Significance. Approximately 10% developed chronic distal ileitis or ulcerative colitis by the end of the first year. The initial infection was due to B. dysenteriae (Flexner) in each instance. Although the acute disease subsided, it had never cleared up completely. In a percentage of these chronic cases B. dysenteriae may still be recovered after the lapse of a year or more; in the majority of them this organism cannot be found on repeated fecal cultures. Secondary intramural invasion by the enterococcus and B. coli occurs through the ulcerations originally caused by B. dysenteriae. If chronic distal ileitis and chronic ulcerative colitis are the result of bacillary dysentery, accurate diagnosis, prompt isolation, and adequate treatment are essential.

Antidysentery serum of high antitoxin content must be given within the first 24 to 48 hours to be effective. Foodhandlers should be supervised.

Allen Jones, Buffalo.

MCGEE, LEMUEL C., CONRAD, HAROLD A. AND WILSON, ANGUS K.

Electrocardiographic Changes with Perforated Duodenal Ulcer; a case report. Ann. of Int. Med., Vol. 10, pp. 1222-1226, Feb., 1937.

A case is reported of a 39 year old coal-miner who was admitted to the hospital in shock and semi-coma, who had collapsed in his home 12 hours previously following an attack of severe upper abdominal pain. A tentative diagnosis of either perforated duodenal ulcer or acute pancreatitis was made. An electrocardiogram showed inversion of T-waves in Leads 2 and 3 with elevation of the S-T interval in those Leads as well as in Lead 4. This finding suggested the possibility of coronary occlusion with posterior surface infarction.

The patient recalled that for the previous six months he had had recurring attacks of rather severe epigastric pain with shortness of breath. The periods of distress were too numerous to recount, but the patient was positive in the assertion that the discomfort was related to exertion and that resting a few minutes provided relief. He had stopped work two weeks before because of marked dyspnea and weakness. The patient died after being in the hospital 70 hours.

At autopsy 3 liters of greenish brown fluid were removed from the peritoneal cavity. Abundant purulent exudate and thick fibrin covered the

*Almost entire ileum and all of colon involved.

omentum and bowel. The fundus of the gall bladder covered a perforation in the duodenal wall. The gall bladder itself was intact, but covered with exudate and fibrin. When the duodenum was opened, two typical, chronic "kissing" ulcers were found, the upper one alone having perforated. This ulcer measured about 5 mm. by 6 mm. in diameter. Careful dissection of the coronary vessels of the heart revealed no occlusion, and after extensive sectioning of the myocardium, no infarction, either old or recent, was revealed. Histological study confirmed the gross pathological findings.

Reference is made to the occasional striking association between disease of the gall bladder and symptoms referable to the heart, noted in the past 30 years.

The electrocardiographic changes noted in this report may have resulted from (1) shock and low systemic blood pressure with insufficient oxygenation of the cardiac musculature, (2) embarrassment of circulation due to displacement of the heart by the elevated diaphragm or (3) a reflex change in cardiac circulation and function initiated by inflammatory process about the duodenum and gall bladder.

MOENCH, L. MARY.

Variations in Response to Therapy in Pernicious Anemia. Ann. of Inter. Med., Vol. 10, pp. 1115-1129, Feb., 1937.

Adequate treatment of pernicious anemia should result in the restoration of a normal blood picture and in a disappearance of those symptoms and signs which are not due to irreversible tissue reactions. This study investigates the amount of potent factors required to bring the erythrocytes to normal and to maintain these cells at such a level if, in spite of apparently adequate therapy, a significant fall in the red blood cell count may occur; and if such a fall occurs whether it is attended by other evidence of clinical relapse.

The total series of patients studied numbered 36; of this total, 33 patients had been given treatment for a sufficient period of time to elevate the red blood cell count to normal, and of these, 32 had been treated in the clinic for periods of time that permit a satisfactory evaluation of data which might yield information about maintenance conditions. Of the group of 32 patients the average length of the maintenance period was 21 months, the shortest period being five and the longest 50 months. The preparations used in treatment were Lederle Liver Extract (3 c.c. of which were derived from 100 grams of liver) and an unconcentrated extract prepared in the laboratories of the New York Hospital (10 c.c. of which were derived from 50 grams of liver). These preparations were given by intra-muscular injection, the average amount consisting of a total monthly dose of material derived from 300 grams (Lederle) or from 200 grams (New York Hospital). The patients were seen in the clinic at least once a month when counts were made and the patients questioned and examined. When the red blood cell count fell appreciably or the patient showed some evidence of relapse the amount of material was increased or was supplemented by whole liver or by Lextron.

In this series of pernicious anemia patients who were in remission the average count for the entire group of women (19) was 4.5 and for men (13) 4.83. These averages are lowered by 10 (5 men and 5 women) of the cases not satisfactorily controlled; 70% of the series gave a satisfactory hematologic response. Of these 10 patients whose erythrocyte counts did not measure up to the normal standard with therapy, which is usually adequate, eight have been apparently fully controlled as far as symptoms and signs are concerned. In two, the disease showed some evidence of activity. All of the women and three of the men in this group received approximately twice the average amount of liver given to 70 per cent of the original group of patients.

Of the 33 cases, 15 reached the 4.5 million level in two months or less. The average total amount of liver extract given was that derived from 670 grams (combined New York Hospital and Lederle Extracts). The average initial count was 2.6 millions erythrocytes. The duration of symptoms prior to treatment averages 13.1 months. Of a second group requiring more than two but under three months to reach this level, there were 11 patients with an average initial count of 1.9 million. The average amount of material used was derived from 1072 grams (combined extracts). The approximate duration of symptoms averaged 23.1 months. A third group (7 patients) required more than 3 months for erythrocyte count to reach the 4.5 million level, and to whom a minimum of 1600 grams and a maximum of 6,600 grams of liver were given. The initial count in these patients was 2.9 million.

Of the total series of 36 patients only eight had never experienced symptoms of peripheral or central nervous system involvement. Following treatment of 28 who experienced symptoms, 4 were entirely relieved, 15 were improved, in 5 there was no change and in 3 they became worse. In 1 the result was indeterminate.

It must, therefore, be concluded that each patient with pernicious anemia must be managed as a separate problem and the dose of liver individualized on the basis of the trend of the erythrocyte count averaged over stated intervals of time. No unqualified prediction can be made as to the length of time necessary to bring the count to normal on the basis of the initial count or as estimated by the response of the average patient, and although the majority of patients are benefitted by treatment, no absolute prediction, as to relief of symptoms, can be made.

FREUND, HUGO A.

Clinical Manifestations and Studies in Parenchymatous Hepatitis. Ann. of Inter. Med., Vol. 10, pp. 1144-1155, Feb., 1937.

A study is presented of the effects of a chemical compound on two men exposed to the vapor of a nitrosamine. These two patients, chemists, while engaged in the manufacture of dimethylnitrosamine, inhaled this chemical poison in sufficient amounts to produce headache, backache, abdominal cramps, nausea, anorexia, weakness, drowsiness and giddiness.

CASE REPORTS

Case 1. T. C., chemist, age 29, single. Chief complaints are pain in the upper right quadrant, nausea, a sensation of weakness in the upper abdomen and occasional abdominal cramps. He dates the beginning of his illness about July, 1933, while engaged in the above mentioned work. August 16 he noticed his abdomen was distended. In the hospital about two and one-half quarts of fluid were withdrawn by paracentesis. Although the abdomen slowly filled again no further tapping was performed. After spending three months in a tuberculous sanitarium and a similar period in bed at home, and a period for thorough examination in New York City, he was advised to return home with instructions to rest during the summer of 1934. Gradually the attacks of pain became less frequent. The patient states he was jaundiced at the beginning of his illness and for a short period in January, 1935. He admits that the entire illness has made him somewhat nervous and depressed. There is no history of clay colored stools, nor dark urine. His habits are good as to alcohol, smoking and eating. There is no family history of tuberculosis or cirrhosis; both parents and brothers are living and well. On physical examination there is tenderness throughout the whole abdomen on light palpation, especially in the upper right quadrant where there is definite muscle spasm. The liver is felt two fingers breadths below the costal margin and is moderately firm and tender. The spleen is not palpable. All reflexes and tests of sensation are

normal. The non-protein nitrogen is 40 mg. per cent, blood sugar 66 mg. per cent and the Kahn test is negative.

On February 17, 1936, the blood count showed: Hgb. 84 per cent. Erythrocytes 3,680,000. Leukocytes 7,000. Color Index 1.1. Reticulocytes 1 per cent. Thrombocytes 349,400. Differential Count: Metamyelocytes 3 per cent; neutrophiles, stab. 20 per cent; neutrophiles, segmenters 26 per cent; eosinophiles 0; basophiles 1 per cent; total of granulocytes 50 per cent; lymphocytes 48 per cent; monocytes 2 per cent. The urinalysis phenolsulphonephthalein test, blood chemistry, sugar tolerance and van den Bergh tests showed nothing unusual. The Bromsulphalein, basal metabolic rate, gastro-intestinal roentgenogram and cholecystograms revealed no abnormal findings. The pulse averaged 80 and the temperature was not elevated during hospitalization.

Case 2. H. B., 26, white, single, chemist. This patient filled the position of the patient just described when the latter was compelled to stop working because of his illness. On November 18, 1934, he began symptoms similar in type and onset to the first patient.

On December 26, 1934, he entered the hospital acutely ill. The sclerae were slightly icteric; there was free fluid in both pleural cavities. The abdomen was distended and contained fluid, but was not rigid. The liver was felt three fingers below the right costal margin. Ascitical fluid ranging from 3,500 c.c. to 6,000 c.c. was removed by parencentesis on seberal occasions. Laboratory findings: Urinalysis negative. Blood count (Jan. 24): Hgb. 80 per cent; erythrocytes 4,600,000; leukocytes 9,900; polynuclears 72 per cent; small lymphocytes 28 per cent; some variation in the size and shape of the red blood cells was noted. Blood Chemistry (Dec. 28, 1934): Icteric Index 16; van den Bergh reaction, faintly positive, direct and indirect; Kahn negative. Roentgenogram of chest showed pneumonitis in the right base. An exploratory laparotomy showed a large amount of yellowish ascitic fluid. Liver extremely engorged, about a hand's breadth below margin of rib, smooth and purplish in color. Spleen markedly engorged and lobulated, purplish in color. Gall bladder and duct somewhat thickened; no stones; emptied readily. The patient died on January 28, 1935. Autopsy: The outstanding findings were 400 c.c. of fluid in the right pleural cavity and about 100 c.c. of blood stained serous fluid in the left. The spleen weighed 320 gms. and was uniformly mushy in consistence. The biliary channels were patent. The liver weighed 1380 grams, was dark greenish, mottled brown and rather firm in consistence. On section it was of similar appearance.

Summary of microscopic findings: Liver: Acute diffuse degeneration of the whole parenchyma with focal and diffuse areas of necrosis. The necrotic areas are infiltrated with round cells and phagocytes. Multiple periportal miliary hemorrhages. Areas of intense regenerative proliferation of liver cells with marked irregularity in size and staining reaction of protoplasm and nuclei.

Some experiments were performed permitting mice and dogs to inhale dimethylnitrosamine and autopsy showed microscopical changes in the livers similar to that found in Case 2.

The selective toxicity of the chemical dimethylnitrosamine appears to be adequately demonstrated in this paper.

RENANDER, AXEL.

(Benign Gastric Tumors) Gutartige Magentumoren. Acta Radiological, 17:491. Oct. 31, 1936.

The author describes two cases of benign tumor of the stomach, one a plum-sized neurofibroma and the other an orange-sized lipoma with a thumb-sized ulcerous crater. Roentgenological diagnosis of benign gastric tumor was made possible by the uniformly rounded appearance of these growths on the roentgenograms as well as the plasticity of the mucous membrane relief around the one tumor and the unaltered appearance of the other tumor at the control examination.

ROTHMAN, MAURICE M., MERANZE, DAVID R. AND MERANZE, THEODORE.

Blood Phosphatase as an Aid in the Differential Diagnosis of Jaundice. Amer. Jour. Med. Sci., p. 526, Oct., 1936.

Phosphatase is apparently concerned with the metabolism of bone, and is found in bone, liver, kidney, intestinal mucosa, blood, bile and feces. As studied in the blood, the serum and plasma phosphatase have been found moderately increased in local bone atrophy, generalized osteoporosis and osteomalacia. In hyperparathyroidism, the findings are 4 to 5 times the normal, and in active infantile rickets, 10 to 13 times above the normal.

Roberts found high values in jaundice. He noted a difference in the phosphatase content of the plasma as between cases of obstructive and non-obstructive jaundice. He studied the phosphatase values in 52 cases of jaundice, 21 obstructive; 31 non-obstructive. The authors cite his conclusion that by means of the phosphatase level of the blood, toxic infections and catarrhal jaundice may be distinguished from that of the obstructive type. The phosphatase values were normal in 5 cases of hemolytic jaundice. The writers cite the observations of many workers, and note the divergence of opinions and conclusions in the matter, some affirming and some denying that the test was of value in the differential diagnosis of jaundice.

Important experiments were conducted by ligation of the common duct in dogs. The writers believe, however, that the phosphatase is valuable. The method employed was as follows: Fasting blood was used. 2 c.c. of plasma (citrated blood) is mixed with 2.3 c.c. of distilled water and 0.7 c.c. of N/10 sodium hydroxid. This produces a pH of approximately 8.9. To this is added 1 c.c. of a 1% solution of sodium betaglycerophosphate. The mixture is then incubated at 37.5° C. for 2 hours, after which its inorganic phosphorus content is determined by the method of Fiske and Subbarow. At the same time, the initial inorganic phosphorus content of the plasma is determined, using another 2 c.c. of the original blood. Both of these values are determined in mgm. per 100 c.c. of blood plasma. The difference of these two values represents the number of mgms. of inorganic phosphorus liberated by the enzyme, phosphatase, from the substrate under the above conditions. Each mgm. thus obtained is expressed as units of phosphatase per 100 c.c. of blood plasma.

Phosphatase values in cases without jaundice or liver disease were found for adults less than 6 units, and for children less than 15 units. In obstructive jaundice, high phosphatase values were found. In cases of non-obstructive jaundice, the authors studies led them to agree with Roberts; that is, in cases of jaundice phosphatase values up to 10 units indicate that the jaundice is non-obstructive in etiology, and values above 10 units indicate an obstructive mechanism.

FRIEDENWALD, JULIUS AND MORRISON, SAMUEL.

Use of Gastric Antacids. J. A. M. A., Vol. 108, pp. 879-885, 1937.

Antacids are used to reduce or neutralize the acidity of the gastric secretion preferably by local action rather than through systemic effects. Sodium bicarbonate and magnesium oxide are thought to be among the most powerful stimulants of gastric secretion. This is because they render the contents of the stomach alkaline, which condition stimulates the secretion of acid.

Sippy, in the treatment of ulcer, attempts to bring about complete neutralization of the gastric contents. Some clinicians while agreeing that removing the irritation of the gastric acid by alkalies is rational treatment, also believe that the amount of alkali administered by the Sippy method is too great. Because of this the Sippy

powders have been altered so that number two contains 0.65 gms. of calcium carbonate and 0.65 gms. of Heavy Magnesium Oxide. If diarrhea occurs Bismuth Subcarbonate may be used to replace the heavy magnesium oxide or powder one substituted for powder two.

Winkelstein tries to avoid the high night acidity curves by using a continuous milk drip containing five gms. of sodium bicarbonate to the quart, regulated so that the patient receives three liters per day. Wasika and Emery have found an alkalinized powdered milk preparation administered every hour to be better than the Sippy regimen.

Hurst uses milk containing 0.65 gms. of sodium citrate with magnesia magna per glass because in addition to their being proficient alkalies the sodium citrate combines with the calcium of the milk and prevents the renin from acting on the caseinogen, thus preventing the formation of irritating curds. His second mixture contains 0.3 mgs. of atropine sulfate and is administered twice daily at eight a. m. and three p. m. Magnesia magma is given to regulate bowel evacuation. Heartburn is treated by giving .4 gms. of prepared chalk between feedings. He also prescribes 15 gms. of powdered charcoal with water at seven a. m.

In treating peptic ulcer alkaline therapy of some kind is indicated. However, many clinicians believe that large doses are harmful and Crohn has shown that neutrality exists only for a short time and it is followed by a hypersecretion of gastric acids. Because of this the tribasic phosphate of calcium and magnesium have been recommended. These salts act locally and not systemically and therefore can be given continuously without toxic effects.

The effect of alkalies is to increase the circulation to the stomach by a slight irritant action, to render mucus less tenacious, and to render the contents of the stomach neutral or alkaline. Antacids are therefore indicated in gastric hyperacidity, in peptic ulcer, in chronic alcoholic gastritis, catarrhal duodenitis and in the neuroses. They should be given either dissolved in water or mixed in it if insoluble one or two hours after meals. The antacids generally used are aluminum silicate and aluminum hydroxide, the basic phosphates, bismuth subcarbonate, sodium and potassium bicarbonate, magnesium salts and calcium salts.

Alkalosis may develop especially when sodium bicarbonate is used over a long period of time. This is very likely to occur in those patients who have a chronic nephritis, pyelonephritis, hepatic cirrhosis, arteriosclerosis or hypertension. It is manifested by such symptoms as headache, drowsiness, anorexia, nausea, vomiting, muscle ache, nervousness, mental depression, vertigo and aching pain in the muscles and joints. In addition, other complications may arise such as the formation of a gastrolith of magnesium and sodium, interference with digestion, and catarrhal gastritis due to a reflex hypersecretion of acid.

Francis D. Murphy, Milwaukee.

ELIASON, ELDRIDGE L. AND ERB, WILLIAM H.

Rectal Prolapse. Ann. of Surg., 105:2, 199-202, Feb., 1937.

The rediscovery in 1925 of the elastic ligature method of treatment of rectal prolapse is the basis for a discussion of the method and the report of three cases.

Weinlechner first treated rectal prolapse by this method in 1883 but it was practically abandoned with the advent of aseptic surgery. The method was discouraging also because of the accompanying pain, urinary retention, and difficulty in expelling gas. The method consisted of the slow amputation of the prolapse by placing a rubber tube into it and tieing an elastic ligature around it.

Kleebarg used the elastic ligature in 1879 only as a means of controlling bleeding while amputating and suturing the rectum. Mikulicz in 1889 popularized the amputation operation and reported seven cases with no mortality. In 1907 Lenormont stated there was a 10% danger of peritonitis.

There have been four cases reported by Reid since his rediscovery of the method in 1925, one by Wangensteen and three by the authors. None of the above unpleasant symptoms was present in these cases. The first case in the authors series was complicated by hemorrhage while attempting to remove the slough and stricture due to lack of close follow up care.

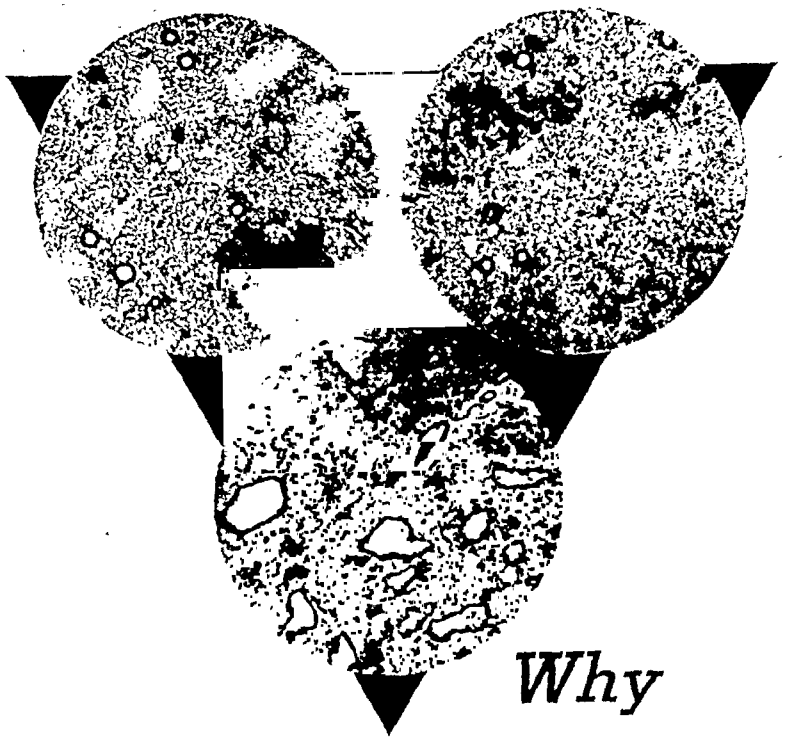
The authors place a thick, stiff, three-quarter inch rubber tube in the rectum, pull the prolapsed portion over it, tie a heavy rubber band around the bowel close to the mucocutaneous junction, and suture the prolapsed portion to the tube to prevent retraction.

This method is believed to be of value in certain cases but not in all. Prolapse in children especially, which make up about 70% of cases, should be treated more conservatively. The strongest indication is irreducible prolapse with infection of the prolapsed portion. There are no reports of recurrence in the literature compared with 6% to 15% with other methods. Close postoperative observation will prevent the main danger, stricture, and hemorrhage will probably not occur if the slough is allowed to separate spontaneously. Slight relaxation of the anal sphincter was noted in one patient 22 days following operation.

Wayne W. Flora, Chicago.

Note: This procedure is a step backward rather than an advance. Obstruction may ensue if the small intestine lies between the walls of prolapsed rectum, anteriorly. It is preferable to determine by direct inspection through the incised rectum whether the small intestine is down and if it is to adequately replace it. To depend upon necrosis in an infected field denies a general surgical principle. Hemostasis is more certain with ligature.

HURST, ARTHUR F. AND KNOTT, F. A.



British Dysenteric Infections. The Lancet, p. 1197, Nov. 21, 1936.

Bacillary dysentery has been endemic in Great Britain since the fourteenth century and the mild and scattered epidemics of today are the direct descendants of the serious and widespread epidemics of the seventeenth and eighteenth centuries, reinforced by infection brought home by soldiers from the Crimean and South African Wars and the Great War.

Attention has recently been drawn to the possible spread of bacillary dysentery in England as a result of the increasing popularity of pleasure cruising creating a source of infection by taking on food at ports of call where dysentery is common.

Modern bacteriological investigations and the clinical records of the past indicate that the dysentery of Great Britain must always have been predominantly of the Flexner and allied Sonne types, although the occurrence in earlier days of occasional outbreaks of high mortality makes it probable that Shiga infections were not quite as uncommon as now. More recently the majority of cases in Great Britain, sufficiently severe to deserve clinical description as dysentery, are also Flexner infections. A few are caused by bacilli of the Schmitz (atypical Shiga) type, and a small proportion of the comparatively common Sonne (atypical Flexner) type give rise to true dysentery. Shiga dysentery is almost unknown. However, numerous epidemics of mild diarrhea are caused by infection with Sonne's dysenteric bacillus, which is isolated from the stools in these cases, although clinically they may bear no resemblance to classical dysentery, or bloody flux.

Ulcerative Colitis and Bacillary Dysentery: Ulcerative colitis is probably a sequel of an acute or subacute infective colitis. In many cases a dysentery bacillus is the original infective agent. However, if the bacteriological evidence is taken into account, it suggests that if chronic ulcerative colitis arises from infection with Flexner dysentery bacillus, the infection must generally play no more than the initial part of damaging and lowering the natural resistance of the intestinal mucosa. In a few cases the Flexner infection may persist and these cases are

Why
KONDREMUL
(CHONDRUS EMULSION)
Is A Better Emulsion

Two steps in the development of Kondremul are responsible for its clinical superiority in the treatment of constipation. These are:

First, the special emulsifying process splits up the oil into uniformly fine droplets of microscopic size.

Second, the use of Irish Moss (Chondrus Crispus) as the emulsifying medium protects each tiny particle with a tough, indigestible film, so that no coalescence occurs, even in the intestinal tract. This explains why there is thorough admixture with the fecal material and no leakage results.

KONDREMUL with Phenolphthalein — combined laxative and regulator.

KONDREMUL with Cascara — adds the tonic laxative effect of non-bitter cascara to Kondremul.

KONDREMUL Plain — a corrective for deficient bowel action.

examples of true chronic dysentery. But in the majority the Flexner bacilli die out completely and other damaging influences, often secondary infections, affect the colon, producing the characteristic chronic disease with its great tendency to relapse. It is in these cases, too, that the specific agglutinins usually disappear from the blood. In this way the apparently contradictory bacteriological findings can be explained.

This paper, like all of Hurst's and his collaborators' papers, is an excellent study of the subject and should merit careful reading by all doctors interested in gastro-enterology. The subjects are so thoroughly discussed as to make a brief review of each paper quite inadequate.

C. W. Wirts, Philadelphia.

HURST, ARTHUR F. AND RYLE, J. A.

The Incidence, Mortality and Treatment of Hemorrhage in Gastric and Duodenal Ulcer. The Lancet, p. 1, Jan. 2, 1937.

In a given case of sudden gastric or duodenal hemorrhage, having excluded such other causes as hepatic cirrhosis, splenic anemia, cancer and the hemorrhagic diathesis, we are usually entitled to make a diagnosis of peptic ulcer, the commonest cause of bleeding from these sites.

Incidence of Hemorrhage in Chronic Ulcer: A full history was obtained from all 586 cases of ulcer investigated in New Lodge Clinic between February, 1921, and February, 1936, and from 751 cases seen in private practice by J. A. R. from 1920 and 1935. The incidence of hemorrhage is about 30 per cent in gastric and duodenal ulcer and 45 per cent in anastomotic ulcer.

Mortality of Hemorrhage from Ulcer: Of 677 patients with hematemesis and melaena from ulcer seen in general practice only nine have died, giving a mortality of 1.31 per cent.

From 1919 to 1935 inclusive, there were 371 cases of chronic gastric, duodenal and anastomotic ulcer admitted to the wards at Guy's Hospital. Of these, 82 or 22 per cent had bled within 48 hours of admission; in 32 of the 82, or 39 per cent, there was a history of an earlier hemorrhage. In 106 of the total 371, or 29 per cent, a previous hemorrhage was recalled. Of the 82 cases admitted for hemorrhage, 54 had gastric ulcers (66 per cent), 22 duodenal ulcers (26 per cent) and 6 anastomotic ulcer (8 per cent). As there were 191 gastric ulcers, 167 duodenal ulcers and 10 gastrojejunal ulcers in the series, the proportion of cases admitted for hemorrhage in gastric ulcer was 27 per cent, in duodenal ulcer 13 per cent and in anastomotic ulcer 60 per cent. The mortality of these cases of ulcer admitted into Guy's Hospital under A. F. H. an account of hemorrhage was 4.8 per cent. The mortality from hemorrhage in patients with a history of previous hemorrhage from ulcer or admitted for ulcer was under 2.5 per cent, and mortality from all cases of ulcer, including those which had never bled was about 1 per cent. Comparing these figures with a private series (J. A. R.) there was a mortality of 3.1 per cent from hemorrhage in cases of severe hemorrhage and a mortality of 0.5 per cent from hemorrhage in all cases of ulcer. In general practice the mortality among patients with hemorrhage from an ulcer appears to be about 1.5 per cent. The authors feel this latter figure to be the nearest possible approach to the natural mortality. If the incidence of hemorrhage in cases of ulcer, whether they have previously bled or not, is only about 0.4 per cent.

Surgery for Hemorrhage from Ulcer (A.F.H.): There have been 586 cases of ulcer (110 gastric, 379 duodenal and 97 anastomotic) in New Lodge Clinic between February, 1921, and February, 1936, and in 3 of these, all duodenal and all operated on while bleeding, the patients have died from hemorrhage. While surgery may frequently achieve success in skillful hands, it can only in very exceptional circumstances be re-

Synopsis of
Digestive Diseases

By JOHN L. KANTOR, Ph.D., M.D., Associate in Medicine, Columbia University; Gastroenterologist and Associate Roentgenologist, Montefiore Hospital for Chronic Diseases, New York. 302 pages, 40 illustrations. Price $3.50.

This book presents simply, clearly, and concisely, the essential facts concerning the diseases of digestion. An effort has been made to preserve the proper balance between stress and subordination, inclusion and omission, and to emphasize throughout, the ways in which gastroenterology fits into the larger field of internal medicine. To this end the opening chapter on classification has been designed for early orientation, clinical syndromes common to many diseases have been elaborated as fully as possible, and a final section has been devoted to digestion symptoms in extradigestive diseases.

Contents—PART I—GENERAL CONSIDERATIONS. Classification of Digestive Diseases. Diagnostic Methods: History and Physical Examination. Special Tests. Therapeutic Methods. Organic Constitutional Inferiority. The Anomalies. Functional Constitutional Inferiority: The Neuroses. Gastrointestinal Allergy and Food Sensitiveness. PART II—DISEASES OF THE DIGESTIVE ORGANS. Diseases of the Mouth, Esophagus, Stomach, Duodenum, Jejunum and Ileum, Colon, Appendix, Rectum and Anus, Liver, Gall Bladder and Bile Ducts, and Pancreas. PART III—DISEASES DUE TO INTESTINAL PARASITES. The Protozoa. The Flatworms: Cestodes. Trematodes. The Roundworms. PART IV—DIGESTIVE SYMPTOMS IN EXTRADIGESTIVE DISEASES. Nervous, Cardiovascular and Respiratory Diseases. Diseases of the Blood, Metabolism, and the Genitourinary System; Plumbism.

Synopsis of
Ano-Rectal Diseases

By LOUIS J. HIRSCHMAN, M.D., F.A.C.S., Professor of Proctology, Wayne University, Detroit, Mich. 288 pages, 174 pages, 6 color plates. Price $3.50.

The technic of diagnosis and of therapeutic measures herein presented requires no elaborate array of costly instruments, nor does it require complicated and expensive electrical or other apparatus. In over one-third of a century's experience in the practice of proctology as a specialty, the author has demonstrated the success of the methods described. These procedures are now presented in this synopsis to guide those who desire to treat that large proportion of ano-rectal diseases which can be treated safely and successfully outside the field of the limited specialist.

Contents—Anatomy. Symptoms Which Should Call Attention to the Rectum. Examination of the Patient. Anesthesia. Limitations of Local Anesthesia and Office Treatment and Indications for Other Measures. Constipation and Obstipation. Fecal Impaction. Pruritus Ani. Anal Fissure and Ulcer. Abscess of the Ano-Rectal Region. Anal Fistula—Anal Sinus. Hemorrhoids. Ano-Rectal Polyposis—Anal Papillitis—Cryptitis. Proctitis and Sigmoiditis. Removal of Foreign Bodies. Benign Growths, and Rectal Stricture. Prolapse of the Anus and Rectum.

Gentlemen: Send me the following

, charging my account.

(5th of a SERIES)

Salines

IN SENILE CONSTIPATION

Salines are most suitable aperients in senescent atrophy of the intestinal muscles. The gentle evacuation provided by the salines is important in old-age constipation, where gently stimulated peristalsis is demanded.

Sal Hepatica

is the mineral saline of two-fold benefit. By gently increasing peristaltic efficiency and heightening osmosis, Sal Hepatica acts to rid the intestines of injurious waste. By helping to maintain the alkaline level in tissues and plasma, Sal Hepatica aids in building resistance against many ailments.

Sal Hepatica also stimulates an increased rate of bile flow from the liver into the gall bladder and thence, into the duodenum.

The synergistic constituents of Sal Hepatica achieve practically the same safe action as those of famous mineral spring waters. The sparkling effervescence makes it easy to take. . . Requests for trial sizes of Sal Hepatica and literature given prompt attention. Why not send for them today?

Sal Hepatica Flushes the Intestinal Tract and Aids Nature To Combat Acidity

BRISTOL-MYERS CO.

NEW YORK, N. Y.

garded as judicious. In less experienced hands, the authors fear that it will immediately increase the mortality from this accident.

General Treatment: When local conditions are favorable treatment should be carried out without transportation of the patient. In all cases a quarter of a grain of morphia should be given at once hypodermically and repeated in accordance with the needs of the case, during the first 24-48 hours. All mouth feeding should be forbidden for 24 or 48 hours and in rare cases for 72 hours. A closer study of the advantages of earlier and more liberal mouth-feeding in severe hemorrhage is needed. The mouth may be rinsed but at first not even water should be swallowed. Normal saline, one-half to three-quarters of a pint, slowly administered by rectum, should be given four-hourly. The latter usually controls constipation about the third day. Injection of proprietary hemoplastic sera is of no value. The hygiene of the mouth must be carefully watched because of the risk of parotitis. When the anxious, earlier phase has passed, medical treatment as for uncomplicated ulcer is gradually instituted. X-ray and other investigations should not be done for three or four weeks.

Transfusion: The authors are inclined to think that transfusion is not without danger and apart from its use as a preliminary to surgery should in general not be given unless the hemoglobin percentage is under 30, and the patient appears to be in danger of death from anemia. About ten ounces is sufficient and transfusion should not be repeated unles hemorrhage recurs.

Iron: Large doses of iron and ammonium citrate (gr. XXX three times a day) can be given safely from the third day following a hemorrhage; they lead to a rapid return of hemoglobin to a normal level and in this way greatly hasten convalescence.

B. B. Vincent Lyon and
C. W. Wirts, Philadelphia.

HURST, ARTHUR F.

Diseases of the Alimentary Canal. The Practitioner, Special Number, Vol. CXXXVII, pp. 409-422, Oct., 1936.

Gastroscopy: Much, possibly too much, has been claimed for gastroscopy as an aid in diagnosis. With its limitations and advantages viewed in their true perspective there can be no doubt that the invention of the flexible gastroscope has added a useful method of gastric investigation. In the detection of chronic gastritis and acute and chronic gastrojejunal ulcers, gastroscopy has proven itself particularly useful.

Treatment of Gastric Duodenal and Anastomotic Ulcer: Hurst cites the over-alkalinization in the treatment of peptic ulcer; the symptoms may be those of uremia and the possibility of alkali poisoning should be remembered whenever a patient who has not hitherto known to be suffering from renal disease develops uraemic symptoms with high blood urea.

Magnesium Trisilicate: Much has shown that this drug absorbs hydrochloric acid without acting as an alkali and can therefore be given in large doses without causing alkalosis. For some months Hurst has given this preparation in thirty grain doses to ulcer patients and alkalosis has never developed.

Histidine: Although there is no doubt that histidine sometimes hastens the healing of an ulcer, especially one of recent origin, Hurst has never seen the slightest benefit result from its use when he tried it in cases in which improvement was slow with the usual treatment. Sandweiss has described some control experiments in the treatment of ulcer with daily injections of 5 c.c. distilled water. Of twenty patients treated the results compared favorably with those obtained with histidine injections, as twelve or 60 per

USEFUL IN A LIQUID DIET

Just to list a few of the many cases where HORLICK'S MALTED MILK is useful in the diet —

1. AFTER OPERATIONS — Its flavor is appetizing to surgical convalescents and its ease of assimilation enables them to appropriate its nourishing food value.
2. IN DIGESTIVE DISORDERS — Remarkably easy of digestion, due to the presence of extracted nutriments of the malted grains, it has often been found to be the only food that can be tolerated and assimilated sufficiently to maintain strength.
3. WHEN SOLID FOOD CANNOT BE TAKEN, it affords a bland and nourishing food-drink.
4. DURING FEVERS OR CONVALESCENCE—A palatable and soothing food, capable of sustaining strength with little tax upon digestion.

HORLICK'S The Original MALTED MILK

Horlick's Malted Milk Corporation
Racine, Wisconsin

Your Patients Will Appreciate

INCREASED PALATABILITY
INCREASED CONVENIENCE
INCREASED EFFECTIVENESS

As supplied in these effervescent forms of standard medicaments:

Aspir-Vess—The combined aspirin-alkali effect.

Bromo-Vess—Bromides of sodium, potassium, ammonium. No salty taste.

Cinsa-Vess—Anti-rheumatic agents—cinchophen, sodium salicylate, colchicine—with alkali. Increased tolerance, increased effectiveness.

EFFERVESCENT PRODUCTS, Inc.
ELKHART, INDIANA

cent became symptom free, compared with 55 per cent of the forty patients treated with histidine. Hurst concludes that the use of histidine as a substitute for the proper treatment of peptic ulcer is unjustifiable.

Jejunal and Gastric Feeding by Tube: A comparison of the two methods of continuous drip feeding in ulcer cases, one into the jejunum (Einhorn) and one into the stomach (Winkelstein) showed the latter maintained complete achlorhydria day and night, while in the former there is a continuous secretion of acid juice into the stomach. Hurst believes the method of Winkelstein is worthy of trial in ulcer cases which do not respond to ordinary treatment.

Gastrectomy: In Hurst's cases in which gastrectomy had been performed for gastric ulcer, five out of five showed free acid still being secreted; for duodenal and anastomotic ulcer, five out of eleven showed free acid. Out of thirteen of his private patients in which a partial gastrectomy was performed for anastomotic ulcer, two died from the operation, one developed a new ulcer immediately after the operation and died after a further portion of the stomach was removed a month later; a fourth died from hematemesis without premonitory symptoms two years after the gastrectomy. Exactly one-quarter of the survivors from partial gastrectomy for duodenal or anastomotic ulcer are now suffering from recurrence of symptoms. Hurst has also had one patient with a large anastomotic ulcer and three with severe recurrent hemorrhage following partial gastrectomy performed elsewhere. In view of the unsatisfactory results of gastrectomy, Hurst is now convinced that gastrojejunostomy is the best operation for the exceptional cases of duodenal ulcer in which prolonged medical treatment fails and that anastomotic ulcers should be excised and the parts restored to their original anatomy, unless pyloric or duodenal obstruction is present, when partial gastrectomy must be performed in spite of its dangers.

Regional Ileitis (Crohn's Disease): Hurst has seen two typical cases of regional ileitis and feels that the disease is only just becoming recognized in England, but with the exception of Holland it remains unrecognized in other parts of the Continent.

CAFFRITZ, EDWARD A.

Nondrainage of the Peritoneal Cavity in Appendiceal Peritonitis. J. A. M. A., 108:1315-1317, April 17, 1937.

Drainage or nondrainage of the peritoneal cavity in peritonitis has lately been the subject of much debate and study. Some surgeons believe that drainage should always be done and some that it should never be done. Others are of the opinion that the procedure should be subject to the surgeon's own discretion.

The author has in the past few years treated twenty-five cases of appendiceal peritonitis by the nondrainage method with very gratifying results. He believes that drainage should be instituted only in those cases in which the primary focus of infection cannot be removed, in cases in which a large amount of necrotic and contaminated tissue is left in the abdominal cavity and in cases of walled-off abscess.

In all other cases he believes drainage is contraindicated. The advantages of nondrainage according to the author are:

(1) There is less morbidity and mortality.

(2) It minimizes the possibility of postoperative mechanical ileus.

(3) It shortens the duration of the illness.

(4) It excludes the possibility of the development of a fistula.

(5) It minimizes the tendency to postoperative hernia.

(6) It minimizes the tendency to postoperative adhesions.

Francis D. Murphy, Milwaukee.

The Frequent Picture of
IMPAIRED DIGESTION
in Gallbladder Disease

UPON the classical symptom complex of chronic cholecystitis is frequently superimposed the picture of impaired digestive function. The patient complains of intolerance to certain foods, fermentative diarrhea or stubborn constipation, generalized abdominal distress; not infrequently fatty stools are observed as a consequence of insufficient emulsification and digestion of fats.

Taurocol Compound (Plessner) has proved of excellent value in the treatment of these conditions. Its rational formula provides bile salts, digestive enzymes, stomachics, and the bowel-normalizing influence of cascara. Its contained bile salts stimulate biliary flow and gallbladder drainage, and aid in the emulsification of fats; its pepsin and pancreatin improve gastrointestinal digestion; its stomachics hasten gastric emptying thus relieving the frequent discomfort of postprandial distention. In consequence, the patient is afforded distinct subjective relief and enabled to enjoy a balanced diet without subsequent distress.

CITY STATE

When acidosis accompanies anesthesia and toxicity follows surgical trauma . . . .

Their effects may be moderated by the administration of Karo before and after operation

WATER BALANCE (24 HOURS)	
Intake	*Outgo*
Drinking Water (600 cc.)	Urine (800 cc.)
Beverages (600 cc.)	Skin (700 cc.)
Solid Food (700 cc.)	Lungs (600 cc.)
Metabolic Water (300 cc.)	Feces (100 cc.)

WHEN carbohydrates are indicated, surgeons prepare patients pre-operatively to prevent acidosis and post-operatively to protect nutrition. Karo serves this dual purpose. Given with a soft diet *before operation* the patient will better resist surgical acidosis. And Karo forced with fluids *after operation* provides vital energy the patient craves.

KARO enriches the glycogen reserves thereby helping to prevent surgical acidosis, decrease post-anesthetic vomiting, stimulate the strained heart and combat shock.

AFTER operation nutrition wanes when the patient cannot tolerate food. Karo with fluids helps maintain the water balance of the body and tides the patient over with basal energy. Karo provides 60 calories per tablespoon. It is relished added to milk, fruit juices and vegetable waters.

KARO is a mixture of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor), well tolerated, not readily fermentable, and effectively utilized.

For further information, write
CORN PRODUCTS SALES COMPANY
Dept. DN-9, 17 Battery Place, New York, N.Y.

★ **Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.**

DAVISON, C. AND STONE, L.

Lesions of the Nervous System of the Rat in Vitamin B Deficiency. Arch. of Pathology, 23:2, 207, Feb., 1937.

Because of the fact that the clinical syndromes, and especially the neuroanatomic lesions induced by the administration of diets deficient in the vitamin B complex to animals are apparently not constant, the authors undertook an experimental study of vitamin B deficiency in the rat. The study included (1) total and subtotal B_1 deficiency; (2) total and subtotal B_1 and B_2 deficiency; (3) controls fed with (a) stock diets, and (b) artificial diets including adequate vitamin rations, and (4) controls subjected to (a) starvation and (b) starvation despite adequate vitamin rations.

In their experiments vacuolation, liquefaction necrosis and chromatolysis of ganglion cells in the mesencephalon, metencephalon and spinal cord, as well as disintegration of the myelin sheaths of the peripheral nerves, were found alike in the animals subjected to diets deficient in vitamin B_1, in both vitamins B_1 and B_2 and in those suffering from pure inanition. Neurologic symptoms such as ataxia, dragging of the legs, convulsions, priapism and retraction of the head occurred in each group. The question of the relationship between these symptoms and the histological changes described was not easily answered. The paralysis might be ascribed to the peripheral neuritis. The convulsions and the tonic retractions of the head might be attributed to the hemorrhages and nerve cell changes in the mesencephalon and metencephalon, and the ataxia and weakness to the starvation. It was believed that the ganglion cell changes of which vacuolation was the most prominent, represented a true pathologic state. The histological changes in animals suffering from inaniton were essentially the same as those in animals deprived of B_1 or both B_1 and B_2. The changes in the peripheral nerves, however, seemed to be most marked in animals subjected only to starvation. It mattered not whether abundant vitamins were given during starvation or not. The clinical symptoms in animals subjected to inanition, however, were not wholly identical with those in animals suffering from vitamin B deficiency, possibly because of the rapid death of the starved animals.

BAKER, A. B. AND LUFKIN, N. H.

Cerebral Lesions in Hypoglycemia. Arch of Pathology, 23:2, 190, Feb., 1937.

From a detailed study of the cerebral changes in three cases of hypoglycemia numerous new and old hemorrhages were found scattered irregularly throughout each brain. These hemorrhages seemed to be most numerous in the brains of the patients who had had the most severe convulsive seizures. Certain histological changes were noted also in the ganglion cells.

In recent years reports of many patients having varied neurological symptoms believed to be related to an accompanying hypoglycemia have been made, and some animal experiments recorded. These reports failed to reveal consistent lesions. The findings in both human and animal material varied from apparently normal conditions to most extensive changes in the cells, nerve fibres and vessels.

The authors also studied the effect of severe hypoglycemic convulsions in rabbits experimentally produced by the injection of insulin. The convulsions were produced once or twice per week over a period of six to eight weeks and each convulsion allowed to continue a varying length of time up to one hour, and then stopped with intravenous injections of 50 per cent dextrose solution. The convulsions were severe but

Gentle Effective
Bowel Action

ZymenoL brings about prompt, bulky bowel movement in *Both* Constipation and Colitis *without drugs* (No Phenolphthalein, No Cascara, No Purgative).

ZymenoL provides the therapeutic merit of emulsified mineral oils *Plus* a non-irritating active effect to induce bulky bowel movement. Sugar free--ideal for Diabetics.

Combined, these features make ZymenoL the ideal treatment for both the stagnant and the irritable, unstable bowel with no important contra-indications.

the rabbits seemed to recover promptly on the administration of the dextrose. The brains of these rabbits showed no cell alterations of pathologic significance and only an occasional hemorrhage into the brain or meninges.

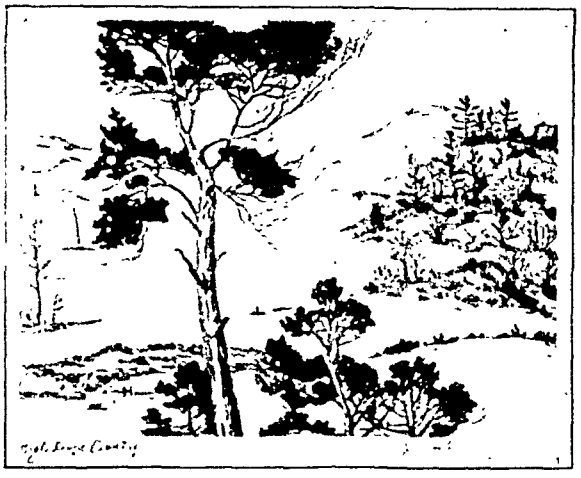
The authors concluded from this study of both human and rabbit material that the ganglion cell changes in the brains were due entirely to postmortem alterations. They explained the presence of severe and varied symptoms during life and the minimal histological changes found after death on the assumption that the function of the nerve cells may be seriously depressed by the lowered blood sugar and result in varied symptoms without death of the cells, and with a return of normal blood sugar the cells may be able to regain promptly their normal function once more.

N. W. Jones, Portland.

NICKERSON, D. A. AND WILLIAMS, R. H. *Malignant Tumors of the Small Intestine. Amer. Jour. Path., XIII:1, 55, Jan., 1937.*

The authors report 10 cases of primary neoplasm of the small intestine occuring in 11,206 autopsies performed in the Mallory Institute of Pathology during the past 40 years, and review briefly the literature on the subject. The 10 cases consisted of 2 leiomyosarcomas arising in the duodenum and 8 carcinomas, 6 of which occurred in the duodenum and 2 in the jejunum. The incidence of the latter to carcinoma of the intestinal canal in the series was 2.33 per cent.

Metastases, especially into the liver and the regional lymph nodes, occurred abundantly in 7 of the 8 cases of carcinoma. The 2 cases of sarcoma showed no secondary growths.



The symptoms and clinical findings are briefly summarized in the report and are of interest. Duration of symptoms before the patients entered the hospital was over 7 months. The clinical picture depended upon the site of the tumor, the type and grade and the presence of metastases. Bloating and epigastric pain after eating, sometimes vomiting or an acute attack of intestinal obstruction occurred. Weakness, loss of weight and strength, altered bowel function and progressive anemia were usually present. The roentgen ray findings in 4 of the 10 cases were dilatation of the stomach with gastric residue without demonstrable gastric lesions and distortion of the duodenum. All were diagnosed as extrinsic tumors or deformities due to adhesions.

N. W. Jones, Portland.

MCCARTY, CLAUDE E. *Sympathectomy for Hirschsprung's Disease and Polyposis. Am. Jour. Surg., 36:2, 531-2, May, 1937.*

A nine year old girl had not had a spontaneous bowel movement since birth and there had been periods of complete obstipation. The presacral nerve, the branches from the third and fourth lumbar ganglia, the lateral roots, and the two principal roots of the inferior mesenteric plexus were divided. The second day following operation the bowels moved naturally. One month later the child was having three normal bowel movements daily. The months after operation there were two stools daily and at the end of a year the bowel movements remained two daily.

A single woman 22 years of age after menstruating once at 12 years started to menstruate regularly every four weeks when 14 years old. The flow lasted seven days and was excessive. Severe pain kept her in bed seven days before and two days after the onset of the flow. Constipation had been present for one year. The use of enemas caused severe cramps. A partial obstruction

Allergy

Allergic conditions of intestinal origin have been definitely benefited by the administration of Soricin. Migraine and vertigo, when due to toxic absorption from the bowel, frequently respond to Soricin. Likewise urticaria, some forms of eczema, and allergic diarrhea have in many cases been relieved with Soricin.

Soricin (sodium ricinoleate) is a detoxifying agent which apparently acts in vivo. It is of value in the treatment of non-ulcerative colitis, "irritable colon," and toxic absorption from the intestinal tract.

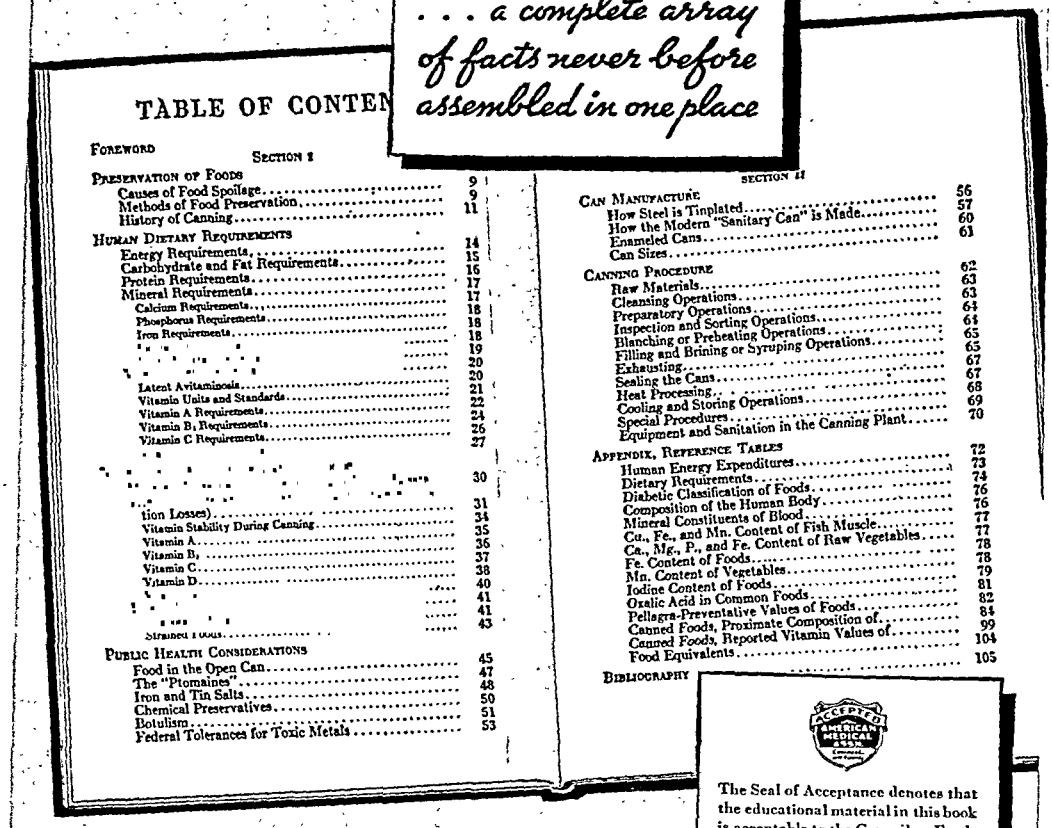
Soricin is available in two dosage forms for internal administration:

Soricin Capsules (Enteric Coated):

10 grain size:
boxes of 20 and 100 capsules each

5 grain size:
boxes of 40 and 100 capsules each

Soricin Tablets (Enteric Coated):



5 grain size: bottles of 100 tablets

The Seal of Acceptance denotes that the educational material in this book is acceptable to the Council on Foods of the American Medical Association.

INFORMATION YOU WILL WANT AT HAND

For nearly a generation commercial canning of foods has been the subject of intensive research by chemists, biochemists and bacteriologists. You know many of the noteworthy contributions of canned foods, but an occasional layman-consumer still clings to some old, unfounded prejudices.

For your convenient reference, the Nutrition Laboratories, Research Department, of the American Can Company, have compiled a complete array of facts about dietary requirements, nutritive aspects of canned foods, canning procedures, etc. A bibliography of scientific literature is included. American Can Company, 230 Park Avenue, New York City.

110 pages of authoritative information, indexed for easy reference.

marked by a two and one-half inch filling defect in the sigmoid was demonstrated by barium enema and X-ray. Also there was a gross polypoid involvement of the entire colon, sigmoid, and rectum. Sympathectomy and X-ray therapy were chosen instead of colectomy.

At operation December 10, 1935, there was found a kink due to attachment of a peritoneal fold across the sigmoid to the lateral abdominal wall and a small adhesion between the ileum and uterus. These were freed and the presacral nerve with its branches was resected. On January 3, 1936, the patient was treated by X-ray. The next menstrual period was normal as to flow and pain. Complete obstruction occurred February 16, 1936, due to temporary lodgment of released "polypoids" in the sigmoid. After four days she passed large polypoid masses and was relieved. X-ray examination of the colon March 12, 1936, showed it to be normal. The patient now has one or two bowel movements daily and the menstrual periods are normal.

Reviewer's Note:

Hirschsprung's disease has been treated by sympathectomy with a fair degree of success, at least temporarily. Some cases fail to respond and in those which do the permanency of the result has not been proven.

The result reported in a case of polyposis treated by X-ray is probably explainable on the basis of the histologic structure of the growths. Biopsy in such favorable cases usually reveals tissue predominantly lymphoid in structure and not the usual adenoma.

Wayne W. Flora, Chicago.

RIGDON, R. H.

Production of Colitis in the Dog with Staphylococcus Toxin. Arch. Path., 23:5, 634, May, 1937.

Rigdon and Leff previously described hemorrhagic and necrotic lesions in the intestinal mucosa of each of two children dying of staphylococcus aureus toxemia. One child had had otitis media, mastoiditis and meningitis; the other osteomyelitis of the tibia and acute pericarditis.

It is known that necrosis and hemorrhage in the mucosa of the gastro-intestinal tract may follow intravenous and oral administration of staphylococcus toxin. In the series of experiments reported, staphylococcus toxin was injected into the colons of twelve normal dogs. This toxin was prepared by growing a hemolytic strain of staphylococcus aureus in veal infusion broth. A 0.02 c.c. volume of the toxin produced hemolysis of 2 c.c. of a 1 per cent suspension of rabbits' red blood cells in physiologic solution of sodium chloride, and 0.1 c.c. injected intracutaneously into a rabbit produced an area of necrosis measuring 2 by 4 cm. In the dogs 0.1 c.c. to 0.5 c.c. of the prepared toxin were injected into the submucosa and mucosa of the colon in different places to the amount of 4 to 6 c.c. in different animals. The animals were sacrificed in from one to fourteen days. During the first six to ten hours after operation the dogs experienced cramps and loose stools, but soon recovered and ate normally. Hemorrhage into and necrosis of the mucosa and stroma followed the injections of the toxin. After desquamation of the necrotic mucosa, ulcers were left which healed in from eight to fourteen days. These lesions were similar to those previously described in the colons of rabbits and dogs following intravenous injection of staphylococcus toxin. They were also similar to those found in the gastro-intestinal tracts of the two children dying of staphylococcus toxemia. The necrosis of the skin of the rabbit following intracutaneous injection of the toxin was also similar, which would make it appear unlikely that there should be two fractions in the toxin, one a "skin-necrotizing" and the other a "gastro-intestinal" toxin.

N. W. Jones, Portland.

AUTHORITATIVE RESEARCH

Gerber has maintained for years its own fully equipped chemical laboratory for the development of new products and control of every process. In addition, for seven years, Gerber has had fellowships in a State College; also an infant clinic in Detroit, for research into all aspects of the preparation and feeding of Strained Foods.

The effectiveness of this research is established by this fact: In the April 10th issue, the Journal of the American Medical Association published an article entitled — "Strained Fruits and Vegetables in the Feeding of Infants". A number of references on strained foods in this article were *reports from research sponsored by Gerber's.*

On request we shall be glad to send you reprints of the four articles referred to in the article mentioned above, viz.: 1—Hanning, Flora: Canned Strained Vegetables as Sources of Vitamin A, J. Am. Dietet. A., 9:295 (Nov.) 1933. 2—A Comparison of Vitamins B and G in Canned Strained Foods, J. Nutrition, 8:449 (Oct.) 1934. 3—Further Studies of the Content of Vitamins A and B in Canned Strained Vegetables, J. Am. Dietet. A., 12:231 (Sept.) 1936. 4—Comparison of the Biological and Chemical Methods for the Determination of Vitamin C in Canned Strained Vegetables and a Study of Its Variation From Year to Year, J. Nutrition, 12:405 (Oct.) 1936. Write Gerber Products Co., Dept. 339, Fremont, Mich.

RETICULOGEN

(PARENTERAL LIVER EXTRACT WITH VITAMIN B_1, LILLY)

Highly concentrated antipernicious anemia principle from liver for Parenteral Administration

PATIENTS may now be comfortably and conveniently treated with relatively infrequent injections of liver extract. Each 0.5-cc. ampoule of 'Reticulogen' is comparable in hematopoietic effect to the ingestion of 3,000 to 4,500 grams (6 1/2 to 10 pounds) of fresh liver. There are 500 International units vitamin B_1 in the 0.5-cc. ampoule.

In the average uncomplicated case of pernicious anemia a dosage of 0.5 cc. of 'Reticulogen' at intervals of one to two weeks is usually sufficient to maintain an adequate red blood cell response.

Ampoules 'Reticulogen' are supplied in boxes of three 0.5-cc. rubber-stoppered ampoules and in 5-cc. rubber-stoppered ampoules.

At Last....

Rapid Demonstrable Healing in Peptic Ulcer

Creamalin — the distinctive colloidal cream of aluminum hydroxide — effectively overcomes the well-known drawbacks of alkaline powder therapy. Acid neutralization is both profound (12 vol. N/10 HCl in less than 30 min.) and unvarying, in contradistinction to the fleeting neutralizing action of the soluble alkalis. Creamalin produces no secondary rise in HCl secretion, insuring the safety of the protective ulcer scab. Since Creamalin is not absorbed, no change in plasma CO_2 or pH occurs, making alkalosis impossible.

* *

Because of these outstanding advantages, ulcer healing with Creamalin is more rapid than has been reported heretofore. Roentgenologically demonstrable healing is observed in 7 to 12 days when Creamalin is given by continuous drip (for which the Creamalin Automatic Drip Control is specially designed), and in 3 to 6 weeks when administered orally. The therapeutic action of Creamalin is equally effective in both gastric and duodenal ulcers.

THE SUCCESSFUL ULCER TREATMENT

GALL, EDWARD A.

The Response of Guinea Pig Bone Marrow to Liver Extract. Amer. Jour. Path., XIII, 4, 575, July, 1937.

The author refers to the work of Jacobson, who showed that normal adult male guinea pigs, fed a diet of oats, carrots and lettuce, react to the administration of liver extract by the development of a significant increase in the number of the circulating reticulocytes. This response, if constant and consistent, would offer a means of biological assay of the potency of liver fractions. Other investigators, however, have questioned the reliability of the test. In the present paper is given the results of a study of the marrow of the guinea pig under several experimental conditions undertaken to determine the effect of liver extract, and if possible to explain the above mentioned disagreement.

Five groups of guinea pigs were studied. Ten animals fed a diet of oats, carrots and lettuce showed densely cellular marrow with evidence of depressed maturation of its cells. Seven animals thus fed and showing marked depletion of cellular elements revealed abruptly accelerated maturation following the administration of a single dose of liver extract. Two other animals similarly fed showed persistent increased maturation on a daily dose of liver extract for 6 and 10 days respectively. Twenty guinea pigs fed on a diet of hay, oats and carrots did not show a depression or inhibition of maturation of the marrow cells, which led to the conclusion that a diet of hay, oats and carrots possessed a substance available in liver extract, but that it was absent in a diet of oats, carrots and lettuce. The nature and source of this substance, whether it is the food substance or vitamin content of the hay or from the molds growing in it, is not determined. Nor is it known whether lettuce contains some inhibitory factor. The general conclusion to be drawn from the study is that guinea pigs under controlled conditions may be found to be a satisfactory means of assaying liver fractions. Changes in the bone marrow elements responded in the main to the rise in the circulating reticulocyte count as reported by Jacobson.

REDISH, JULIUS

Hodgkin's Disease of the Stomach with Fatal Gastric Hemorrhage. Arch. Path., 23:6, 844, June, 1937.

Lesions of the wall of the stomach due to Hodgkin's disease are rare. The first case was reported by Schlagenhaufer in 1913. Redish finds the records of twenty-two cases, which were confirmed by autopsy, in the literature, to which he adds one more. The gross appearance of the stomach in the different cases has varied; some have shown diffuse infiltration, some bulky tumor masses and ulcerations.

The case now reported was that of a 54 year old white man, who presented himself at the hospital for the removal of a painless enlarging mass of the anterior thoracic wall. He was well nourished and complained of no symptoms of illness. Four days after entering the hospital he vomited a large quantity of bright red blood and died two days later. On the lesser curvature of the stomach there was found an ulcer measuring 7 cm. in diameter. The margin was elevated and thick. The base consisted of firm, grayish-white tumor-like tissue, which shaded off gradually into normal gastric wall. A second and similar ulcer, 2 cm. in diameter, was in close proximity to the other. The peripancreatic lymph nodes, spleen and anterior wall of the chest were involved in the process. The histologic picture of tissues from these organs was characteristic of Hodgkin's disease. Many large mononucleated and multinucleated giant cells were present. Clinically the case was of interest because of the absence of symptoms and sudden death from gastric hemorrhage. Pathologically it was of particular interest because of the rarity of the lesion.

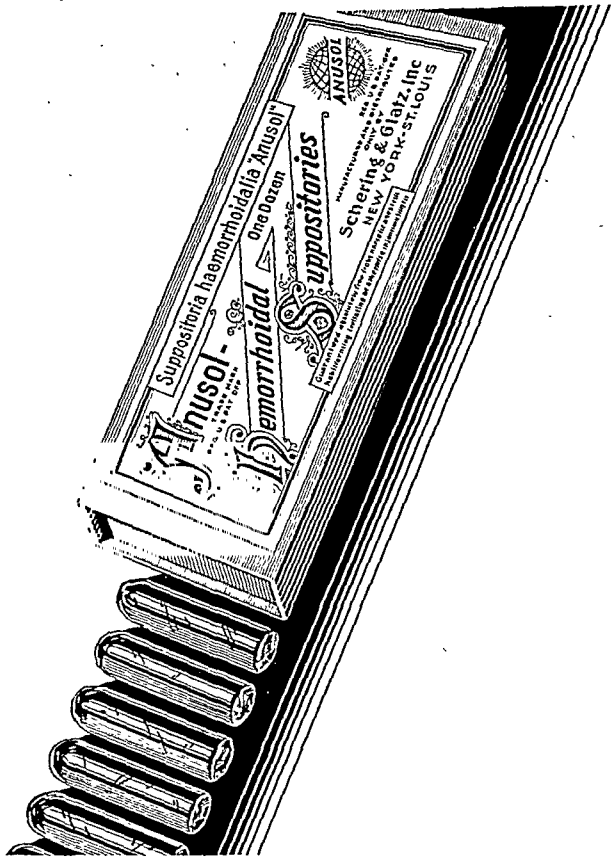
ALT, HOWARD L. AND SWANK, RAY L.

Thrombopenic Purpura Associated with Catarrhal Jaundice: Report of a Case. Annals of Inter. Med., Vol. 10, pp. 1049-1053, Jan., 1937.



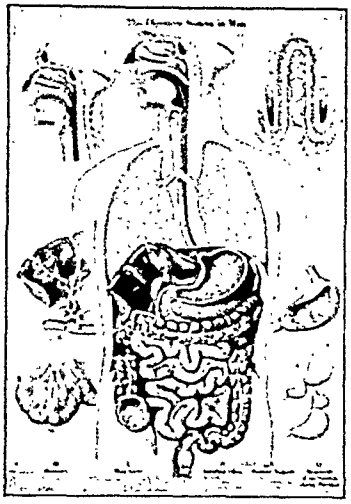
A patient has been observed in whom an acute thrombopenic purpura occurred simultaneously with an acute catarrhal jaundice.

A male, age 24, was admitted to the hospital complaining of malaise, epistaxis and jaundice which followed an upper respiratory infection one month before, and the gradual development of anorexia, muscular aching, constipation, discomfort in abdomen, highly pigmented urine, lighter colored stools and petechial spots for three days prior.

The significant laboratory data show an absence of blood platelets; no clot retraction; increased bleeding time; 3+ bile in the urine; a strongly positive benzidine test for occult blood in feces and in urine; increased quantitative *van den Bergh*; increased icterus index and a marked increased dye retention on functionally testing the liver. On duodenal intubation and administration of 100 c.c. of magnesium sulphate, a thin greenish mucoid secretion was obtained.

The patient was treated by transfusion of citrated blood and a injection of whole blood. Subsequently calcium gluconate, viosterol, and liver extract were given each day. He became entirely well and was discharged from the hospital three weeks after admission. There has been no recurrence of symptoms one and one-half years after the illness occurred.

Accompanying this report is a discussion of the etiologic relationship between thrombopenic purpura and catarrhal jaundice. Also evidence is



FOUR POINTS in the medical treatment of hemorrhoids are of utmost importance: the rectal suppository must be therapeutically effective, safe to use under any circumstances; it must be devoid of accessory or systemic effects; it must be easy and convenient to use. How well Anusol Suppositories measure up to these requirements you have probably found out by first hand experience. Shall we send you a liberal trial supply of Anusol Suppositories. Please ask for it on your letterhead.

ANUSOL SUPPOSITORIES ARE SUPPLIED IN BOXES OF 6 AND 12

FISKE, F. A. AND AEGERTER, E. E.

Primary Carcinoma of the Liver Cells with Peritoneal Metastasis. Arch. Path., 21:1, 58, July, 1937.

Although primary carcinoma of the liver is not particularly a rare tumor, the authors review briefly the literature and report a case of primary liver cell carcinoma, as distinguished from primary carcinoma of the small biliary ducts, because of extensive peritoneal metastasis—an unusual occurrence.

In brief resume certain points of clinical interest may be gleaned from the paper. Primary cancer of the liver of both types are most frequently found in Orientals. Seventeen per cent of all cancer deaths in the Philippines fall into this group. Cirrhosis is a common accompaniment—85 per cent with carcinoma of the liver cells and 50 per cent with carcinoma of the bile ducts. The tumor is more frequently found in the right lobe, and the right diaphragm is often fixed. The liver may be smaller than normal by reason of the accompanying cirrhosis. Jaundice occurs in 61 per cent. Pain, fever, ascites, edema and enlarged spleen are frequently noted. Extrahepatic metastasis has been found in only 20 per cent of the cases. For this reason surgical removal has been successful in a fair percentage of cases and is a procedure to be recommended.

The case reported presented massive metastasis throughout the peritoneal cavity. The mode of spread seemed to be through the lymph vessels.

HIRSCH, EDWIN L.

Primary Lymphosarcoma of the Liver with Metastases to the Marrow and Secondary Anemia. Arch. Path., 23:5, 674, May, 1937.

The author reports a case of primary periportal lymphosarcoma of the liver with extensive metastases to the bone marrow by way of infiltration through the walls of branches of the portal vein. The case seems to be the second one of primary lymphosarcoma of the liver on record. The first case was reported by Sternberg (1934) and was believed to have originated on the basis of aleukemic lymphadenosis (pseudoleukemia). The lymphoid tissue of the liver, which is sparse in amount, rarely becomes malignant.

In the reported case the tumor cells were small, round and compressed, and resembled lymphocytes. They penetrated the walls of large and small divisions of the portal vein in many places. The lumens of the vessels contained thrombi of tumor cells, which were evidently dislodged easily by the blood stream. The walls of the bile ducts were also invaded in places. The extensive invasion of the bone marrow led to much destruction of the original marrow cells, and this fact was the probable cause of a severe, intractable secondary anemia, which had been uninfluenced by any kind of therapy.

STEWART, H. L., CANTAROW, A. AND MORGAN, D. R.

Changes in the Liver of the Cat Following Ligation of Single Hepatic Ducts. Arch. Path., 23:5, 641, May, 1937.

The authors undertook the study to determine the comparative effects of obstructing single lobes of the liver of the cat with those of total obstruction. Seventeen cats were used in the experiments. One or more ducts leading from the left lobes were obstructed and the tissues were studied after periods of stasis from one day to five months. Their conclusions were that the changes in obstructed portions of the liver following ligation of single hepatic ducts are, with few exceptions, essentially similar to those which result from ligation of the common bile duct. The changes are, however, less marked and less rapidly progressive. The cirrhosis is monolobular; focal necrosis is less and appears later; the hepatic cells at the periphery of the lobules contain little or no stainable lipid although the interior cells may contain much; lobular atrophy progresses inward from the periphery; repair and re-

Advice for Patients Who Must
AVOID SWEETS

When you tell a patient to avoid sweets, this means also to avoid sugar-sweetened canned fruits. Cellu Canned Fruits are a good alternative for these diets, because Cellu Fruits are packed without added sugar. Food values are about half those of fresh fruit. Sixteen varieties to choose from. *They're delicious!* Write for sample.

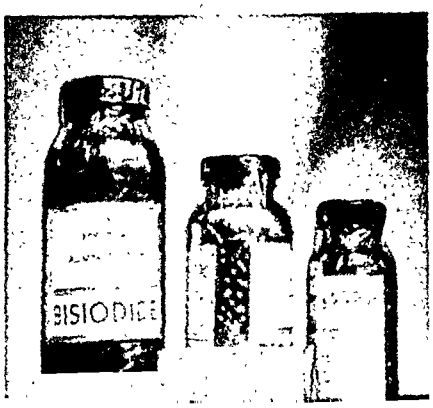
SCHLOSS, J., ETTINGER, A. AND PRATT, J. H.

Diagnosis of Diseases of the Stomach by Gastroscopic and X-ray Relief Studies. Abstracted from Am. Jour. Med. Sci., Feb., 1937.



During the last two decades morphologic evidence of the condition of the stomach wall has increased considerably the number of correct diagnoses as proved by biopsy and necropsy. The authors present studies on a hundred cases examined by X-ray relief method and gastroscopy. The essentials of both procedures are discussed at some length and it is stated that we may expect the X-ray examination is superior where localized lesions, if not too small, are present; whereas generalized pathological processes and very fine superficial changes are more the domain of the gastroscope. The lesions which X-ray examination fails to reveal can usually be visualized with the gastroscope, while those which can scarcely be seen by gastroscopy seldom cause difficulties for the roentgenologist.

In discussing gastritis the writers note that in the recent American literature, gastritis does not find as prominent a place as in the European and they have felt that the more general use of both X-ray relief technique and gastroscopy in Europe is responsible for this discrepancy. X-ray diagnosis of gastritis is usually based upon indirect signs such as hypersecretion, hyperperistalsis, broadening and increased rigidity of the rugae; it rarely succeeds in demonstration of the so-called "granulated relief." These "granula" are direct signs of hypertrophy and correspond to the "wart-like" swellings of the mucosa seen by gastroscopy, which method also shows direct signs of gastritis representing epithelial changes such as spongy velvet-like appearance of the surface, edema, circumscribed hyperemia, old and fresh hemorrhages and verrucous swellings. The enlarged fold is due to functional changes of the submucosa and muscularis mucosae rather than to true gastritic processes (Forsell, Henning). The most impressive X-ray sign is a frequent but not a constant finding in hypertrophic gastritis. Schindler subdivided the anatomic picture into three groups: Superficial, hypertrophic and atrophic gastritis. Actually features of the different groups of Schindler's classification are seen in the same case of chronic gastritis. Henning expresses this in the gastroscopic diagnosis. The authors feel that two types should be discussed separately: i.e., the gastritis with multiple erosions and the complete atrophy without demonstrable signs of chronic inflammation. They saw that pain and other symptoms disappeared as the erosions healed. The patient was kept on a strict diet until the erosions were gone. The symptoms do not always correspond with the gastritic changes found; they may be mild in one case and pronounced in another instance; the constitution, psyche and personality of the patient playing an important part in his subjective reaction to the disease. The authors feel that the X-ray of atrophy is more or less guesswork and tables are given to prove this. Generalized lesions of the stomach are more easily diagnosed with the gastroscope. Regarding gastric ulcer small lesions which the writers classify as erosions, are more accurately diagnosed by gastroscopy than by X-ray. They mention that Gutzeit found in 100 cases of gastric ulcer the diagnosis was possible in 45 cases by X-ray and in 75 by gastroscopy; agreeing with the writers' experience in a small number of cases.

As to the diagnosis of carcinoma of the stomach there

Bisiodide

IN THE ORAL TREATMENT OF SYPHILIS

Obtainable in the following sizes:

1000 CAPSULES

DEPENDABLE CHOLERESIS
free from undue purgings

Decholin increases bile secretion by the liver cells 100-200%; it is of proved value in the treatment of chronic cholecystitis, cholangitis, hepatitis, catarrhal jaundice, and functional hepatic insufficiency and intoxication. No undesirable cathartics are contained in the Decholin tablet, as in the case of so-termed cholagogues. Decholin acts directly on the pathologic process in the liver or biliary tract and not on the large bowel. Yet, chronic constipation, due to deficient bile flow, yields to its intense choleretic action.

was in the authors' series satisfactory agreement between X-ray examination and gastroscopy. Post-operative stomachs usually show severe gastritis changes. Among the conclusions drawn by the writers are these: The combined use of X-ray relief technique and gastroscopy is an additional help in diagnosis and in the investigation of unsolved problems in the pathology of the stomach. For the diagnosis of gastritis, gastroscopy is by far superior to X-ray relief technique. Erosions and atrophy of the stomach mucosa can be diagnosed for all practical purposes by gastroscopy alone. For the diagnosis of stomach tumors and post-operative changes, X-ray relief method and gastroscopy supplement one another in an almost ideal way.

Allen Jones, Buffalo.

HEERMANN, S. J. AND GINS, JOHN A.

Hyperinsulinism Associated with Calcified Tumor of the Pancreas. J. A. M. A., Vol. 108, No. 17, pp. 1402-1405, April 24, 1937.

Hyperinsulinism due to excessive doses of insulin was originally described by Banting and his associates in 1923. Since that time many cases of spontaneous hyperinsulinism have been reported. It is characterized by nervousness, tremor, hunger, anxiety, sweating, fatigue, emotional instability, incoordination of the finer movements, vasomotor phenomena, such as pallor, flushing, confusion, difficulty of articulation, syncope, collapse, and unconsciousness. Convulsions may occur. Gastro-intestinal symptoms simulating ulcer, irritable colon, cholecystitis, pancreatitis, appendicitis and many cases classified as gastric neuroses.

The author reports a case of a man who complained of weakness, chilliness, headache, vertigo, blurring of vision, and collapse. Dyspnoea on exertion developed later. He lost thirty-five pounds of weight over a period of three years. Emotional instability was noticed by his family. Physical examination was essentially negative. A glucose tolerance test was done and a diagnosis of hypoglycemia was made. An exploratory operation for a pancreatic tumor was done, and a hard, calcareous tumor was found in the head of the pancreas and removed. The patient recovered from the operation and the glucose tolerance test became normal with the disappearance of the previous symptoms.

Francis D. Murphy, Milwaukee.

HOLMAN, CRANSTON.

The Diagnosis of Gastric Carcinoma and Peptic Ulcer. J. A. M. A., Vol. 108, pp. 1383-1385, April 24, 1937.

The diagnosis of gastric cancer has been made easier by the improvement in X-ray technic, but nevertheless it still is a difficult problem. Because of this, the examination of the gastric contents has been carefully carried out on 152 cases. The method used is that suggested by Bloomfield and Polland. It is made after fasting twelve hours with histamine used as a stimulus in a dose of 0.1 mg. to each 10 kg. of body weight.

The fasting contents are withdrawn, the histamine is injected subcutaneously, and the stomach contents are continuously aspirated for thirty minutes, and the contents divided into three ten-minute specimens. The greatest ten-minute volume of secretion and the highest titratable acidity attained are considered the indexes of gastric function.

The conclusions drawn from the results in these 152 cases are that a low or anacidity is strong evidence of carcinoma; a normal or high acidity points to ulcer. This method of diagnosis was found to be more accurate than other methods.

Francis D. Murphy, Milwaukee.

IN TUNE *with* MODERN THERAPY

Artificial Fever in the Treatment of Ulcerative Colitis: A Preliminary Report*

By

L. KRAEER FERGUSON, M.D., FERDINAND FETTER, M.D.

and

TRUMAN G. SCHNABEL, M.D.

PHILADELPHIA, PENNSYLVANIA

THE frequent discouraging results obtained in the treatment of ulcerative colitis are well known to all those who have had patients suffering from this disease under their care. In a considerable experience in the treatment of this disease we have been unable to confirm the work of those authors who look upon ulcerative colitis as the result of an infection by a specific organism. In our therapeutic efforts, we have noted, as have others, that those procedures which were associated with the production of a fever gave the most beneficial results. Thus, in the use of vaccines or sera, a therapeutic effect was noted in proportion to the reaction which followed the injection of these foreign proteins. Likewise, blood transfusions which were followed by a post-transfusional reaction appeared to give more immediate results than those which were uncomplicated by a chill or a rise in temperature.

Because of these observations, we decided to try treating ulcerative colitis by artificial fever produced by the Kettering hypertherm.† The treatment was begun as an experimental procedure, and during the period of therapy no other treatment for the colitis was given except a smooth diet.

The air-conditioned cabinet known as the Kettering hypertherm uses the principle of radiant heat to elevate the patient's temperature, humidified hot air being circulated around the body. This apparatus has been described in the literature frequently (1), so that repetition here seems unnecessary. In treating patients with ulcerative colitis, we were using the non-specific effect of fever, i.e. its general effect on the body's defense mechanisms, rather than its specific killing effect on an organism, as in gonococcal infections. We felt, therefore, that relatively short fever sessions at relatively low temperatures would be as effective as long sessions at high temperature levels. Our usual method of treatment consisted of 2½ to 3 hours of fever between 104° F. and 105° F. (rectal), 3 times a week. The number of treatments varied between 7 and 17, the average being 12 per patient.

The early and continued improvement noted in all of the patients we have treated made a preliminary report of this method of therapy seem worth while in spite of the fact that we do not as yet have a large series of cases.

SUMMARY OF CASES TREATED

1. A. S., black female, 19 years. History of bloody diarrhea in fall of 1934 and spring of 1935. Admitted 11/12/35, complaining of loose watery bowel movements, as many as 20 daily, often containing blood.

11/15/35: proctoscopic examination showed the mucosa of the lower 20 centimeters of large bowel to be red and thick, dotted with small ulcers which bled on slight trauma. Culture of the ulcers showed Strep. viridans and B. coli. Feces were negative for parasites or ova. It was suggested that fever therapy be given.

11/29/35: first fever treatment.

12/3/35: patient much improved after 3 fever treatments, having about 8 movements per day. Proctoscopic examination showed mucous membrane to be still edematous, with bleeding on slight trauma.

12/18/35: condition much improved after 9 treatments; 4 to 8 partially formed movements daily. No blood.

12/20/35: proctoscopic examination showed marked improvement in the bowel. Ulcers now practically healed, except in a few areas. These show definite evidences of healing.

12/29/35: patient discharged from hospital; 3 to 4 movements daily.

Follow-up 4/13/36: 4 movements daily. No bleeding. Proctoscopic examination showed bowel normal in appearance, except for slight contraction of the lumen.

1/22/37: patient perfectly well and at work as a maid until present time, a year after treatment. Began to have 2 to 4 movements a day, occasionally with slight bleeding. Examination showed a granular mucosa, somewhat narrowed bowel lumen, no ulceration. Patient feels perfectly well. Was advised to have further fever therapy but refused because of economic conditions.

2. F. H., white male, 31 years. Admitted 7/22/36 with a history of bloody diarrhea 8 years before admission and complete relief until April, 1936, when he began to have frequent stools following the flood in Pennsylvania. Bowel movements 15 or more daily, liquid and containing blood; often containing clots and associated with left-sided abdominal pain and tenesmus.

7/24/36: proctoscopic examination showed lumen of bowel narrowed and mucosa thickened and dotted with small ulcers which bled easily on slight trauma. Culture: B. coli and Strep. fecalis.

7/22/36 to 9/4/36: patient had various types of medical treatment, during which time he had little or no improvement, with bowel movements ranging from 5 to 23 daily, average about 8 to 10.

9/5/36: first fever treatment.

9/14/36: patient's diarrhea had stopped and he was having 3 to 4 movements daily with no bleeding from the bowel.

9/18/36: after 6 treatments the mucous membrane still showed marked inflammatory reaction and bled easily on slight trauma. Mucopurulent exudate.

9/28/36: after 10 fever treatments, patient was having 2 formed bowel movements daily. Clinically almost well.

10/23/36: after 17 fever treatments, proctoscopic ex-

*From the Department of Fever Therapy and the Proctoscopic Clinic of the Philadelphia General Hospital, Philadelphia, Pa.

†These cabinets are being used at the Philadelphia General Hospital through the kindness and cooperation of Dr. Walter M. Simpson, Director of the Kettering Institute for Medical Research, Miami Valley Hospital, Dayton, Ohio

Submitted May 12, 1937.

amination showed somewhat granular mucosa. All the ulcers were healed. No blood or pus seen.

10/24/35: patient discharged, symptom-free. One to 2 bowel movements daily.

No follow-up.

3. M. A., white female, 24 years. Admitted 11/11/35, complaining of diarrhea; 5 to 10 movements daily. The stools seemed to be almost pure blood and bowel movements were associated with abdominal pain. In addition, marked weakness and dizziness, loss of 15 pounds of weight. Proctoscopic examination showed diffuse hyperemia with granular mucosa but no ulcerations. Bowel bled easily on slight trauma. Lumen of the bowel reduced. Culture showed B. coli, Strep. viridans, Strep. fecalis.

11/30/35: after 3 fever treatments, patient having two partially formed movements daily with no bleeding.

12/6/35: after 5 treatments, one formed movement daily. No symptoms. Proctoscopic examination showed the edema and hyperemia of the lower bowel and rectum to have practically disappeared. Patient was given 4 more fever treatments.

5/8/36: patient returned, three months pregnant. Bowel was normal in appearance, but she had slight bleeding from a few small internal hemorrhoids.

10/12/36: patient delivered. No bowel symptoms during pregnancy, except slight constipation relieved by mineral oil.

Follow-up 3/3/37: no further complaints.

4. P. N., white male, 36 years. Admitted 10/17/36, complaining of sudden appearance of diarrhea, one week's duration, with 20 to 30 liquid stools daily. Loss of 25-30 pounds in weight.

10/23/36: proctoscopic examination showed purulent exudate covering the mucosa of the rectum and lower bowel. Marked hyperemia of mucous membrane, with irregular superficial ulcerations which bled easily on slight trauma.

10/29/36: first fever treatment.

11/4/36 to 11/11/36: no fever treatments because of respiratory infection.

11/11/36: after 6 fever treatments, 8 to 9 formed movements daily. No mucus or blood.

11/27/36: proctoscopic examination still showed some edema and hyperemia of bowel. Ulcers healed. Seven fever treatments given. Patient refused further therapy.

12/11/36: 3 to 4 movments daily. Gained 20 pounds in past two weeks.

12/17/36, symptom-free. 3 to 4 movements. Proctoscopic examination showed slight contraction of bowel, otherwise bowel appeared normal. Patient has been observed frequently; last time 3/5/37. Local examination shows no lesions. Patient is having no symptoms.

5. A. A., white female, 27 years. Admitted 6/25/36 with history of colitis for 6 years, with remission during two pregnancies. The colitis appeared in attacks lasting two to three months at a time. Bowel movements numbered 8 to 10 daily, with blood and mucus. Proctoscopic examinations showed a diffuse acute inflammatory reaction of the rectum and lower colon, with marked edema and hyperemia and bleeding on the slightest trauma. Cultures were taken which showed the Bargen organism. Patient was treated with transfusions and intensive calcium gluconate therapy by mouth and generalized ultra-violet irradiation. Vaccines of Bargen's organisms were given from August to October, 1936. During this time patient improved somewhat; then she developed a cold. Bowel movements increased in number to 8 to 10 daily. Proctoscopic examination showed a diffuse hyperemia of the mucous membrane of the rectum; bowel contracted; haustral folds obliterated. Mucous membrane granular in appearance and bled easily on slight trauma. There were no frank ulcerations.

1/29/37: first fever therapy.

2/12/37: after six treatments, patient was having 1 to 3 movements daily with no bleeding. Proctoscopic examination still showed a diffuse granular appearance of the mucous membrane with bleeding on slight trauma. The lumen was much contracted.

2/23/37: after 11 fever treatments, 1 to 2 movements daily. No symptoms. Proctoscopic examination showed very marked improvement of bowel. The intensely red granular appearance of the bowel noted at last examination was changed to a more normal pink color. Still some residual narrowing of the lumen.

3/8/37: patient discharged symptom-free. Bowel practically normal in appearance.

Comment: All of these cases appeared to give the typical clinical and proctoscopic findings of idiopathic ulcerative colitis, and each one has responded very favorably to fever therapy. The clinical improvement has preceded the improvement in the proctoscopic appearance. In most cases, after 3 to 4 fever treatments in 7-10 days, the number of stools was markedly reduced and bleeding and tenesmus were less. The patients' appetites improved and their weights began to increase. In spite of the clinical improvement, we have continued the fever treatments until the proctoscopic appearance has also improved, except in one patient, case number 4, who refused to have more than 7 fever treatments. In this patient, the appearance of the bowel on proctoscopic examination continued to improve, in spite of the fact that his fever treatments were not continued. This has raised the question in our minds as to whether the fever treatments may be discontinued as soon as clinical improvement is well established, with the expectation that the bowel will continue to improve until it reaches or approaches the normal. In later cases it is our intention to stop the fever treatment when clinical improvement is well established.

The use of artificial fever in the treatment of ulcerative colitis is not regarded as a treatment which will produce a permanent cure, but it has been the method which has produced the most rapid clinical improvement in our hands. This short preliminary report is made in the hope that others may try this type of therapy.

We wish to express our appreciation to Dr. R. S. Boles, Dr. F. J. Kalteyer, Dr. S. A. Loewenberg, and Dr. David Rieman for their permission to include these patients in this report. We also wish to express our appreciation to the nurse-technicians, Miss Eileen McCarthy, Miss Isabelle Michler and Miss Edna Mae McTague, who gave the fever treatments under our direction.

Studies in Intermittent Heat Sweats
The Chlorides and the Acid-Base Balance

By

LEO L. HARDT, M.D.*

and

ALICE PALMER, B.S.†

CHICAGO, ILLINOIS

THE loss of hydrochloric acid through vomiting has long been recognized as a means of producing alkalosis. McCollum (1) and his co-workers, in 1920, were able to produce gastric tetany and alkalosis in dogs by mechanical obstruction of the pylorus. They were able to prolong the lives of these animals by administering sodium chloride. Later, Maizels (2) and Tucker (3) demonstrated similar states of alkalosis in patients suffering from functional or organic obstruction of the stomach resulting in excessive loss of chlorides from vomiting.

Simpson et al. (4) in their work on the ultra high frequency pyretotherapy of neurosyphilis, found that the patients lost from two to five liters of sweat during the five hour febrile period. The plasma chlorides were found to have declined an average of 40 mg. per cent in 80 per cent of the patients at the end of the febrile period. In five instances the fall exceeded 100 mg. The average sodium chloride content of the sweat was 650 mg. per cent, 20 to 26 grams of sodium chloride being lost during the five hour period. The hydrochloric acid disappeared from the stomach within thirty to ninety minutes.

One of the patients developed typical hypochloremic tetany while others experienced nausea, vomiting, fatigue, abdominal cramps and muscular twitching. These symptoms were largely abolished by the ingestion of four to six liters of .6 per cent sodium chloride solution.

Beck and Dill (5) in 1932, and Schofield (6) in 1933, during the work on Boulder Dam, found that physical activity at high temperatures produced great loss of chlorides and water. Bischoff et al. (7, 8, 9) concluded from their experiments that an alkalosis was produced by diathermy, short radio waves, or external heat. The pH of the plasma was elevated above the normal reading for the quinhydrone electrode and the alkaline reserve increased. Hopkins (10) also observed a rise in the plasma pH with temperatures of 105° over a thirty to forty-five minute period, but an average decrease in the carbon dioxide combining power.

These states of alkalosis may be explained in part by the loss of carbon dioxide through hyperventilation and of lactic acid in the sweat, the regulatory mechanisms of the body apparently being unable to compensate for such rapid losses. Hopkins (10) accounts for the diminished carbon dioxide combining power in her subjects by a shift of the bicarbonate ions from the blood into the tissues and urine, and an increased stability of acid oxyhemoglobin as the carbon dioxide tension of the plasma fell.

The following experiments were designed to study the effect of a series of short sweat periods upon the chlorides and the acid-base balance, allowing a rest period between each sweat for the body to adjust itself to the losses encountered. Such repeated sweats compare in a measure with the intermittent sweating engaged in normally during hot summer days, and to the periodic sweating present in certain fibrile diseases.

EXPERIMENTAL PROCEDURE

The experiments were conducted during the cold months of the year when normal sweating is at a minimum. Fourteen normal adult subjects, 18 to 37 years of age, were given four 20 minute sweat periods in a hot dry room in which the temperature varied from 140° F. to 160° F. One-half to one hour of rest was allowed between each period. The skin of each subject was prepared before each sweat period by thorough cleansing with soap and water, alcohol, and ether, and the sweat collected from the chest and back by gently scraping the skin from below upward with the open mouth of a large test tube. The subjects were carefully cautioned to limit the sweat sample to the eccrine type and to avoid as far as possible contamination with the apocrine type of sweat. About 75 c.c. of sweat was collected for analysis from each subject during each of the four periods. These sweat samples nearly filled the vessels, which were tightly stoppered and the sweat analyzed within a short time (two to three hours). The temperature, pulse rate, blood pressure and weight of each subject were recorded before and after each period. Samples of venous blood for the determination of the CO_2 combining power and chloride content were taken before and after the completion of the tests.

Fluids were given in all but two subjects, in the form of a mixture of orange juice, lemon juice, and water, the chloride content of which was 8 mg. 100 c.c. Beer was substituted for the fruit juice in two instances containing 3.1 mg. of chloride per 100 c.c. The total amount of fluid allowed each subject was 1000-1500 c.c. and no fluid was given after the second sweat period.

All urine passed during the entire period of observation was collected, a specimen being obtained for analysis at the end of each period. No stools were passed and the respiratory losses were not determined. The approximate sweat loss was calculated from the

*Associate Professor of Medicine, Loyola University Medical School.

Submitted May 12, 1937.

equation: *sweat loss* equals *weight loss* minus *urine loss* plus *fluid intake*.

RESULTS

1. The majority of the group complained of a headache, a feeling of oppression, and exhaustion, but only one member was overcome, lost consciousness for a minute and discontinued the tests. This occurred during the fourth period. A few subjects were nauseated, one member vomiting a pint of fluid after the experiments were over. He suffered from a severe throbbing headache throughout the tests.

2. The blood pressure readings fell into four groups. In five subjects the systolic pressure tended to rise throughout the four periods, the average elevation being 10 mm. of Hg. In two subjects the same level was maintained, while in five subjects it tended to fall: the total drop averaging 11 mm. of Hg. In the two remaining instances it rose during the first two periods and fell during the last two.

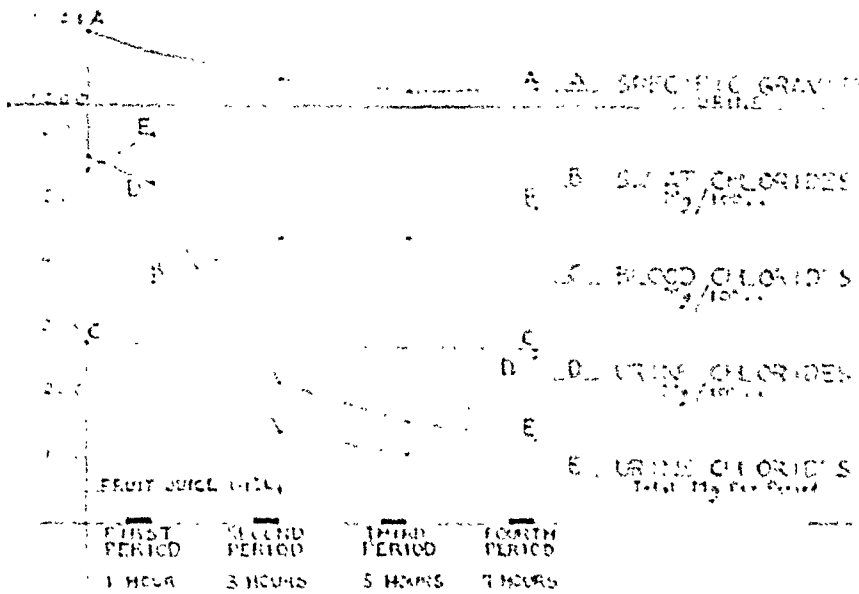
The variations in diastolic pressures corresponded in general to the systolic except in subjects G and D; in whom the initial readings were low and beer had been substituted for the fruit juice mixture. In these subjects the diastolic pressure was indeterminate during the first two periods, but returned to normal levels in the fourth period.

3. The pulse rates increased in all subjects, the average rise being 24 beats per minute. The temperature readings (oral) were elevated from .2° to 3.2° F., with an average increase of 1.5° F. The maximal changes in temperature occurred in the earlier periods.

4. The chloride concentration of the sweat (Table I) increased in the later periods in all subjects except one, the average chloride loss for the four periods being 7222 mg. The urine chlorides, (Table I) however, became progressively less with each period, although the concentration in the specimens after the fourth period was usually increased over the preceding one. The average urine chloride loss was 1,062 mg. The total chloride loss from each subject averaged 8284 mg., the chloride intake ranging from 31 mg. to 120 mg., the average net chloride loss being 8184 mg. The blood chlorides (Table II) were decreased an average of 12 mg. per cent. In nine subjects they were decreased, remained constant in three, and were elevated in two.

5. The CO_2 combining power of the blood (Table II) increased in seven subjects, remained constant in one, and was depressed in five, the average for the group being a rise of 1.4 Vol. per cent.

6. The pH of the sweat varied from 4.8 to 8.6, the average of the initial specimens being 6.42 and the final specimens 6.67. In twelve of the fourteen subjects the pH tended to increase with successive sweatings, while in only two instances was the final pH less than the first.



The pH of the urine varied from 4.4 to 6.7, the group average being elevated in the second and third periods and dropping below the original level in the final period. The average of the initial specimens was 5.47 and the final group 5.2.

7. No sugar or albumin appeared in the urine tests. The specific gravity fell during the second and third periods from an initial 1.020-1.030 to 1.001-1.006. In two subjects the fourth period reading was 1.020, but the remainder of the group maintained the low levels.

8. The net fluid loss ranged from 680 c.c. to 1,400 c.c.

Chart 1

The effect of sweat periods on the chlorides

DISCUSSION

Under the conditions of our experiments large quantities of chlorides were excreted in the sweat, the concentration of the sweat chlorides in general increasing with each period, while both the chloride concentration and total chloride content in the urine

tended to decrease with each period (Chart 1). This low chloride content of the urine was associated with a low specific gravity. It is difficult to explain the rising chloride concentration in the sweat and corresponding fall in the urine, inasmuch as the average blood chloride concentration was decreased only 12 mg./100 c.c. and in two instances was increased (Chart 1).

Simpson (11) observed a 40 mg. per cent decrease in the plasma chlorides in 80 per cent of a group following a five hour continuous febrile period, which suggests that the rest periods in our series made possible a mobilization of the chlorides from the tissues. The ingestion of 1,000 to 1,500 c.c. of a fruit juice not an infallible indication as to the presence of alkalosis but only indicates the alkali reserve of the blood. The variability of the plasma alkaline reserve must depend in part on mobilization of alkali from the tissues, which varies with the individual's tissue reserve. It is significant that Hopkins' fever periods were much shorter than those of Bischoff.

In twelve of the fourteen subjects the pH of the sweat tended to increase with each successive period, suggesting a compensatory mechanism to combat the tendency toward alkalosis present in heat sweat experiments.

The symptoms of headache, vertigo, nausea, vomiting and exhaustion which arose during our experi-

mixture, or beer, replaced but a small portion of the chloride loss resulting in an average net loss of 8184 mg. Results indicate that such fluids wash the tissue salts out in the sweat, the depletion rising rapidly with any increase in sweat loss, the kidneys tending to conserve the diminishing chlorides of the body.

The carbon dioxide combining power of the blood became elevated in but seven of the thirteen subjects, the average for the entire group constituting a rise of 1.4 volumes per cent. Bischoff et al, (7, 8, 9) concluded in their hyperpyrexia experiments that the alkali reserve was increased, while Hopkins (10) reported an average decrease in the carbon dioxide combining power. Since both reported plasma pHs above normal limits, it would appear that the CO_2 C.P. is

ments in some of the subjects, closely parallel those observed by Hench, Slocum and Popp (12) in their prolonged hyperpyrexia experiments, and by Hardt and Rivers (13) in their cases of alkalosis following the excessive administration of alkalies. In our group, however, the temperature and blood pressure range was small, and evidence of only mild alkalosis was present. These symptoms in our series may have resulted from the marked depletion of chlorides from the tissues. Simpson et al (4), in the pyretotherapy of neurosyphilis, found these symptoms abolished by the administration of .6 per cent sodium chloride.

In diseases with intermittent febrile periods and sweats such as tuberculosis and malaria, and in the normal intermittent sweating on hot summer days,

an opportunity is present for the blood to replenish itself at the expense of the tissues, and blood chemistry studies will not reveal the extent of the depletion of tissue chlorides. Such depletion may play an important role in lowering the resistance of the individual.

CONCLUSIONS

1. Excessive sweating results in a marked loss of chlorides from the tissues.

2. During repeated heat sweats the chloride concentration of the sweat increases while that of the urine decreases.

3. The pH of heat sweat tends to increase with succeeding periods of sweating.

4. In intermittent heat sweats the tissue chloride depletion is much greater than the blood chloride content would indicate.

The authors wish to express their appreciation to Dr. A. J. Carlson of the Department of Physiology, University of Chicago, for his help and suggestions in this work.

Food Habits of the Patient with Peptic Ulcer

By

MARGARET ELDER*

and

EDWARD S. EMERY, Jr., M.D.†

BOSTON, MASSACHUSETTS

FROM time to time articles appear in the literature which suggest that peptic ulcer may originate from faulty diets. Various writers have suggested that inadequate amounts of vitamins may be responsible for this disease (1) of which, vitamins A and B have been particularly stressed. There is also a sufficient amount of other evidence to make one consider some form of deficiency as a cause of this disease. Aron, Weiss and Holtzmann (2) reported that injections of histidine would prevent the development of ulcer in dogs, upon which they had performed an operation similar to that introduced by Mann and Williamson, although recently, Sandweiss (3) has been unable to confirm this work. The successful production of experimental ulcers in dogs has followed operations which have sidetracked or depleted the animal of its important digestive juices, such as the pancreatic, biliary, and duodenal secretions (4). The obvious explanation for the development of ulcers following these procedures has been an inadequate neutralization of the gastric juices; yet, it nevertheless follows that such procedures must disturb the animal's digestion and may produce some kind of deficiency. In a recent paper, Ivy (5) has reported a series of animals fed on a diet which included raw pancreas who did not develop ulcer following a Mann-Williamson operation.

The justification of considering that ulcer may result from a deficiency appears warranted, if one compares its behavior with pernicious anemia which is now known to be caused by a deficiency. Both are chronic diseases characterized by remissions and exacerbations. It is accepted that pernicious anemia occurs in certain constitutional types, and Draper and others (6) have stressed the importance of constitution in the etiology of peptic ulcer. Therefore, it seemed worth while to study a group of patients with peptic ulcer with the purpose of determining whether they showed an inadequate dietary, either in a general way, or for specific foods.

METHOD OF STUDY

Food histories have been taken on 25 patients suffering from either a gastric or duodenal ulcer and on 25 controls. A chart was made out in which the various types of foods were grouped under the heading of meat, fish, eggs, milk, butter, fruit, vegetables, cereals, bread, relishes and deserts. Places were left for checking any food eaten and whether it was taken once a day, once a week, once a month, or less often. The last place enabled the patient to write in how much of each food was taken at one serving. In the beginning these outlines were given to the patients to fill in, but it was found impossible to get satisfactory reports from even the most intelligent patients, if they were allowed to fill in the questionnaire themselves. Therefore, each patient was questioned by one of us (M. E.), who then filled in the answers as the questioning proceeded. By this means we were able to obtain what we believe was sufficiently accurate data on the individual's diet. Similar studies were made on 25 other individuals serving as a control, about half of which were taken from patients on the surgical wards and in whom there was no reason to suspect dietary disturbances. The remainder was made up from friends living outside the hospital.

After the data had been accumulated, it was decided to express all the food factors in terms of the amount taken per day. This is the method usually employed in referring to protein, carbohydrate and fat, and it seemed best to express all the other dietetic factors in the same way. In order to obtain an idea of the relative intake of vitamins, these have been reduced to a unit value. The method which we used for doing this has the advantage of being easy and was satisfactory because we were interested only in determining the relative amount of these substances which were taken by the different groups. The vitamin content of a given food is expressed in most food

TABLE I

Showing the dietetic factors present in two "Normal" diets, and the amounts of these factors actually ingested by 25 patients with peptic ulcer and 25 controls

*See text for calculation of vitamins.

tables by plus marks, varying from one to four. If an arbitrarily chosen weight of food is considered to contain that number of plus signs given in a food table, a relative unit of intake may be reached. We used 25 grams as an arbitrary measure of the food. If a patient ate 25 grams of butter, he was considered to have ingested 3 plus

*Dietitian, Mary Hitchcock Hospital. Formerly Assistant Dietitian, Peter Bent Brigham Hospital.

†Associate in Medicine, Peter Bent Brigham Hospital.

Submitted May 22, 1937.

vitamin A and one plus vitamin D. If he ate 100 grams of butter he would have ingested four times the amount, or 12 plus vitamin A and 4 plus vitamin D. By this method it is possible to calculate the relative intake of vitamins for one day and thus obtain a comparative figure for all patients.

Because the taking of a food history may involve a personal equation so far as the attitude of the history-taker is concerned, it seemed best to have some check on the accuracy of our histories. As a control we calculated the amount of food ingested on theoretically normal diets. For this purpose two diets were studied. One was made up by one of us (M. E.), the other was taken from a leaflet made up by a group of dietitians under the direction of Miss Frances Sterne. The results from both so-called normal diets were calculated before the results from our food histories were obtained. As will be seen from a study of the tables, the diet of Miss Sterne provided an appreciably greater intake of food than the one made up by us. Perhaps the difference can be explained by the fact that Miss Sterne's diet is supposed to represent an ideal diet; whereas, ours is an expression of what we believe the average normal patients eat.

TABLE II

Shows how 25 patients with ulcer and 25 controls distributed their intake. The figures express the number of servings per week which these individuals averaged

Foods	Ulcer Patients	Controls
Meat	7.32	8.21
Fish	2.2	1.44
Fats	4.4	4.48
Milk	2.53	2.67
Butter	24.2	22.28
Eggs	3.24	3.32
Oysters	2.68	4.04
Vegetables	10.46	12.04
Refined Cereal	9.32	7.37
Coarse Cereal	2.4	3.56
Dark Bread	13.13	13.52
White Bread	2.8	3.15
Relish	2.3	2.3
Dessert	2.3	2.2

RESULTS AND DISCUSSION

Table I shows the relative amount of various food factors which would be taken if a patient had eaten the two theoretical diets, and the amount eaten by our group of normal patients and those with an ulcer. If one compares the diet taken by the normal and the patients with ulcer, it is apparent that there is not much difference between them. On the whole the ulcer patients consumed a greater amount of all the substances than the normals, which is most easily shown by the fact that the ulcer patients on the average, ingested 2421.28 calories, whereas, the normals took 2019.68 calories. The ulcer patients averaged 99 grams of protein daily, which is certainly an adequate amount. The ulcer patients also tended to take an adequate intake of fat, which averaged 118 grams per day in this series. The intake of minerals as represented by calcium, phosphates and iron was also somewhat higher among those with ulcer than among the normals. Vitamin C was the only factor which was consumed in smaller amounts by the ulcer patients than the normals, namely, 67 units per day, as opposed to 87 units. However, there is no reason to feel that this represented an inadequate amount of this vitamin. A comparison of the dietaries determined by our food with the theoretical diets shows no evidence for a deficient intake. Although there were slight differences in the amount of vitamins taken, these were not such as to appear significant.

Table II shows the relative amounts of different types of food taken by the normal persons and those with an ulcer. Again, the differences seem to be of a minor order and do not have any apparent significance. A study of the individual items of food taken by the two groups showed that the patients with ulcer had as varied a choice of foods as the normal individuals.

SUMMARY

From this study, therefore, there seems to be no evidence that patients with an ulcer take an abnormal diet as concerns the total amount of the various food factors with which we are now familiar, nor do they take an unbalanced diet in the sense of eating certain articles of food to the exclusion of others.

It seems reasonable to deduce, therefore, that if peptic ulcer is the result of some form of deficiency, that deficiency occurs not from faulty food habits but from the lack of some intrinsic factor.

The Treatment of Peptic Ulcer by the Diet of Goldberger and Wheeler*

By

HARRY A. WARREN, M.D., DALE G. FRIEND, M.D.

and

EDWARD S. EMERY, Jr., M.D.

BOSTON, MASSACHUSETTS

SINCE the studies of Pavlov, clinicians have attempted to influence the gastric acidity of patients with peptic ulcer by dietetic measures, but diets high in fat and low in proteins or carbohydrates do not decrease the acidity sufficiently to be of practical value. It is known now that food may also affect the acidity by its content of vitamins. If it should prove to be possible to control the acidity by regulating the intake of vitamins without producing undesirable effects, a useful addition to the therapeusis of peptic ulcer would be attained.

The best approach to this problem seemed to be by means of the diet which Goldberger and Wheeler used to produce pellagra. It is now generally accepted that pellagra is the result of a deficiency, and in 1915 Goldberger and Wheeler were able to produce experimental pellagra by giving volunteers a diet which contained only those foods on which patients had been observed to develop the disease. The diet was low in animal protein, and consisted chiefly of white wheat flour, cornmeal, hominy grits, cornstarch, white rice, granulated cane sugar, cane syrup, sweet potatoes, pork fat, cabbage, collards, turnips, turnip greens, and coffee. With this diet, 6 of the 11 volunteers developed pellagra within 194 days. The average protein content varied between 41 and 54 grams; the fat between 91 and 134 grams; and the carbohydrate between 387 and 513 grams.

Since their original work, Goldberger and Wheeler and their associates have tested a number of other foods for the pellagra preventive factor by experiments on dogs. From these studies they have discovered that several of the foods used in their original diet were relatively good sources of the pellagra preventive factor, and using this work as a basis, they have since made up a diet which is more efficient in the production of this disease.

It seemed to us, for several reasons, that this diet might be useful for treating patients with ulcer. Goldberger found that by a judicious use of the diet he was able to keep his dogs at any stage of the disease that he wished. Thus, he could maintain them in a condition bordering on pellagra without, at the same time, actually producing the disease. It is known that quite a number of patients with pellagra have an achlorhydria. Although the relationship of the disease and the achlorhydria is not yet clear, it is possible that a diet which will produce pellagra may also lower or abolish the gastric acidity. If the gastric acidity could also be controlled in the same way that these investigators controlled the pellagra, the physician would command a useful procedure. Therefore, we determined to try a group of volunteers suffering with peptic ulcer on the diet of Goldberger.

Since we started this investigation, Alvarez, Pilcher, Foley, Mayer, and Osterberg have reported the results of a study with a similar object in view. They attempted to control the production of hydrochloric acid by a diet low in vitamin B_1. They obtained no definite change either in the gastric acidity or the pepsin concentration and concluded that a diet deficient in vitamin B_1 by itself was not likely to produce much reduction in gastric acidity. Because the diet of Goldberger is not deficient in vitamin B_1 and is different from that of Alvarez and his associates, we continued our work.

METHOD OF STUDY

This study was carried out in the Gastro-Intestinal Clinic of the Out-Door Department of the Peter Bent Brigham Hospital. We chose only those patients who were intelligent enough to understand the object of our investigation, and only after we had explained fully the nature of our study, and that it was purely experimental.

Five patients volunteered to take the diet. Each patient was given a typewritten copy which had been made up by the dietitian, and on which the various foods were grouped according to the amount of pellagra preventive factor, as determined by Goldberger. They were allowed prunes, oatmeal with sugar and salt, baking powder biscuits, butter, black coffee, fat salt pork, Irish or sweet potatoes, floured gravy, beets, navy beans, American cheese, coffee, jello, carrots, boiled rice, evaporated apples, cornmeal mush, and cornmeal muffins made out of white cornmeal. The patients reported once a week, at which time their weight was taken and the hemoglobin and red blood cell count was determined. Gastric analyses were made every two or three weeks, and a test meal of 60 c.c. of 8 per cent ethyl alcohol was used, the specimens being titrated in the usual way with Topher's reagent and phenophthalein.

Goldberger found it difficult to get prisoners to follow the diet even with the promise of a pardon in return for their cooperation. In spite of this fact, we were able to obtain data which seems to us worthy of consideration.

PRESENTATION OF DATA

Because of the variation in the way the patients followed the diet, the divergence of results, and the small number of cases which were studied, it seems that the data can be presented best by a summary of each case.

Patient R. H. ODD. 184,170 was a 30-year old white male with a history of periodic attacks of symptoms of ulcer for four years. Roentgenologic examination showed an irregular duodenal cap with bilateral notching, and a demonstrable crater. There was definite tenderness over the ulcer. He was placed on a Sippy diet with relief from symptoms. After two weeks of the Sippy diet he was

*From The Medical Clinic of the Peter Bent Brigham Hospital.
Submitted May 22, 1937.

given the experimental diet with alkaline powders every two hours during the day. He was maintained on this diet for 63 days. The first six weeks he lost three pounds, but he did not complain of weakness, and continued with his work on an ice truck. He had no symptoms of epigastric distress during the experimental period. There was no significant change in the blood. The first gastric analysis done one week after going on the diet showed a fasting free acidity of 114, and a total acidity of 127. After the alcohol test meal, the free acidity was 55 with a total acidity of 68. After nine weeks on the diet there was no decrease in acidity. Then the patient refused to continue the diet because of his distaste for the food. Except for one or two occasions when the patient admitted eating meat, he followed the diet satisfactorily, so far as we know. He was free of symptoms during the whole experimental period.

Patient P. B. ODD. 182,110 was a 42-year old white male with a history of ulcer symptoms of 12 to 15 years' duration. Eleven years previously he had an operation for a perforated duodenal ulcer, and since that time he had suffered from frequent attacks of ulcer distress. Roentgenologic examination revealed a constant deformity in the duodenal cap, a bilateral notching, and a definite crater. For several months previous to this study, the patient had been taking frequent doses of milk and powders without relief of his symptoms. He was started on the experimental diet and was followed for 125 days. During the first twelve weeks he lost four pounds but varied very little thereafter. A red count at the beginning of the study was 4,200,000. Nine weeks later it was 5,200,000. He used 6 to 8 alkaline powders a day throughout the experimental period. The first gastric analysis showed a fasting free acidity of 16 and a total acidity of 32. Following the test meal the free acidity was from 11-52 and the total acidity 50-64. During the first two weeks of the diet he continued to have considerable epigastric distress both during the day and night. During the third week, however, he began to feel much better, and continued to be comfortable until he had a recurrence of the ulcer distress twelve weeks later. The gastric analysis done after three weeks and nine weeks showed no significant variation from the original test. After ten weeks on the diet the roentgenologic examination showed the irregularity of the duodenal cap, but no crater could be visualized. The diet was then increased to allow one serving daily of string beans, lettuce or turnips, food graded as "slight" in the pellagra preventive value. After twelve weeks on the diet the gastric analysis showed no significant reduction. In spite of this fact the patient was more comfortable than at any time in the previous six months. Foods somewhat higher in their pellagra preventive value were gradually added. He returned two weeks later complaining of nocturnal distress. Because he was not desirous of going back to the original diet, he was given skimmed milk to be taken at hourly intervals during the day with alkaline powders at intervals of a half hour. One week later he felt better, but a week after this complained of much epigastric distress. He was then given a Sippy diet in place of the experimental one. At no time did this patient develop symptoms or physical signs of pellagra. We believe that he followed the regime faithfully. He was symptom-free for some period of time after following the diet. We cannot give any reason for this relief.

Patient N. B. ODD. 185,117 was a 38-year old white male with a history of epigastric distress for four and a half months previous to the time we saw the patient. Six weeks before our seeing him his duodenal ulcer perforated and was closed. At the time he came under our observation he was having no distress, and a roentgenologic examination showed a small, contracted, irregular duodenal cap with no demonstrable crater. Gastric analysis showed no free acidity in the fasting specimen and a total acidity of only 7. After taking a test meal the free acidity was 51 and the total acidity 58. He was maintained on the experimental diet for 56 days. During that time he lost no weight and did not complain of epigastric distress. The gastric analysis after five weeks on the diet showed essentially the same findings as before. As he had no distress before starting the diet and none while taking it, it was impossible to make him follow a strict regime.

In contrast to these three patients who followed the diet with moderate comfort, there were two others who were unable to continue because of a recurrence of epigastric distress.

Patient J. V. ODD. 181,643 was a 46-year old Italian laborer who had had intermittent abdominal distress for three years. Roentgenologic examination showed thickened gastric rugae and an irregular duodenal cap. Gastric analyses showed a persistently high acidity, the amount of free acid always above 65 and the total acid above 70. Previously he had been following a Sippy diet with relief. He was placed on the experimental diet but suffered a return of pain and went back to the Sippy diet after two days.

Patient C. E. ODD. 172,619 was a 32-year old Italian housewife who had been followed in the Gastro-Intestinal Clinic for two years. Roentgenologic examination showed an irregular asymmetric duodenal cap and a definite crater. In March, 1926, she had a return of her symptoms and was placed on a Sippy diet. One month later she was quite comfortable, although she still had the nocturnal distress. She was placed on the experimental diet, and one week later complained of a return of severe epigastric distress. Skimmed milk was added to the diet at hourly intervals. Although this gave some relief, she was unwilling to continue the experimental diet and was allowed to go back on the Sippy regime. Both of these patients were nervous Italians and objected particularly to the diet, quite aside from the question of discomfort.

DISCUSSION

A review of the data reveals that no positive results were obtained by putting the patients on the experimental diet. In no case was there a lowering of the gastric acidity, a change in the blood, or a development of any evidence of pellagra. Perhaps the patients did not follow the diet closely enough or for a long enough time. Whatever the reason, it seems evident that it is impractical to treat patients with peptic ulcer by this diet. We believe that some of the patients followed it as closely as any person would do, unless some great inducement such as a cure could be offered. One patient was maintained on the diet as long as 125 days without any positive results. It is possible that a longer period of observation might have produced changes, but we did not wish to carry them to the point of developing pellagra. Goldberger and

Wheeler kept their eleven volunteers on a similar diet for 194 days. Six of these developed definite signs of pellagra, but did not do so until after 160 days of the diet. We considered that 125 days was a sufficiently long period to test out the practical application of the diet and still not run the chance of producing pellagra. We were interested in the relative degree of comfort which some of the patients enjoyed while on the diet. However, no conclusions can be drawn from this fact because it is well known that patients suffering from a chronic disease may develop temporary relief after starting a new regime.

CONCLUSION

Five patients with a duodenal ulcer were placed on a diet low in the pellagra preventive substance, with the object of trying to reduce the gastric acidity. Two of these followed the diet for a period of several days. Two followed it for an average of 59 days, and one as long as 125 days. None of the patients developed any change in their gastric analysis or blood findings. Two of the patients had temporary relief which we could not associate with the diet. Although it seems possible that such a diet might be used to reduce the gastric acidity, if a study could be carried out under more carefully controlled conditions, it appears impractical to use such a diet for the treatment of patients with peptic ulcer.

Dental Caries and Paradental Disturbances*

III. The Dietary History and Its Value in Dental and Medical Practice*

By

NINA SIMMONDS, Sc.D.†
SAN FRANCISCO, CALIFORNIA

IN the course of studies being carried out in the College of Dentistry at the University of California on the relation of diet to dental problems an endeavor has been made to secure as accurate a dietary history as is possible from the patient, or from the patient's mother in case of a child. Since few of us recall many details regarding our food habits before the age of 15 years or so, whenever possible, even in the case of adults, we have interviewed the patient's mother (personally or by correspondence) regarding these early years.

We were fully aware, before we attempted to take dietary histories of patients, that the experience of most persons, who have endeavored to learn what a person's food habits have been by questioning the individual, has been rather disappointing. But we were very anxious to secure such data so have attempted to work out a technique which gives a by and large estimate of an individual's nutritional background. As a result of this experience it is believed that in most instances it is possible to secure a fairly accurate (in a relative sense, of course) estimate of the present and past nutritional record of an individual, provided sufficient time, and a moderate amount of tact and diplomacy are used.

However, it is not intended to give the impression that the degree of accuracy of interpretation of results, such as one expects in animal research, is possible. But the data have shown that it is possible to say in most instances whether or not unsatisfactory nutrition may be a factor in the etiology of the disorder, which has brought the patient to our attention. Furthermore, it is possible to evaluate the various dietary factors (in a general way) which in turn gives a rather clear picture as to which dietary essentials have been present in smallest amounts. Paper IV of this series will discuss the problem of the evaluation of the dietary history.

The fundamentals of an adequate diet and the foods supplying them have been known for several years. But a detailed dietary study of approximately 450 persons suffering from various dental and medical disorders has shown that very few of these persons are taking a satisfactory diet. In most instances studied the reason was not a financial one. The reason appeared to be a lack of an understanding that one of the prerequisites for optimum health is that the diet should contain liberal amounts of all dietary factors. It is fully recognized that a diet may contain adequate (liberal) amounts of all dietary essentials but, due to the body's failure to assimilate them, malnutrition or even deficiency diseases may result. It cannot be stressed too often that the mere fact that an individual is not suffering from one of the deficiency diseases is no indication that his (or her) diet is optimum from a nutrition standpoint. Although we fully appreciate that (1) poor mouth hygiene, (2) endocrine disturbances, (3) hereditary factors, (4) developmental defects, (5) general health and (6) lack of professional care, often complicate dental problems, we question whether the newer knowledge of nutrition is as yet being applied by the majority of persons; we do not believe that optimum nutrition on a large scale over a period of years (except among

*Research conducted under grants made by the University of California, College of Dentistry; California State Dental Association; California Academy of Periodontology; Board of Research, University of California; and Good Teeth Council for Children, Inc.
†From University of California, College of Dentistry.
Submitted May 22, 1937.

certain primitive peoples) has been given a chance to show what it can do in the prevention of dental disorders. However, it appears that there are certain dental problems which are primarily inheritance problems over which nutrition has little or no control. An example in point: certain enamel problems. That all persons are not capable of the same degree of health (which in turn also refers to dental health) is undoubtedly true; in other words, inheritance may and in many instances does set a limit to what a person is capable of from a health standpoint. Economics may or may not complicate one's health problem.

In the light of the experience in taking about 450 dietary histories, a series of questions has been formulated which forms part of this paper. No one is more cognizant than the author of the fact that the usual answers to questionnaires are frequently not of great value, but it is not intended that this set of questions be given to a patient. They are for the guidance of the dentist, the dietitian, the physician, or other persons sufficiently trained to take dietary histories. Naturally all questions do not apply to all patients. As soon as one is familiar with the many factors which may enter into the nutritional background of an individual, the questionnaire can be dispensed with, but until one is familiar with the technique it serves as a reminder of important points.

The questionnaire is divided into several parts: Part I consists of eleven questions which apply to the diet and health of the mother and also to the general health of the family. Part II (to be answered by the mother, if possible) is concerned directly with the food habits of the individual up to about 15 years of age. This section is further divided into two parts: (1) dietary habits up to the age of 6 years; (2) from age 6 to 15 years of age. Ages are relative of course. Part III is devoted to "Some Health and Hygiene Factors" which may or may not complicate the nutrition problem (to be answered by the mother, if possible). Part IV consists of questions to be answered by the patient, i.e., food habits in general after 15 years of age. Part V is composed of questions relative to "Health and Hygiene Factors" which may have complicated the nutrition problem from about the age of 15 to the present time. In all instances the age division is relative. It has been found that the majority of persons interviewed recalled in a general way their food habits after the age of 12 to 15. They did not remember details of menus of course, but any individual even before the age of 12 knows whether the family lived on a ranch (and the kind of a ranch, fruits, stock, wheat, or dairy, etc.) a small farm, in a village where it was possible to have their own cow, a few chickens, and possibly a few fruit trees, or whether the family lived in a city where all foods had to be purchased. This information is of importance in a nutrition history due to its bearing upon the food supply of the family.

Unless the income is rather large such foods as milk, meat, butter, eggs, fresh and canned vegetables are not used so abundantly, due to the cost, as they are when available on a farm. In other words, in many instances all that is necessary is to secure the "nutritional set-up" of a family, and with a moderate amount of experience one can estimate with a fair degree of accuracy, as human studies go, what the food supply has consisted of. Personal likes and dislikes must always be taken into consideration; an abundance of food of high nutritive value may have been available but due to a personal idiosyncrasy (not necessarily an allergy) the individual has not taken the type of diet he or she could so easily have taken.

If the market orders of a family appear to contain an abundance of high nutritive value foods, this does not necessarily mean that an individual has taken a highly satisfactory diet. But if the market orders over a considerable period of time are known to have been inadequate (and there has been no outside source of food) naturally the diet of the individual members must have been inadequate. The statement that all persons sat at the same table and so must have eaten the same diet has long been known not to be true; amount of food eaten and likes and dislikes complicate the problem.

Not infrequently a person has had two or more periods in his life from a dietary standpoint. For example, an individual may have been born on a ranch and lived there for the first 15 years of his life. Milk, eggs, butter, fruits and vegetables were abundant; he liked these foods and ate liberal amounts of them. He was out of doors a great deal especially in summer so sunshine played its part as a source of vitamin D. No severe illnesses complicated his childhood. From the age of 15 to 40 he may have lived in a city with an entirely different set of conditions as regards his food supply and outdoor life. These details are very important from the standpoint of a dietary history.

Another person may have had an entirely different childhood even though he did live on a farm. He may have had a long series of illnesses which not only complicated his nutrition problem but also kept him from leading the active outdoor life of a country child. Another patient may be one of a family of six or more children who lived in a city on a small income. Dut to expense, milk, butter, cheese, eggs, meats, fresh or canned fruits, and vegetables had to be used in small quantities; cereals and their products being less expensive foods, had to be used in greater abundance. The mother may not have known enough about food values to spend the food money as wisely as it could have been spent. Cereals and their products are primarily energy foods. If a patient recalls that from an early age he has taken either or both tea and coffee, one is fairly safe in estimating that less milk has been consumed than is believed necessary for a child, due in part to the limited quantity of the fluid intake. In other words, each patient must be considered as an individual. It often takes considerable time and patience to learn the many factors which have played a rôle in an individual's nutrition-set-up.

DIETARY HISTORY

Patient No. ..... Date.....
Name..... Telephone No.....
Address..... Nationality.....
Date of birth..... Language spoken.....
Place of birth..... Height..... Weight.....
Type of body build: Slender.....Normal.....Stocky....

Width-Weight: (Consult Width-Weight Tables for Boys and Girls; Men and Women; of Helen B. Pryor, M.D., Stanford University Press, Stanford University, California).

PART I

The following 11 questions apply to the MOTHER of the patient, or to the general health of the family.

1. What was the state of your health during the 10 years before the patient was born?.....
If not in good health, please name illness or illnesses and treatment .....

2. What were your dietary habits a few years *before your pregnancy* for the patient, *during the pregnancy* and *while nursing* in respect to:

a. Meats, including fish (name kinds).. . . .
b. Eggs .....
c. Vegetables (fresh and canned) ....
d. Fruits (fresh and canned) ....
e. Milk .....
f. Cheese .....
g. Cereals (which are/were your favorites) . . .
How often used? ....
h. Bread—white, whole wheat, or rye ..
i. Tea of coffee—or both .....
How many cups on an average per day?

3. Were you an out-doors person?... . .

4. Were you in good health during pregnancy for patient? .....

5. Amount of nausea: Few months?.
During entire pregnancy? ... .
If quite miserable, please make a general statement as to the amount of food retained? . . ..

6. In general what is the state of health of the various members of the family? ....
Have any of the various members of the family ever had tuberculosis? .. . .
Arthritis? . . . .
If various members of the family have had "many illnesses" please name them . . ..

7. Is there a history of deafness in the family?
If so, which members? . . ..

8. Have any members of the family had kidney stones? .. . . Bladder stones. . . . If so, which members, and at what ages? .. ..

9. Is there a history of allergy in the family—eczema, hay fever, asthma? If so, what form and which members? ... .

10. Are you (mother) of a nervous temperament?..

11. What is the dental condition of the various members of the family? ....
Grandparents: Maternal... ... Paternal . .
Father (also his brothers and sisters) . . . . ..
Mother (also her brothers and sisters) . .
Brothers (if any, of the patient) ... .
Sisters (if any, of the patient) ... .
Does the patient have better teeth or poorer teeth than other members of the family? ....
Or are his (or her) teeth above average? ....

DIETARY HISTORY

PART II
DIETARY HISTORY OF PATIENT UP TO ABOUT 6 YEARS OF AGE

The following questions in Parts II and III to be answered, if possible, by the patient's mother, father, or near relative. (Note: "you" and "your" refer to *patient* unless otherwise stated).

1. What number child are you in the family? (1st, 2nd, 3rd) .....
How much did you weigh at birth? .....
How long a time between you and previous child? .....
How many children are/were there in the family? ....

2. Were you breast fed? .....
If so, for how long? .....

3. If not breast fed, what type of formula were you given? .....
Was a preparation such as Mellin's used? .....
Horlick's malted milk?..... Cereal, gruel, plus milk ....
Were you fed a condensed milk? .....
If so, at what age and for how long? .....
Were you fed an evaporated milk? ....

4. Were you a difficult feeding problem as a baby? ..... Were you several months old (about how many months) before a diet was found to agree with you?.....

5. Whether or not you were breast-fed, about *what age* were such foods as the following given:
Orange juice . . ... How much?..... At the age of a year about how much were you being given?.....
Cod liver oil or preparations having same or similar dietary properties..... How much?... ... At the age of a year about how much were you being given?... ...
Apple sauce . . .. Prunes... ... .
Eggs ..... Meat ....
Scraped apple or other fruit such as bananas.....
Mashed potatoes..... Puréed veg. (name kinds).....

6. What other foods such as cereals, bread and butter were given and in what amounts? .... Were these foods used generously or moderately?.....

7. Did you have a good appetite as a small child under 6?. . . . Or were you one of those children who "never had any appetite?"

8. What were your candy habits before the age of 6? . . ..

9. Were you given much sugar on your cereals or in other foods, such as cocoa, up to the age of 6?.... ....
Cookies? .. .. Cake? .....

10. In general, UP TO THE AGE OF 6 YEARS, were the following foods used: Liberally? Average? or Sparingly? (If *Liberally* please mark *XXX, Average XX, Sparingly X*).
Milk—as milk, or as cocoa or other milk drinks.... .....
Milk—in custards, puddings, or in ice cream... ... .
Milk—in creamed soups, creamed vegetables, creamed meats .. ..
Eggs—as eggs .. In custards.....
Fruits—apples or oranges (please state which or if both were used) .....
. . ..
During the winter (including late fall and early spring).
During the summer (including late spring and early fall).
Cheese, if used, the kinds . ...
Cod liver oil or other preparations supplying extra vitamins A and D . Name preparations used..... .
Fish—kinds (how often used)? . ...
Cereals (name kinds used most frequently) . ....
Vegetables (name kinds) . . ..
Bread—White, Whole wheat, or Rye . .. .
Meats—kinds (how prepared) . .....
Sweet foods, such as jams, jellies, candy, honey, cakes, cookies . ...
. . ..

(Please give as much information about the use of milk, eggs, fruits, cereals, meats, cod liver oil, and sweets as it is possible to recall. Outdoor and sunshine habits will be asked for later) . . ..

DIETARY HISTORY

Between the Ages of 6 and About 15 Years

What changes were made in the diet between the ages of 6 and 15 years in regards to the foods listed below? If certain foods were used *liberally* for a few years, then *average* or *sparingly* for several years please indicate this.

Please indicate: *Liberally XXX; Average XX; Sparingly X.*

Milk—as milk or as cocoa or other milk drinks ..
Milk—as custards, puddings or ice cream.....
Milk—in creamed soups, creamed vegetables, or creamed meats .. .. Butter. . . . Eggs.....
Cod liver oil or other preparations supplying vitamins A and D ....
Fruits or fruit juices:
Oranges. . ... Apples.....
Bananas . . . . Peaches.....
Other fruits . . ..

have such as: dancing lessons, singing lessons, Scout Activities, Camp Fire Activities? .....

28. How much time do you devote to school activities, such as athletics, class offices, or dramatics, etc.....

29. In addition to your outside activities, do you go to the movies or to parties frequently enough to interfere with getting sufficient rest? .....

When do you go to the movies? .....

Do you feel tired much of the time? .....

Please give as much information as possible about the general health, the question of rest, the problem of overfatigue, or any nervous disorders which may have occurred.

DIETARY HISTORY
PART IV

The following questions to be answered by the patient when over 15 or so years of age.

Between the ages of 15 and 25 and from 25 to the present time. What has been the trend in your dietary habits in regards to the following foods?

If used almost daily please mark XXX, once or twice a week XX, and only occasionally X. (Of course, the amounts used are of importance, but as one becomes familiar with the technique of taking dietary histories, these can be estimated fairly well according to the "nutritional-set-up" of the individual. No dietary history of this nature could be more than a by-and-large estimate of a person's food habits, but it has its value nevertheless).

	Between ages 15 and 25	25 years to present time
FRUITS		
Apples		
Bananas		
Oranges		
Grapefruit		
Peaches (fresh, canned, dried)		
Apricots (fresh, canned, dried)		
Lemons		
Pineapple		
Prunes (fresh or dried)		
Also seasonal fruits, as strawberries		
CEREALS		
Favorite cereals (please list)		
Bread, white or whole grain (Average No. slices per day)		
Was rice a favorite cereal?		
Cornmeal (yellow or white)		
VEGETABLES	Between ages 15 and 25	25 years to present time
Tomatoes (fresh or canned)		
Carrots (raw or cooked)		
Lettuce and other greens		
Potatoes: White		
Sweet		
Cabbages (cooked)		
(as cole slaw)		
Onions (raw or cooked)		
String beans		
Greens: Beet, dandelion, turnip tops, spinach		
Please name ones used)		
Navy beans, or other dried beans and peas—please name which ones		
Lima beans		
Nuts, including peanuts		
MEATS, SEA-FOODS and DAIRY PRODUCTS		
Meats (including liver, etc.)		
Fish (kinds)		
Shell-fish		
Eggs, (as eggs)		
(in other foods, i.e. custards)		
Cheese (cottage)		
(other cheese)		
Milk, as milk, cocoa, and other milk drinks		
Buttermilk		
Did sour milk in any of its various forms ever enter into your diet?		
Ice cream, milk shakes, or the other fountain drinks containing milk or ice cream		
Were meats and vegetables often served creamed		
Were creamed soups or macaroni and cheese served frequently		
Were custards, or the other puddings using milk used freely for desserts		
SWEETS		
Sugar on cereals—in coffee, cocoa, etc.		
Candy		
Are you especially fond of candy of the Life Saver Type?		
Cakes and cookies		
Pies, doughnuts		

Have you taken any cod liver oil or other preparations of vitamins A and D in recent years? .....

If so, when and for how long? .....

What preparations did you take? .....

Have you taken any yeast tablets, Bemax, or the other vitamin B preparations? .....

If so, details .....

On an average how many glasses of water do you drink per day? .....

Other fluids, such as tea, coffee, fruit, or tomato juice.....

Have you any marked dislikes among foods? .....

If so, what foods? .....

As you recall your winter diet over the past 10 to 15 years (depending upon the age of the patient) was it largely one of cooked foods, for example: cereals, griddle cakes, eggs, meats, potatoes, and other cooked vegetables, bread, butter, cookies, cakes, pies, coffee, or tea or both?

In other words, was a minimum of milk, raw foods(or canned tomatoes) used? .....

Have you ever made any marked change in your diet? .....

If so, what change? .....

When? ..... Why? .....

Do you chew gum? ..... How often? .....

Do you tend to be regular in your eating habits? .....

If not, why? .....
By and large, what is your liquor consumption? .....

Please state whether AT THE PRESENT TIME you eat sparingly (S), moderately (M), or freely (F), of the following foodstuffs:

Meat	Fish	Bread White Whole Grain	Fruits (name those used most freely)	Cheese	Eggs (No. per week)

Butter	Fresh Milk	Buttermilk (glasses daily)	Cocoa or chocolate Cups daily	Potatoes	Tomatoes Raw	Tomatoes Cooked	Tomatoes Juice

Vegetables Cooked	Vegetables Salads	Cereals freely Name those used	Tea Cups daily	Coffee Cups daily	Cakes	Pies

Rich pastry	Candy	Rice	Macaroni or spaghetti	Olive oil or other salad oils	Nuts

Cigars No. daily	Cigarettes No. daily	Do you smoke a pipe? No. daily	Any other items of interest

Will the menus requested below give a fairly accurate estimate of your PRESENT food habits? .....
If not, why not? .....

Please mention the time of meals, and also the time of taking extra food. Include all candy, milk shakes, ice cream cones, nuts, fruit, etc., taken between meals.

Please submit menus for TWO WEEKS, giving the APPROXIMATE AMOUNT of food eaten at each meal, such as 1 glass of milk (8 oz. or otherwise), 1 cup of coffee with or without cream and sugar, 2 eggs, 2 medium sized servings of potatoes, average serving of meat, etc.

PART V

SOME HEALTH and HYGIENE PROBLEMS which may have complicated the NUTRITION PROBLEM. (From age of about 15 to the PRESENT TIME).

1. About what age did you stop growing? .....
Did you grow several inches between about 15 and 20 years of age? .....
How many inches? .....

2. Have you always been about your present build? ..... Or did you have a tendency toward obesity when younger? .....

3. Between what years did most of your teeth decay take place? .....

4. During the past two to three years have you had more tooth decay than for several years prior to this time? .....

5. What kind of tooth brush do you use? Hard ..... Medium ..... Soft .....
How long have you used this kind? .....

6. Do you use tooth paste? .....
If so, what kind or kinds? .....
If powder, what kind or kinds? .....

7. What changes, if any, have you made in your tooth brushes, powder, or paste during the past two years? .....

8. Have you been troubled with bleeding of the gums? ..... If so, how? ..... Has a physician ever prescribed a special diet for you? If so, for what illness? ..... Did you follow directions carefully? ..... Results? .....

9. Does your dentist say your mouth shows good evidence of mouth hygiene? .....

10. What illnesses (and of what duration were they) have you had since you were about 15 years of age? .....

11. Have illnesses complicated your nutrition problem?

12. Have you been subject to colds during the past 10 years? .....

13. Have you been chronically tired for years? .....
If so, to what do you attribute this? .....

14. During the past 10 to 25 years (depending upon age of the patient) have you been out of doors much except possible weekends? ..... If so, please give a few details as to approximate time spent in sunshine, Were you in hiking clothes, swimming suit, or in shorts? .....

15. Is your occupation now such that you spend most of your time in-doors? .....

16. Does your skin burn easily? .....
Or, do you take a tan? .....

17. How much rest do you take (sleep)? .....
Is this more or less than you have taken over the past 10 to 15 years? .....

18. Do you have time to rest an hour in the afternoon? ..... Would you be willing to do this? .....

19. Are you or have you been for several years under great emotional strain? .....
Are you inclined to worry? .....

20. If patient is a mother, how many children and what are their ages? .....
How many were breast fed? .....
For how long? .....

21. In general, what has been your state of health for the past 10 to 15 years? .....

Please mention any other items of interest pertaining to health or dietary matters not included in the above questions.

The interpretation of the nutritional history will be undertaken in the next paper. The evaluation of the various nutritive factors such as calcium, phosphorus, protein, and the vitamins will be discussed. It should

be emphasized however, that the evaluation is of course only a by and large estimate; it is obvious that it could not be otherwise. The *importance* of the evaluation of the various dietary essentials in the dietary history is likely to be *over estimated.* It is not at all necessary to attempt an evaluation but at times it is easier for a patient to understand why it is necessary to add certain foods to his diet if, for example, the point is made that his diet could be rated only Low to Fair in calcium whereas the goal should be excellent for all factors. *For practical work* the problem which is of importance is whether or not unsatisfactory nutrition may be playing a rôle in the etiology of the disorder from which the patient is suffering. When one has an understanding of the fundamentals of nutrition it is believed that if the questions listed are answered intelligently, it will be possible to say whether faulty nutrition may be a factor in the disorder.

The question of the *assimilation* of the various dietary factors is of course the all important one. The dietary history gives no information on this point except in so far as the general health of the individual may be concerned. That factors beyond the control of the individual may influence assimilation is well known. On the one hand, one may take what appears to be an inadequate supply of calcium or other dietary factor but may have extraordinarily efficient assimilation. Are these persons the exception or are they the rule? Probably the exception. On the other hand a person whose food habits are apparently excellent may be unable to utilize so effectively the elements present.

The object of asking for two weeks menus is not with the idea in mind that these menus will be an indication of the individual's food habits over the past several years. They may be, but not necessarily so. The purpose in asking for them is to learn what the person's nutrition set-up is at the present time in order to be able to make suggestions which will require the fewest changes in his routine food habits. At times of course it is necessary to make a number of rather radical changes, but experience has shown that the fewer the changes the greater the possibility of a patient adhering to the new diet. For example, if the data suggests that a person's diet is low in vitamin B and whole grain cereals and whole grain breads (so-called) are distasteful to him, it is much better to suggest another source of vitamin B such as yeast tablets even though they may be more expensive than to urge the cereal preparations. Each person's food problems are different but when it is once known what his dislikes are and what foods are difficult for him to secure for one reason or another, it is a relatively simple matter to adjust all these differences so that his diet will be optimum in all dietary factors.

In nutrition work it is not of great importance what a person ate today or yesterday but it is of importance what an individual's nutrition interests or nutrition-set-up has been for the past 10 to 20 years. Deficiency diseases are the spectacular phase of nutrition work. Many persons are unquestionably taking diets below the optimum in dietary essentials but not low enough to bring about deficiency diseases. However, borderline cases of scurvy, beriberi, and pellagra are being recognized with increasing frequency.

It is not intended to give the impression that the relation of diet to disease belongs in the field of dentistry; only a well trained physician or a dietitian working under his direction should prescribe diets for special illnesses such as diabetes, gastric or duodenal ulcer, or other conditions where diet is of special importance. But it would seem that it is entirely within the province of the dentist to suggest a more adequate diet for a patient unless, as just stated, the individual is on a special diet under his physician. One of the best books on normal nutrition is by Dr. L. Jean Bogert entitled "Nutrition and Physical Fitness." Any one interested in nutrition would profit greatly by reading it.

That factors other than diet enter into many dental and medical problems, no one would deny but by the same token that many of the distressing conditions seen by dentists and physicians have been aggravated by faulty nutrition is undoubtedly equally true.

SUMMARY

Although factors other than nutrition unquestionably play a rôle in dental and medical disorders, data suggest that knowledge of a person's nutrition-set-up is of importance in dental and medical work.

A series of questions which have been found useful in securing a nutritional history is given. When a person is familiar with the dietary properties of foods it is not a difficult matter to decide whether an unsatisfactory diet may be playing a rôle in the disorder. For practical work this is all that is necessary.

However, in a forthcoming paper the evaluation of the dietary history as regards the calcium, phosphorus, protein, and vitamin content will be discussed. The interpretation of such data is of course relative; it is obvious that it could not be otherwise.

That a person may be taking a highly satisfactory diet and yet be poorly nourished due to poor assimilation of the dietary essentials is recognized; this important point should never be lost sight of.

Syphilis of the Stomach

By

HARRY J. MAYER, M.D.

LOS ANGELES, CALIFORNIA

THE diagnosis of gastric syphilis should be of interest to gastro-enterologist, internist, syphilologist, surgeon, roentgenologist and pathologist. According to critical reviews of the literature by Hartwell (1) and Pusch (2) in as few as thirty-five cases is the diagnosis acceptable on the basis of adequately recorded histo-pathological evidence. In approximately three hundred reported cases, the foundation for the diagnosis rested on clinical grounds, including:

1—a positive Wassermann reaction, 2—favorable

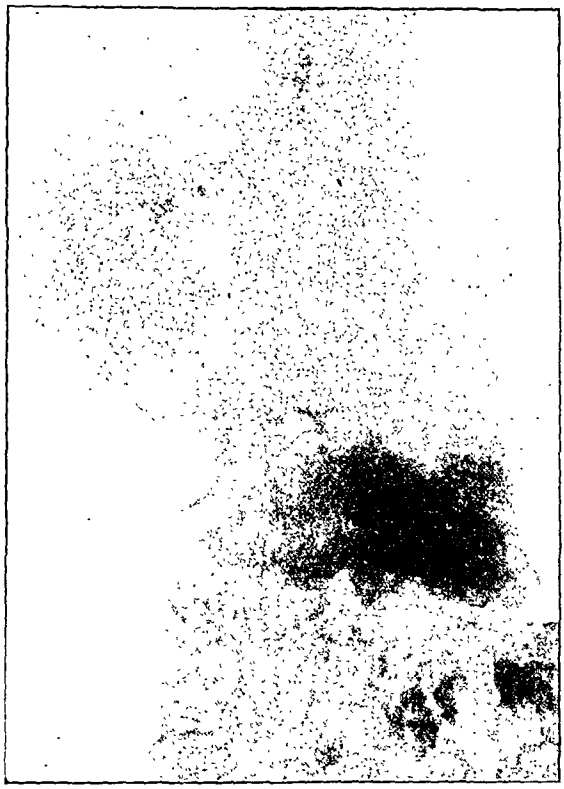

Fig. 1

response to anti-syphilitic therapy and 3—roentgenological simulation of either ulcer or carcinoma.

A review of the literature reveals that the diagnosis of gastric syphilis may be compatible with negative serologic reactions. In 7.5% of cases in the extensive series reported by Eusterman (3) the Wassermann was negative.

There may be, furthermore, in absence of symptomatic and/or roentgenologic improvement following application of therapeutic test no confirmation of clinical diagnosis. The condition of 29% of patients in this series of specifically treated cases was reported as being unchanged and 7% as having died (4). No roentgenologic change was observed in 46% of these patients re-examined with X-rays after anti-syphilitic treatment (5).

Rarity of morgue incidence is stressed by all contributors to the literature. Turnbull (6) of London, is quoted as finding a single possible case of luetic stomach in 3,000 necropsies. Symmers (7) at Bellevue in a study based upon 4,880 autopsies found among 314 syphilitics only one case of gastric involvement of a specific nature. Singer and Meyer (8) at Cook County did not find a single instance in 5,000 autopsies. The case to be described here is the second of its kind encountered by a local group of pathologists (9) in 15,000 postmortem examinations, covering an experience of 25 years.

A survey of the authenticated cases shows that frequently the diagnosis was unsuspected pre-operatively or antemortem, being fortuitously arrived at by the pathologist.

Although the serologic reactions in the case to be described were practically negative and the final response to intensive anti-luetic therapy indifferent, the clinical diagnosis was adhered to regardless of persistent roentgenologic hour-glass deformity simulating carcinoma (Fig. 1).

REPORT OF CASE

W. U. was a white man, 47 years of age, unmarried automobile salesman, whose chief complaints on first admission to Cedars of Lebanon Hospital, August 5, 1936, were epigastric distress, vomiting and loss of weight. Past history revealed luetic infection in 1917 which had been treated. Veterans' hospital records disclosed blood Wassermann and spinal fluid as negative in 1935. The onset was in 1933, when patient had pain-food-ease sequence and relief by alkalies. Symptoms during the year preceding entrance to hospital had been increasing in severity, patient experiencing epigastric discomfort described as a sensation of distension aggraved by solid food, emesis giving relief. Attacks were most severe after midnight. Large quantities of mucus were present, gross blood being seen on one occasion. Liquid was better tolerated than solid food. Alkalies, anti-spasmodics and hypnotics were ineffective in allaying distress. A loss of weight of thirty pounds was precipitated by a semi-starvation treatment (?) with colonic irrigations inflicted by a cultist institution. Physical examination showed a white man of good color, whose bodily nutrition was well maintained despite loss of weight. Resistance to palpation was encountered in the epigastrium but no tumor mass could be felt. Although the Romberg was negative, inequality of patellar reflexes was noted. Leucocyte counts ranged from 15,000 to 10,000, neutrophiles 73.5 to 80.5%, hemoglobin 89 to 93% and erythrocytes 4,800,000.

Fig. 2. Large superficial ulcer.

Fig. 3. Enormously thickened stomach wall, bisected and everted.

Stools were chemically positive for occult blood on two occasions and negative a like number of times. Investigation of hepatic function yielded a negative galactose tolerance test and an icterus index of 7. Gastric contents contained free HCl and gave positive guaiac tests. Two Wassermann reactions shortly before and after specific treatment was commenced were doubtfully positive, the Kahn precipitation test being negative. At the conclusion of fourteen weeks of antiluetic treatment, both Wassermann and Kahn tests were negative. An electrocardiogram showed slight elevation of T take-off in Leads I and II and an upright T wave in Lead IV, suggesting possible coronary artery involvement.

X-ray on August 7, 1936, showed a persistent hour-glass deformity (Fig. 1). On re-examination Sept. 5, roentgenologist reported infiltration was increased as compared with previous exposure. Serial refills of the stomach with barium at monthly intervals during the following eight weeks showed expansion of upper and lower loculi, hour-glass constriction of the midportion persisting. August 8, it was observed that patient's general condition did not correspond with the degree of carcinomatous involvement simulated by X-ray findings. In view of the luetic history although the Wassermann was doubtfully positive and the Kahn negative, a provisional diagnosis of syphilis of the stomach was made.

Patient was given daily intramuscular injections of 1/6 gr. mercury succinimide and 225 grains of sodium iodide, orally, for three weeks preliminary to neoarsphenamine. There was no amelioration in symptoms after five weeks of hospitalization. Although X-ray indicated increased infiltration and despite chiding from roentgenologist and others, patient was dismissed without surgical exploration. Since patient's body weight had been maintained, it was felt that ultimately he would respond favorably to further antisyphilitic treatment.

Additional treatment was given totaling 5 gr. mercury succinimide 3 Gm. neoarsphenamine and 24 gr. thio-bismol, along with sodium iodide. Three weeks after dismissal from hospital, patient had gained fifteen pounds in weight, showing definite symptomatic improvement.

An exacerbation of repeated attacks of emesis preceded by abdominal distress, (replacing epigastric discomfort), commenced October 9. Pain and emesis increased in severity during the ensuing month. A loss of five pounds in weight took place in the week preceding re-entry to hospital, patient reporting vomiting considerable quantity of bright blood on one occasion. Surgical exploration now seemed advisable, diagnosis on re-admission November 16 being gastric syphilis.

Operation was performed November 17 by Dr. Isaac Y. Olch. The stomach was found to contain a mass of enormously thickened or edematous inflammatory tissue extending across the middle. Above this mass of scar tissue the stomach was dilated resulting in a definite constriction or hour-glass deformity. Because of the extent of the edematous inflammatory tissue, it was impossible to excise scar. Gastro-enterostomy was done anteriorly. Following evisceration 11/30/36 patient died 12/4/36.

On postmortem examination was found a large superficial ulcer (Fig. 2), with a slightly rolled up edge covering about one-half the area of the open stomach, the wall of which was enormously thickened (Fig. 3). The induration extended along the lesser curvature practically to the esophageal opening, the base of the ulcer encircling the midportion of stomach being of firm fibrous tissue. The lining of the aorta was greatly roughened being raised into irregular folds (Fig. 4). In both lungs was an extensive consolidated bronchopneumonia with abscess formation. Microscopic section through the edge of stomach ulcer shows the enormous thickening, edema and dense fibrosis in the submucosa. The round cell infiltration is diffuse and extensive (Fig. 5). In sections of the aorta there was round cell infiltration about the vasa vasorum.

The pathological and roentgenologic findings in this case agree with the excellent description by Pusch (2). The thickening is concentric and sufficiently predominant between cardia and pylorus to result in hour-glass deformity. The annular involvement is primarily intramural with extensive secondary superficial ulceration.

As first observed in America by Flexner (10) the

Fig. 4. Gross appearance of syphilitic aortitis.

pathological process is localized chiefly in the submucosa. The ulcer is not gummatous but rather an indirect form of necrosis of mucous membrane brought about by combined softening of submucous infiltration and obliteration of blood vessels in the same situation. The mucous membrane thus deprived of its nutrition becomes necrotic, is removed, the ulceration resulting. As Boyd (11) points out, it is by no means easy to say even under the microscope if a piece of stomach wall is or is not syphilitic. The only adequate proof—that of sp. pallida has not been incontrovertibly offered.

Judged by existing pathological criteria, there is adequate anatomical evidence in this case to justify the diagnosis of syphilis of the stomach.

COMMENT

A laboratory finding which may bear only a chronological relationship was a gradual reduction in the leucocyte count from 15,000 to 10,000 accompanied by the disappearance of occult blood from stool. The neutrophile trend, however, was upwards. In any event, the preceding observation lent a bit of moral support to the differential diagnosis, the interpretation being that of a favorable response to treatment in a secondarily infected ulceration of a specific rather than a carcinomatous growth.

Carman's (12) observation in 1917 of the disproportion between patient's generally good condition and the extent of gastric involvement, roentgenologically simulating malignancy has been emphasized by many subsequent contributors to the literature. Even with this thought in mind, it was not easy at all times to maintain courage in adhering to diagnosis of gastric syphilis in the face of refractory response to what is ordinarily regarded as specific therapy in specific disease. Since the odds, statistically, favor the diagnosis of carcinoma, the consequences of mistaking a malignant for a syphilitic lesion are likely to be disastrous from a diagnostic standpoint. It is not surprising, therefore, that early surgical exploration has been recommended by internists and syphilologists as well as surgeons whenever the slightest suspicion of carcinoma is entertained.

In giving indications for laparotomy, Meyer and Singer (13) point out that it is generally agreed that only a relatively short period for the therapeutic test is warranted. Einhorn is quoted as recommending a test period of from two to four weeks. Bockus and Bank (14) quote O'Leary and Eusterman as regarding six weeks as the average time.

Stokes is cited as believing that six weeks is too long to wait when there is some chance for radical removal if prompt operation is performed. He recommends two injections of 0.3 Gm. of arsphenamine to be followed by operation if no improvement occurs.

In the writer's opinion the loss of time being the most serious objection to the therapeutic test in event the lesion proves to be carcinomatous is of little therapeutic significance. Either carcinoma or syphilis of

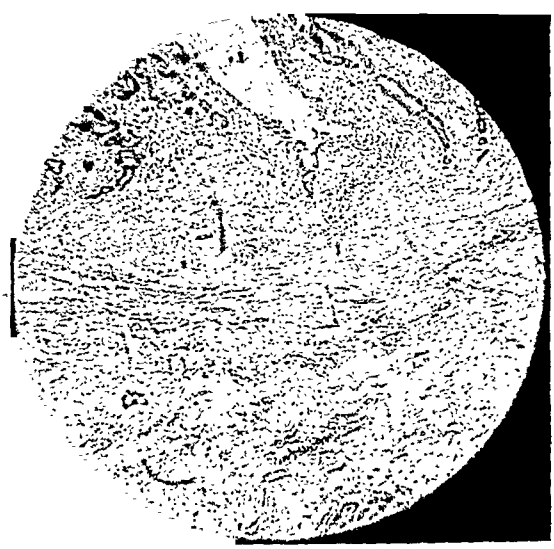

Fig. 5. Microphotograph of a section through the mucous membrane shown in Fig. 2. Cellular infiltration edema and hypertrophy of submucosa.

the stomach of a roentgenologic magnitude apparent in Fig. 1 on surgical exploration is likely to be found non-resectable.

SUMMARY

This case of gastric syphilis is reported because:

1. The diagnosis was confirmed by histo-pathological study.

2. The diagnosis may be compatible with (a) negative or weakly positive serologic reactions (b) failure of symptomatic and/or roentgenologic improvement after intensive antisyphilitic treatment.

3. It resembled late carcinoma therapeutically as well as roentgenologically insomuch as neither condition is amenable to treatment.

Carcinoma of the Small Intestine as a Hidden Cause of Anemia

By

A. R. HATCHER, M.D., F.A.C.S.

and

K. E. VOLDENG, M.D., M.S., F.A.C.S.

WELLINGTON, KANSAS

PRIMARY carcinoma of the small bowel is not frequently encountered. At the Mayo Clinic, of all the carcinoma of the gastro-intestinal tract, from the cardiac end of the stomach down to and including the rectum, only .62% are located in the small bowel (1).

The symptoms arising from carcinoma of the small intestine, as a rule, result from either obstruction or anemia. When obstructive features are present, a correct diagnosis is reached with little difficulty; however, when such a bowel or abdominal history is lacking, a resulting anemia may present a most puzzling diagnostic problem to the physician.

The following case report demonstrates: first, how baffling and intractable anemia and debility may be as a result of a concealed carcinoma of the ileum, and second, the remarkable absence of any abdominal findings or symptoms directly referable to an intestinal new growth, which had undoubtedly been present for many months.

The history of this patient about to be recited is involved. It will, however, be given in a somewhat detailed fashion in order that the reader may thoroughly evaluate the situation.

The patient, a woman, aged 54, first consulted us in regard to her present illness in May, 1934. At that time, her chief complaint was "spells of weakness and easy fatigue associated with distress over the heart." She had had what she called an attack of "Flu" three months previously, following which her heart palpitated on exertion, and she would tend to have short spells of sharp pains in her left chest. Following an attack of palpitation, she would be extremely weak and compelled to lie down. Her appetite was poor, with a resulting weight loss of twenty pounds during those three months. She was somewhat nauseated at times. The patient has had fever of 100° F frequently during the past few weeks with occasional sense of chilliness.

Hemorrhoidectomy had been carried out elsewhere two months previously. The first attempt in the surgical procedure had to be postponed because of severe pains in the back and through the chest, apparently coming on following the preoperative hypodermic. The operation was successfully performed two days after this episode, with subsequent satisfactory healing of the rectum.

Evaluation of the history brought out numerous minor complaints which were, however, of no significance in this record. An appendectomy and a Baldy-Webster suspension of the uterus was done in 1920. In 1922, several stones were removed from the gall bladder, and three years later a complete cholecystectomy was done. All of this surgery was carried out by us. Recovery from these surgical procedures was uneventful. Both tonsils were removed in 1925. Her health in general had been very good during the past few years.

Physical examination as noted at that first visit was as follows: Patient is a middle-aged, white female, who has apparently lost some weight and appears to be in poor general health. Temperature is 99° F. Pulse rate is 96 per minute. Respiration is 20 per minute. Blood pressure is 140/64, measured in millimeters of mercury. Her weight is 145 pounds. The skin has an ashy, grey, pasty appearance, and the mucous membrane suggest anemia. Hair, scalp, eyes, ears, nose are normal. The teeth, gums, and throat are in good condition. The thyroid gland is palpable, but not enlarged. No glands or stiffness of the neck can be found. Chest excursion is normal on each side. The breath sounds are normal. The apical heart beat

Submitted February 20, 1937.

Fig. 1. Photograph of gross specimen. Upper arrow is passing down ileum toward tumor and the lower arrow is situated in the distal ileum as it passes away from the tumor.

is heard best in the sixth interspace, 12 centimeters from the sternal border. The heart beat is forceful, and the second sound is accentuated over the entire precordium. No murmurs can be elicited. The muscles at several areas on the chest wall seem tender to firm pressure, and this is particularly noted posteriorly on either side of the sixth dorsal vertebrae. The back is otherwise normal. The abdomen is rounded and soft, and no tumors are found. There is a slight tenderness on deep palpation over the cecum and mid-epigastrium.

Examination of the pelvic organs shows the uterus to be of normal size and well-fixed anteriorly. The left ovary cannot be palpated; however, there is a small, firm, freely movable mass in the right adnexal region which is undoubtedly a somewhat enlarged ovary. The rectum shows considerable sensitivity and sphincter tone is more marked than usual. All deep tendon reflexes are exaggerated although no pathological responses can be demonstrated.

The patient had been seen and treated in the years past by one of us, for minor spells of easy fatigue, palpitation, and nervousness. The history at this time naturally suggested somewhat the same story that she had told us in those past years, for which an organic basis was never found. Because, however, of (1) fever, (2) weight loss, and (3) apparent general debility, it was felt that something organic must have appeared in order to produce those findings.

A period of hospitalization for more thorough study and observation of the patient was carried out with the following additional information. The patient consistently had an afternoon rise in temperature usually between 99° F. and 100° F. A catheterized specimen of urine showed a faint trace of albumen and 80 pus cells per cubic millimeter. Hemoglobin estimated by the Dare method was 83%. The red blood cells numbered 4,180,000; the white blood cells, 8,750 per cubic millimeter, and the morphological study of stained, differential blood smears did not show any points of significance. Inspection of the rectum showed one area of residual scars of recent surgery and several small internal hemorrhoids. A shallow fissure was found in the posterior commissure of the anal canal. Sigmoidoscopic examination was negative. A trace of occult blood was present in the fecal matter; however, this was while the patient was on a full diet, and this finding was not considered significant. During her hospital stay, the patient complained of numerous aches and pains throughout the chest, back, and abdomen, although none of these seemed to aid in interpreting her case. The temperature gradually resumed a normal level, the pulse maintained a normal rate, and she improved generally. Repeated examinations of the urine proved this difficulty to be subsiding. She was dismissed from the hospital after ten days in a much improved condition, and continued as an ambulatory patient on treatment for her (1) general health, (2) urinary infection, and (3) apparent nervous instability.

During the next three months, the patient remained considerably improved. Her appetite was fair and her bowels continued entirely regular. Her weight remained at 145 pounds. Her weakness was still noted and she occasionally had fleeting pains through the region of her heart, and noted palpitation on moderate exertion. She occasionally had mild gaseous indigestion after meals. The urine became normal.

The patient returned in September of that same year, four months after her first examination, complaining of a return of her general weakness and recurring afternoon fever averaging usually about 100° F. The gastro-intestinal tract remained symptomless. She slept well, had a fairly good appetite, and there was nothing in her history to arouse suspicion regarding the source of any trouble. The patient appeared to be more anemic. The pulse rate was 90 per minute. The blood pressure was 126/70 measured in millimeters of mercury. Her temperature was 99° F. Physical examination revealed no additional features. At this time her hemoglobin was 60% (Dare). The red blood cells numbered 3,480,000, and the white blood cells 13,300 per cubic millimeter. Study of the stained smears demonstrated considerable achromia and poikilocytosis of the erythrocytic elements. The urine showed 20 pus cells per cubic millimeter, but was otherwise normal. Analysis of the gastric contents after an Ewald meal demonstrated values for free hydrochloric acid 14, and total acid 32. An agglutination test for Malta fever was negative. X-ray visualization of the entire gastro-intestinal tract showed no pathology. Sigmoidoscopic examination was negative with the exception of the presence of an irritable rectal canal with small irregular internal hemorrhoids and small posterior fissure. Slight bleeding occurred in this fissure following instrumentation of the rectum and the patient stated she had noted a streak of red blood in the stool at times.

Our impression at the time of this second examination was that this patient's symptoms were due chiefly to her anemia which we felt was caused by her poor nutritional state and in part by slight rectal

Fig. 2. Metastatic nodule in liver tissue.

bleeding. During the remainder of the patient's life, the anemia was the outstanding feature, and our efforts were directed toward irradication of this problem. The rectum was treated locally, and she was given strenuous anti-anemic therapy.

Some symptomatic improvement resulted in the following few weeks; however, there was a tendency at times to note palpitation, shortness of breath, weakness, and pains over the heart on slight exertion. In spite of many weeks of anti-anemic therapy and conservative therapy for her rectum, only slight improvement was noted in her anemia. The urine remained free from significant amounts of pus. A low grade afternoon fever continued quite regularly and her general debility constantly was prominent. The patient noted frequently a vague sense of fullness and deep dull distress in the right upper abdomen. Anemia was the only satisfactory explanation we were able to give for any of these subjective symptoms. Her condition remained unsatisfactory, but there were times when the patient felt considerably stronger. We were at a loss to know what was causing the patient's anemia and *why* it did not respond to numerous schedules of stringent blood building therapy.

In the early months of 1935 we continued attempting to build up the patient's general health through every possible route. In spite of our efforts, examination of her blood in May showed 62% (Dare) hemoglobin and the red blood cells numbered 3,200,000 per cubic millimeter. Marked achromia, anisocytosis, and poikilocytosis were present with numerous macrocytes. We never were able to find a nucleated red cell in any of her blood smears. A trace of occult blood continued to be present in the stools; however, this feature was again discounted because of her general diet, liver preparations, and possible occasional drop of blood from the rectum. The slight right ovarian enlargement remained unchanged in size or character.

We had been handling this patient for ten months and were unable to improve the anemia or find the cause of the trouble, so our suggestion at this time was that the patient have a complete examination by another consultant; and this course was immediately followed.

This investigation resulted in a negative report with the exception of the marked secondary anemia and a finding of blood in the stools. No note was made regarding the small tumor which we had found in her right pelvis. This consultant suggested that further rectal surgery be carried out in the belief that this was the source of her bleeding. This examination concluded a very complete laboratory and Roentgen examination; and we were all again unable to find what we constantly suspected: a malignant growth.

Strenuous anti-anemic therapy was continued and every effort made to increase the patient's general physical state. She was anxious to visit relatives who lived in the lake section of Wisconsin and this trip was advised in hopes that such a rest would further increase her general health. She was followed closely by a physician in that locality who promptly reported back that the patient was not improving. In fact, the anemia and general weakness became more pronounced.

She was advised to consult another clinic group at once; and on August 29, 1935, the patient presented herself to that group for a thorough investigation. Here again an attempt was made to explain the weakness, physical and mental depression, fever and anemia. They verified the findings of a firm, possibly cystic, moveable mass in the right side of the pelvis, which they also thought probably ovarian, since it could not be localized through X-ray examination of the stomach, colon and sigmoidoscopic examination for a distance of 24 centimeters. These consultants did advise the patient to remain for a motor meal in order to investigate particularly the ileocecal coil, however the patient refused this re-check. This clinic group might have identified the tumor, had such a procedure been carried out. Their only suggestions were to continue liver and iron therapy and to have periodic examinations of the tumor in the pelvis. Finding a trace of occult blood in stools was not considered of prime importance.

The patient returned home and seemed to show a slight improvement. She became afebrile and her strength was definitely better. We repeatedly examined the pelvis in regard to the right pelvic tumor and made a note that it had remained unchanged since our first examination over a year ago, and that the tumor was undoubtedly ovarian and of no real significance. We also appreciated the fact that previous pelvic surgery might have distorted the pelvic anatomy.

Improvement was only temporary and her condition again began to fail. Because of the extreme seriousness of her condition and our utter inability to either make a diagnosis or to successfully treat her, she was advised to consult still further.

In October, 1935, she visited another consulting physician who again carried out a thorough investigation, the results of which gave us no additional findings. This physician felt the anemia belonged to the so-called hypochromic type, and his only suggestion was to continue with iron and liver therapy. Again the possibility of a malignant growth seemed to be ruled out.

The patient's condition gradually became more severe and constant bed rest became a necessity.

In November, 1935, she was again hospitalized by us for the purpose of giving her repeated blood transfusions combined with a regime of absolute bed rest. Examination again revealed a severe secondary anemia and a constant daily fever of between 100° and 101° F. Hemoglobin was estimated to be 50% (Dare). Red blood cells numbered 3,280,000 per cubic millimeter. The only other finding which we previously had always noted was the presence of small amounts of blood in the stools. The abdomen was entirely negative to examination and the bowels were very regular. The patient did complain from time to time of vague upper abdominal symptoms and nausea. However, we could place no significance to these features. During the course of six weeks, blood was given intravenously and intramuscularly at frequent intervals to a total of 1780 cubic centimeters. Liver and iron was administered by intramuscular injection. A re-check of her gastric analysis showed a comparatively low amount of free hydrochloric acid, so this acid was supplied with each meal with a resulting lessening of her nausea. Considerable improvement was evidenced during the first weeks of this hospitalization, and her hemoglobin was elevated to 70% (Dare) and the red blood cells numbered 3,790,000 per cubic millimeter. She continued to show a mild leukocytosis, however the morphology of the white cells remained normal. Her condition in general was the best it had been for several months and her temperature only occasionally reached 99.4. She was again sent home on a restricted schedule of activity and a continuation of anti-anemic and general measures. This improvement was of relatively short duration, and she promptly showed a return of her severe anemia, fever and extreme weakness.

Our impression was that this was either a malignancy which we were unable to identify; or, it was a primary blood disease which was not amenable to any therapy which we had to offer. We were at a complete loss to know what next to do. We had repeatedly considered the advisability of performing an exploratory abdominal laparotomy; however, it seemed useless to enter an abdomen which neither history or clinical findings could point to even a suspicious organ. We were convinced that the small pelvic tumor was an innocent, right ovarian enlargement. We advised bed rest at home, liver, iron, sedatives when nervous, vitamines and a nourishing diet. She continued to fail; and during the last week of her illness, her weakness, weight loss, and general debility was most marked. She veritably melted away under our own eyes and we were ignorant of the cause. During the last few days of her illness the fever was extreme and her pulse was practically imperceptible. Twenty-four hours before her death, the patient expelled a large, liquid, bloody stool. This was not of the tarry type, however it was not bright red. This hemorrhage convinced us that she had a tumor of the bowel as the chief cause of death which we knew must inevitably follow in a few hours. Death occurred on April 13, 1936, over two years following the onset of her illness.

POST-MORTEM REPORT

The autopsy was performed at a funeral home eight hours post-mortem.

The body is that of a white female, apparently about fifty-five years of age. There has been marked weight loss and there is a marked pallor to the skin and mucous membranes. Old upper, right rectus and lower, mid-line abdominal surgical scars are present. The eyes, nose, ears, and mouth are essentially negative. Nothing of note is evidenced on the extremities other than emaciation and pallor.

A "Y" type autopsy incision is made, exposing the thoracic and abdominal cavities.

The Thoracic Cavity: The pericardial sac is normal in size, shape, and position, and contains about five cubic centimeters of clear, straw-colored fluid. No adhesions are present. Both pleural cavities are free and contain no excess fluid. There is considerable hypostatic congestion, but no true consolidation is present. The diaphragm is in a normal position on both sides. Mediastinal contents and hilus glands show nothing of note.

The Abdominal Cavity: The solid organs are in normal position and nothing unusual can be seen on superficial examination of the abdominal contents. There are dense adhesions in the region of the gall bladder fossa which fix the duodenum and hepatic flexure of the colon firmly against the undersurface of the liver. The appendix is absent. The cecum is free. Many enlarged lymph glands are present medial to the cecum, representing a marked lymphadenopathy of the mesenteric and retroperitoneal chain of nodes. These glands extend up along the root of the mesentery to the pancreas. The largest node measures 2 x 2 x 3 cm. Evidence of surgical uterine suspension is present which holds a small regular uterus anterior in good position. The right posterior part of the fundus

Fig. 3. Portion of small nodule found in wall of jejunum. The jejunal mucosa is not related to the tumor nodule.

is adherent to a fixed, firm, tumor mass in the right pelvis, which at first seems to be a right ovarian tumor. This, however, proves to be primarily in the small bowel and has no connection with the right tube or ovary which are normal and free. The left tube and ovary are also normal. One loop of small bowel is plastered down around this mass; however, it can be freed fairly easily. The involved ileum is intimately associated with the mass; and in order to facilitate this part of the examination, the ileum is well resected from the ileocecal valve. This bowel is traced directly into the pelvis for a distance of about twelve cm. where it is then found to be apparently a part of the tumor. An resection is made at this point. The wall of an abscess is broken, allowing the escape of a greenish-yellow, purulent material measuring about fifty cubic centimeters. The remainder of the tumor, as it passes to the rectum, is intimately associated with the rectum; but it does not appear to be the primary source of the pathology. The entire mass, with the sigmoid colon and female organs, is resected en bloc, and will be more completely described later.

Bowel: There is no change of significance to be found in the colon.

Lungs: Not any of the large examples of the lower lobes. No gross evidence of pneumonia is present. Multiple small nodules of tumor are present throughout the lungs, especially at the bases.

Spleen: The spleen is slightly larger than normal, and is pale. On the anterior surface of the left lobe is found a small, hemispherical, encapsulated mass, one centimeter in diameter, beneath which is a tiny infarct. On cutting this mass it is found to measure two centimeters in diameter, is white in color, and quite friable. The trabeculæ of the nodule are sharply demarcated from the liver substance. No capsule is present. On microscopic section of the nodule of the liver, only liver cells are found. There is one small nodule, located deeply in the right lobe, measuring one centimeter in diameter, and has the same gross appearance as the larger tumor. The liver substance on cut section has a marked "nutmeg" appearance.

Gall Passages: The common duct is of normal size and the hepatic ducts are patent throughout. The gall bladder and cystic duct have been removed previously.

Pancreas: The pancreas and duodenum are normal.

Small Bowel: Careful inspection of the small intestine from duodenum to mass in jejunum reveals only one point of interest. This is a small firm, fibrous nodule, measuring eight millimeters in diameter, and located in the intestinal wall of the jejunum about eight centimeters from the duodenum. Cut section of this nodule points to the probability that this tumor is not connected with the mucosa or serosa. The cut surface is white, granular, and semi-firm. On microscopic examination, this appears to be an adenoma of the jejunum.

The pancreas is normal.

Spleen: The spleen is about twice normal size. The capsule is of a bluish-black color and seems quite tense. The pulp, on section, is dark and friable. No nodules are present.

The kidneys are essentially negative. The cut surface is pale.

The adrenals are negative.

The female organs are negative except as noted elsewhere.

The urinary bladder and ureters are normal. A small amount of cloudy urine is present.

The above described pelvic mass is removed *in toto*, along with the uterus, ovaries, tubes and sigmoid colon. Careful dissection of this mass shows it to be made up primarily of a polypoid tumor involving eight centimeters of the ileum. The site of the original tumor is about fifteen centimeters from the ileocecal valve. The tumor mass has perforated and allowed an abscess and inflammatory reaction to surround this loop of ileum. Because of its size and obstructive nature, it is impossible to see grossly how even liquid bowel content could pass by the tumor without considerable difficulty (Figure 1). The entire mass measures about five centimeters in diameter. Soft, fluid fecal matter is present throughout the colon and lower ileum. The lymph nodes, on section, are white in color; the cut edge is fairly sharp, and there is a softening and friability associated with the central portions of several nodes.

Microscopic study of tissue from this case demonstrated that the lesion of the ileum was an adenocarcinoma (Figure 2), and the same type of new growth was found to make up the mesenteric lymphadenopathy and liver nodules. Section of the small jejunal tumor revealed this to be a small clump of normal appearing glandular structures (Figure 3). The exact nature of this tissue nodule is problematical, however, it seems unrelated to the malignant tissues, and may represent a nest of heterotopic pancreatic cells. There was marked fatty degeneration of the liver, and considerable cloudy swelling of kidney parenchyma. The spleen pulp was engorged and the lymph structures of these organs was hyperplastic.

COMPLETE PATHOLOGICAL DIAGNOSIS

1. Adenocarcinoma of the ileum (perforating and hemorrhagic in nature).
2. Metastatic carcinoma of sentinal lymph nodes and liver.
3. Small adenoma of jejunum (pancreatic cells).
4. Parenchymatous changes in liver and kidneys.
5. Emaciation.
6. (Previous surgery) Cholecystectomy, appendectomy, and Baldy-Webster suspension of the uterus.

DISCUSSION

In spite of what we felt were continued determined efforts to establish a diagnosis in this case, the lesion which had been gradually squeezing out life remained completely hidden until two days before death, when a massive block stool spelled cancer of the bowel. The features of progressive anemia, debility, and fever could not be explained, and furthermore, failed to respond to any treatment.

It is just this point which has been stressed of recent months by several authors, and we wish to again call it to the attention of our medical group. In any case of unexplained debility and anemia, a hidden carcinoma of the small bowel is quite possible.

This brings us to face our first criticism: more repeated efforts should have been made to visualize the small bowel by newer radiological diagnostic methods. In previous years, the major part of the small bowel has been considered quite impossible to visualize. This conception has changed to the point that, as Weber states: (1) "the roentgenologic examination con-

scientiously and properly performed can be made to be quite as accurate and reliable in the diagnosis of diseases of the small intestine, as it has become in the diagnosis of diseases of the esophagus, stomach and colon."

The second criticism we offer is that an early exploratory surgical procedure should have been carried out, in which case at least the hemorrhaging lesion could have been readily removed, even though a cancer cure might not have been possible. Such a procedure might have added years to this patient's life, and if done early enough, would have carried possibility for complete cure. We hope through this report to stress these two criticisms and offer them as urgent suggestions to those doctors who may see such rather rare clinical problems as the one recited.

SUMMARY

1. A case of carcinoma o the ileum is presented.
2. Continuous slight bleeding of a hidden small intestinal carcinoma may produce "unexplained anemia."
3. More careful roentgenological examination of the small bowel is urged in cases of suspected gastro-intestinal bleeding.
4. Laparotomy may be the only means of discovering a bleeding carcinoma of the small intestine.

Errors in Gastro-enterologic Diagnosis

By

MEYER GOLOB, M.D.*
NEW YORK, NEW YORK

AFTER many years of gastro-enterologic practice I am convinced that success in this field rests largely on the ability to make a correct diagnosis. This is, of course, to a certain extent true of all other branches of medical art, but in the gastro-intestinal field as in no other, is the available information so equivocal, even though we have the fullest cooperation from the patient. And it may very well be added, in no other field are mistakes in diagnosis so serious in their immediate consequences, nor so far-reaching in their ultimate results.

The psychology of the gastro-intestinal patient is peculiar. It would seem that the majority of those who are referred after their ailments have become well-established visit the consultant not so much to find out what he thinks, as to judge of that doctor's cleverness and professional acumen, by concealing from him all the data which they alone can supply, as if to see if he still can make a diagnosis in spite of all the hindrances they can possibly throw in his way. Some will volunteer no information — it must be drawn from them by prolonged and searching questioning. Others wilfully conceal their symptoms. Others again will greatly magnify their ailments, or will minimize them by gross understatement. Frequently — in clinic practice especially, the patient will be unable to command language in which to describe what he has felt. Or again he may be so hypersensitive to suffering of any kind that all his statements must have allowance for exaggeration. Or he may be so insensitive that he pays little attention to suffering that would unnerve one less phlegmatic in character.

It was of such material that Alexander Moore (1) must have been thinking when he wrote: "Mistakes in diagnosis are of three kinds: (1) the diagnosis of a lesion is made when disease is not present, a wrong affirmative diagnosis. (2) Disease is present but is not discovered, a wrong negative diagnosis, and (3) a lesion is found but is not properly identified, a wrong differential diagnosis." Thus is set forth, in one terse paragraph, a whole chapter in modern medicine.

A surprisingly large number of patients come to our clinic bearing with them X-rays taken elsewhere, accompanied by fanciful diagnoses which very likely bear no relation to either the physical findings on entrance, or the correct reading of the roentgenographs supplied. All too frequently commercialism enters in to influence the interpretation of the X-ray pictures. The physician who first examines the patient decides what symptoms and history indicate, and refers his patient to a roentgenologist — not for independent and unbiased examination, but for a *confirmation* of his findings.

Very often we find that the original roentgenograms led to an erroneous diagnosis because of spastic phenomena which may be present from a number of different causes. The skilled roentgenologist will allow for possible spasm, and the experienced gastro-enterologist may even be assisted in making his diagnosis because of the existence of a spastic condition is confirmation of certain pathologic conditions which may previously have only been surmised. But with a roentgenologist lacking in special knowledge of the behavior — normal and abnormal — of the gastro-intestinal tract; and a so-called gastro-enterologist who fails to make his own interpretation of the X-ray findings, after taking into consideration all the other data he has been able to obtain by physical examination, laboratory findings, and a searching inquiry as to the past medical history — the chance of arriving at an accurate diagnosis is very small indeed (2).

"High pressure salesmanship" has induced many physicians, who have no special training nor inclination for gastro-enterologic work to enter this field because a fluoroscope or X-ray outfit was presented to them so alluringly that it seemed a very easy way of becoming a "specialist," with a more leisurely life and larger emolliments which are *supposed* to accompany specialization. Is it much wonder that such

*Assistant Professor of Medicine, New York Medical College and Flower Hospital.
Submitted May 16, 1937.

grave mistakes continually occur in making diagnoses under such conditions?

An example of such errors is offered by three cases which came under observation following a negative roentgenographic report, reached because the gastric examination had shown no filling defect nor six-hour residue. Yet the chemical analysis done later revealed a true malignant achylia with unusually rapid emptying, while another Roentgen study showed a gaping pylorus and rugae largely effaced. In all three cases the sedimentation rate was found to be greatly increased. If these laboratory procedures had been done *before* the Roentgen study, how different might the interpretation have been!

As it was, reconsideration of all data led, in two cases, to a final diagnosis of infiltrating carcinoma of the posterior stomach wall, while the third proved to be a case of linitis plastica. There is a practical lesson to be learned here: Never accept a negative X-ray finding as final unless it is fortified by concurring clinical and laboratory findings. In gastro-enterology, as Koch said of tuberculosis, "Absence of proof is no proof of absence."

FAILURE TO IDENTIFY LESION

We now come to Moore's third postulant: The lesion is found but is not properly identified. A phlegmatic individual presented a clinical picture which was not in most respects characteristic of the silently bleeding duodenal ulcer which operation later revealed. The pre-operative diagnosis was hypochromic anemia. The X-ray report was negative for both pre-pyloric and post-pyloric ulcer. Gastric chemistry recorded high acid values, and occult blood was detected in the stool. The operation revealed a small lesion on the posterior wall of the duodenum, with a shallow crater incapable of retaining a central fleck of barium. X-ray had also failed to show the duodenitis — precursor of ulceration — which might have helped in the pre-operative recognition.

WRONG DIAGNOSIS DUE TO IMPROPER ROENTGEN TECHNIQUE

Among the great quantity of roentgenograms which are brought to our clinic by patients referred from outside sources, there are but few which are technically adequate, or have any real diagnostic value. Not only is the photography itself poor; the entire procedure would appear to have been carried out with the idea of making as much commercial profit as possible for the roentgenologist, without regard to the needs of the physician who is attempting to make the diagnosis from these X-rays, or to the benefits which the unfortunate patient — who must foot the bill — hopes to derive from undergoing the ordeal of being roentgenologically examined.

The dorso-ventral position seems to be the only one most commercial X-ray men are aware of. They pay no attention to the body habitus of the particular individual under observation, and as a result, bony landmarks are not uncommonly wholly beyond recognition. Again and again the very viscus which is supposed to be under examination will be partially or even wholly invisible. Most of these "sets" of gastro-intestinal tract roentgenograms consists merely of 24-hour observations following the ingestion of the barium meal. It is quite impossible to ascertain the rate of colonic motility in a period of this length. Seldom is the necessary information in regard to the condition of the appendix elicited. No attention is paid to its filling time, to whether or not emptying is delayed, whether it is freely moveable, or is fixed by adhesions, and practically never is there any attempt to palpate the appendix under screen observation in order to see if tenderness can be elicited. Yet no gastro-intestinal examination is complete if no attempt has been made to gain this information.

Not only is the motility of the appendix passed over as of no importance; the movements of the colon itself are seldom routinely observed and recorded. Roentgenography, without collateral roentgenoscopy, is of small value for gastro-intestinal diagnosis, for the "mechanics of the digestive tract" are of equal, if not greater importance than its outlines, or the density of its shadows. Only those who have had both bedside and laboratory experience, who have seen these conditions many times not only in the clinic but at the postmortem table as well, are competent to interpret radiograms, or to make them in the first place. Merely owning an X-ray machine does not supply a man with such knowledge, any more than the possession of a rapier makes him an expert swordsman. The family physician who has equipped himself with a fluoroscope has not by such a purchase automatically become an expert radiodiagnostician. Yet it is this type of ameteur work which we find everywhere in the gastro-intestinal field at the present time. To quote an able editorial by Burrill B. Crohn (3): "To let an inexperienced radiographer attempt the diagnosis of gastro-intestinal diseases is, unfortunately, only a waste of the patient's money and time, and a source of error to the family physician." The following is a case in point:

A woman 42 years of age, complained of diarrhea of several months' duration. Her family physician administered an opaque meal, fluoroscoped her and pronounced the stomach normal. The too-rapid emptying of the stomach was attributed to a 'neurosis,' and remedial medication given in the form of a bismuth salt powder. The remains of the barium meal and the bismuth salt combined to cause a partial obstruction of the intestine. After the lapse of several weeks another roentgen examination was made — this time with a flat plate. This showed barium still retained above an obstruction at the recto-sigmoidal junction. Proctoscopy revealed a cauliflower mass at this point. Had proctoscopy been done at the first complaint — as it probably would have been done had not the physician first consulted happened to possess a fluoroscope, although he was not equipped to do an instrumental examination of the rectum — much invaluable time would have been saved, and a fatal termination delayed, or avoided entirely.

When one considers what valuable information properly done radioscopy *can* convey, the failure to employ this diagnostic aid in the right way becomes little short of a crime against society. By no other means can we study the degree of pliability of the stomach wall, nor ascertain so well the function of the pyloric muscle; nothing else shows us the motility of the entire gastro-intestinal tract, how the viscera are separated, or how the terminal loop of the ileum lies in relation to the position of the cecum — a most important detail — knowledge which only the fluoroscope can supply. Palpation under the fluoroscope tells where tenderness exists deep in the abdominal cavity, and by changing the direction of the rays, and shift-

ing the position of the patient we can get views at practically all angles — an inestimable advantage.

Of course there are drawbacks and circumstances which lead to confusion, especially if the fluoroscopic examination is not backed up by flat roentgenography, and searching physical examination. As an example of this, Ettinger and Davis (4) have remarked, "Two circumstances make the fluoroscopic diagnosis of a niche extremely difficult for the roentgenologist. One of them is the great irritability of a diseased cap, which may be so marked that the actual time for perception of the silhoutte of the cap will be too short to recognize any details. A quick snapshot, however, makes a record which may be studied and evaluated later. Secondly, while usually the niche is represented as an area of increased density, swelling of the mucosa may obstruct the entrance to its lumen so much that only a slight trace of barium covers the base of the niche, and only a very faint shadow of the niche results, which escapes detection by fluoroscopy."

Still another consideration, is the danger of overexposure of the patient to the roentgen rays. We frequently dare not apply the rays long enough to enable us to visualize and examine suspected departures from normal outline and function. Combining fluoroscopic examination with the exposure of serial films lessens the chance of diagnostic error, by giving us data for counter-checking, and permitting us an opportunity to confirm by a leisurely examination of the films, the impressions gathered by fluoroscopic inspection.

CASE REPORTS ILLUSTRATING ERRORS

A history of several months' duration, obtained in the Gastro-enterological Department of the New York Medical College and Flower Hospital, from a man of 31 years, was generally vague, and in no way suggestive of ulcer, either above or below the pylorus. The gastro-intestinal X-ray series which he brought with him showed several plates in which the cap was not smoothly outlined. Presumably, because the bulb silhouette was not completely filled in, the roentgenologist had interpreted the irregular contour as indicating the presence of a duodenal ulcer. Yet chemical analysis of the stomach secretions produced acid values much too low for duodenal ulcer. Upon close study of the X-ray films a serrated appearance was noted in the outline of the greater curvature which may well have been attributed by the physician to indentation of the substance of the lower pole of the stomach by gas present in the transverse colon. Had the colon been properly cleared out before the X-ray exposures were made — a preparatory measure which should *never* be omitted, all such mistakes would have been obviated. Actually, the serrated appearance was caused by a large carcinoma arising from the greater curvature of the stomach. This was found at laparotomy to be inoperable because of metastasis to adjacent viscera.

Another case illustrates the folly of depending solely upon fluoroscopy in making a diagnosis of gastro-intestinal lesions: A woman in her late sixties showed a 6-hour residue on fluoroscopy of the barium meal. This was considered sufficient basis for a daignosis of gastric cancer. Another physician who examined this patient was interested only in the cardio-vascular system, and pronounced the case one of myocardial insufficiency. Circulatory failure soon brought about a fatal termination. A chronic gastritis, secondary to functional disarrangement of the circulation, had produced symptoms referable to the gastro-intestinal tract. The gastric symptoms occupied the high light in the clinical picture, obscuring the basic cause, and making the first clinician who examined the patient quite overlook the myocardial decompensation. Had X-ray films been available for leisurely examination, the absence of a filling defect would have been a complete negation of the diagnosis of carcinoma. The clinician would then, in all probability have bethought himself that a chronic pulmonary emphysema, with the myocardial weakness it can bring about, often causes a passive congestive gastritis so severe and to give rise to duodenal bleeding and ulceration. So, had fluoroscopy been combined with roentgenography, the symptoms of gastric distress, vomiting, etc., would have been recognized as cardiopathic instead of being primary to the gastro-intestinal tract, and the diagnosis of circulatory failure would have been readily reached.

Inadequate technique and improper interpretation of gastro-intestinal roentgenograms reach their acme when pathology of the appendix is in question. In the greater number of patients referred to our clinic, who come bearing their X-rays with them, the roentgenographic diagnosis will contain some reference to the appendix as a probable seat of trouble. Not a few patients come *after* they have been relieved of their appendices, but not of the symptoms which were previously attributed to disease of this portion of the intestinal canal. Many more bring a negative diagnosis, because the pictures made of them either did not show the appendix at all, or showed no drainage from it, or again, the films yielded no signs of the appendix but did reveal evidences which had been taken to indicate that the ileo-cecal valve was incompetent. The diagnosis of chronic appendicitis was usually based on visualization of the organ 24-hours after the barium meal was ingested; that of valve incompentancy on the visualization of a barium suspension enema — which is in itself an artifically induced incompentancy. No 24-hour examination can include proper study to determine incomplete filling, delayed emptying, and fixation of the appendix. To do this properly would mean continual observation until all barium had been emptied from the colon. And so long as the cecum and the ascending colon are still filled with the barium residue the appendix cannot empty because of regurgitation. Only when the proximal colon is empty, a cathartic having been used to insure complete voiding, if palpation under the fluoroscope still elicits tenderness, can we say positively that the appendix is at fault.

In respect to ileo-cecal incompetency — the readings taken before coming to us were invariably made from a suspension enema picture made *before* the medium had been evacuated. Most of the plates did not show the mucosal relief of the colon following the expulsion of a greater part of the enema material. No attempt was ever made to check the roentgenographic findings by those of the laboratory. For example, in true ileo-cecal incompetency indicanuria is common. When analyses were made of the urine of patients referred with this diagnosis indicanuria was not demonstrated. Such an examination, made before the X-ray series is undertaken, will serve as an important check, and help solve many diagnostic enigmas.

ERRORS IN INTERPRETING GASTRO-DUODENAL DISEASES

The factors of error in the diagnosis of gastro-duodenal disease made by X-ray alone have been well summed up by Kirklin (5) (in part): Failure to make due allowance for normal variants, or to exclude conditions simulating disease; reliance on secondary and indirect phenomena, and on a limited roentgeno-

graphic examination. My own experience supplies many examples of this first postulant. Ignoring the possibility of a spastic condition being present in the alimentary canal is probably the prime cause. Spasm is normal in certain parts and under certain conditions. Pathologic circumstances may arise which convert this normal spasm into most abnormal activity. Yet this is in a measure offset by the fact that not a few pathologic conditions betray their presence by evoking abnormal spascity. Very often it is the secondary and indirect phenomena which the competent and alert roentgenologist will observe and analyze which make diagnosis possible. But the X-ray is a machine, and most of those who employ it alone turn out machine-made results, varying the formula so little that one can usually foretell precisely what they have written down, even before unfolding the reports. All too many physicians, otherwise conscientious, have come to regard X-ray as a short cut to diagnosis and are willing to accept as gospel whatever interpretation a roentgenologist, often grossly deficient in the special knowledge required for proper deductions from the films of the barium-filled gastro-intestinal tract, may report the findings to be.

PROPER AND IMPROPER METHODS OF COLON ROENTGENOGRAPHY

Though there are many errors possible in examining the colon the most common are (1) Using roentgenography without invoking the aid of a fluoroscopic screen study, and (2) relying on a morphology plate alone, without seeking graphic evidence by inspection of the mucosa in relief, after the opaque medium has been evacuated from the colon. A competent internist, using his gloved hand, may with the aid of the fluoroscopic screen, view spastic phenomena with the naked eye, turning his patient from side to side until the whole digestive apparatus above the large bowel has yielded up its pathologic secrets.

Yet in such an examination diverticuli may be missed entirely, and ileo-cecal incompetency also. When studying the barium enema — if the first plate taken does not show the terminal ileum's outline, but the evacuation plate does show it, we may deduce a reflux from the cecum into the ileum; that is, ileocecal incompetency. The same deduction is justified when at the ninth or twelfth hour after ingestion of the barium meal, the ileum is empty, but when viewed at the end of the twenty-fourth hour, is found to be filled again. This too, indicates incompetency of the ileo-cecal valve.

DETECTING DIVERTICULI

Diverticuli can best be detected when the colon has been emptied of the barium, and one is able to view mucosa in relief only when the suspension enema has been completely withdrawn. Remembering that a colon may be morphologically normal, yet physiologically abnormal, it will readily be understood that either fluoroscopy or X-ray photography will fail to demonstrate everything, so that only by a combination of the two methods can we hope to discover both anatomical distortions and physiological disturbances. In one case which came under my inspection, a diverticulosis of the distal colon had been missed entirely, and was only brought to light when the double contrast method had been employed.

CO-RELATION OF ROENTGENOGRAPHY AND PHYSICAL FINDINGS

A roentgenographic diagnosis may be absolutely correct, yet if taken without consideration of the physical findings, absolutely misleading. This is illustrated by the case of a woman reported to be suffering from rectal constipation. Bi-manual pelvic examination, however, disclosed a cause, not only for the constipation, but also for the headache, backache and other symptoms for which the constipation — itself no more than a symptom — had been held responsible.

Relaxation of the recti muscles and extensive perineal tears involving the levatores ani were revealed by the pelvic examination. These were first remedied by suitable operative procedures. The supposed gastro-intestinal tract symptoms then disappeared.

X-RAY DIAGNOSIS OF GALL BLADDER DISEASE

"Mechanical cholecystography" accounts for many errors in the popular procedure for the diagnosis of gall bladder disease. How often is the patient questioned as to what has happened after he ingested the dye, but *before* the roentgenographic exposures were made? Even a slight diarrhea may be sufficient to carry off the dye before it could collect in the gall bladder densely enough to permit visualization. Knowing nothing of this, the roentgenographer will be unable to visualize the gall bladder, so will send in a report that the dye has not filled the gall bladder, making the findings 'positive' for a pathologic condition.

PROPER METHOD OF VISUALIZING THE GALL BLADDER

But when such a patient is given a mixture of opium, bismuth subnitrate and mistura creta in appropriate doses, he will sleep through the night and retain the dye long enough to permit its absorption in the gall bladder. Then if he undergoes a second X-ray examination, his gall bladder will be reasonably well visualized.

In two other cases where nothing could at first be made out of the gall bladder, it was noted that biliary drainage brought away only an oily material. This was due to the existence of cystic-duct catarrh. When this had been evacuated the gall bladder could be visualized, although rather faintly.

BILIARY DRAINAGE BEFORE ROENTGENOGRAPHY ESSENTIAL

The bile should always be examined before roentgenography is undertaken. If this is properly done biliary drainage will frequently furnish all the information required. This will spare both physician and patient additional trouble and expense.

Very frequently the outline of the gall bladder may be normal, but disease, nevertheless, will be present. More than this, drainage of the gall bladder is necessary before an X-ray examination is made if for no other reason than to fill the viscus with fresh bile, which entering laden with the dye, will give a sharp contrast such as stale bile will never offer. In some cases we cannot find out why the gall bladder does not show up on the X-ray film. But the routine of drain-

age and trans-duodenal lavage alone, was sufficient to clear up the pathologic condition — even if it never was adequately diagnosed.

Mention has been made of the importance of stomach chemistry in throwing light in otherwise obscure diagnostic factors. It is unfortunate that this valuable assistant to gastro-intestinal practice is not more widely employed. When rapid gastric clearance is seen under the screen its meaning may be wholly misinterpreted, unless it is checked up by the findings of gastric chemistry. In an elderly individual, rapid gastric clearance *may* mean a gaping pylorus — sometimes due to syphilis, but more often to a developing malignancy. Yet unaided the roentgenologist would report such a stomach as 'negative' to both these conditions. At best the screen only records motor function; chemical analysis tells of secretory activity — or the lack of it — which is just exactly as essential to adequate and complete diagnosis of gastric disturbance. The appendix may fill and empty normally, yet heightened gastric chemistry may throw an entirely different light upon the X-ray findings. A 'silent' duodenal ulcer may remain undiscovered unless persistent hyperchlorhydria, which Moynihan (6) has called "the term for the surgical condition of duodenal ulcer," is revealed by a chemical examination.

Gastroptosis, the "dropped stomach" of lay parlance, is the cover under which many an inefficient diagnostician — roentgenographic and clinical — has taken refuge. The number of patients who, having undergone operation, return with a diagnosis of "adhesions" would be a cause for laughter, were it not fraught with such tragic possibilities. Far more often the diagnosis should be "poor surgery" or "inadequate roentgenography." To quote Kirklin again: "On the roentgenologist devolves a two-fold duty: to find evidence of disease when disease is present, and to avoid a diagnosis of disease when disease is absent." It is harder *not* to find disease because of an inclination on the part of most examiners "to interpret all unusual phenomena in terms of pathologic change."

The economic embarrassment now burdening the rank and file of the medical profession appears to me to be the underlying cause of much of the demoralization now prevalent in gastro-intestinal diagnosis. In trying to make good the tremendous losses which all have incurred by the utter inability of perfectly honest patients to meet their financial obligations, many have been misled by specious arguments and attractive advertising into believing that it will be a relatively simple matter to "specialize" in roentgenographic diagnosis. Many a naturally analytical mind has thus been converted into a machine-made diagnostician. It is but evidence that physicians are primarily human beings; that they try to obtain a share of the rewards of advertising — whether outspoken or indirect — which they see reaped in abundance by purveyers of cosmetics, tobacco and vapid entertainment, while the doctor remains unpaid and unappreciated. It would seem that the gastro-enterologist is peculiarly susceptible to these evil influences. He should, therefore, struggle with all his strength to maintain the high standards of his specialty, and ever bear in mind the tremendous importance of diagnosis in the carrying out of that particular line of medical practice.

CONCLUSIONS

The specialty of gastro-enterology occupies a wide area in the field of medicine and requires an elaborate background. The proper practice of this specialty demands a peculiarly wide experience in general medicine, a keenly analytical mind, and a willingness to embrace the new, but only when that 'new' gives evidence of correlation with all that has gone before. Many men have been induced to enter gastro-enterology who are fitted neither by training nor inclination for the proper performance of its most exacting requirements. Our calling has been cheapened, and a reproach cast upon all those who have long striven to maintain the standards thus ruthlessly degraded.

The application of the X-ray to gastro-intestinal diagnosis has offered peculiarly easy conditions for inefficiency and fraud to creep in, and for ignorance and egotism to usurp the position which properly belongs to those who have raised the standards now overthrown. It has been demonstrated that gastro-intestinal roentgenography, unallied with roentgenoscopy, and uninterpreted by comparison with the findings of the amemnesis, the physical exploration and the laboratory analysis, is bound to be full of errors.

The confusion of standards existing today in gastro-enterology should be remedied. A legal definition for a gastro-enterologist should be established by suitable medical legislation, as has been done in several other specialties. The man who desires to assume that title should be compelled to submit evidence of his fitness to a competent board. Long practice in general medicine, close association with clinical gastro-enterology in a properly conducted clinic, with post-graduate work supervised by competent authorities — these should be the least of the pre-requisites for registration as a specializing gastro-enterologist. Until such a standard has been legally established confusion will continue to reign, and gastro-intestinal diagnosis will continue to present the contradictions and confusions which it has been the intention of this paper to present for criticism and correction.

Tumors of the Small Intestine: A Review of the Literature and Report of Eight Additional Cases*

By

JUSTIN J. STEIN, M.D.
HINES, ILLINOIS

DURING the past five years there has been an encouraging increase in the number of articles written on the subject of small bowel tumors. Many cases who have died with symptoms of intestinal obstruction have probably had as their etiological factor such undiagnosed tumors. So little is known about tumors of the small bowel and since such few symptoms have their origin within its confines, it may be referred to as "the unknown area" of the abdomen.

The malignant growths occurring in the small bowel are carcinoma and sarcoma. The benign tumors most commonly found are myomas, polyps, hemangiomas, lipomas, adenomas, fibromas and cystic tumors. These benign tumors are usually discovered accidentally at operation or at necropsy for the most part, since probably less than half of them produce any symptoms.

The etiological factors in the causation of tumors of the small bowel are entirely theoretical. The most commonly suggested theories are based upon the absence of abrupt angulations in the small intestine, the fluid nature of its content and the alkalinity of the intestinal fluid. The above listed factors differ considerably from those found in the large bowel. It must be admitted, however, that there is no real basis to account for the rarity of tumors of the small bowel as compared with other parts of the gastro-intestinal tract.

INCIDENCE

At the Mayo Clinic, based upon a study of cases between January 1, 1919, and October 1, 1929, inclusive, carcinoma occurred in the small bowel thirty-one times as compared with 2,775 times in the large bowel and rectum and 2,646 times in the stomach (1). To date Hartman (2) has found only 70 cases of carcinoma and 27 cases of sarcoma of the small bowel at the Mayo Clinic. As compared with the above he found only 44 cases of benign neoplasm. The most common benign neoplasms found were myomas, polyps and hemangiomas. In a review of the statistics of 41,838 necropsies of the Vienna General Hospital, Johnson (3) found 3,585 cases of carcinoma, of which 343 were intestinal; 10 of these were located in the ileum and none in the jejunum. In a series of 780 carcinomata of the intestinal tract, Leichtenstern (4) found only 16 primary in the ileum. Rowley (5) reviewing 15,000 laparotomies at the Hartford Hospital found only one sarcoma and one carcinoid tumor of the small bowel. Gotten (6) of Memphis, was able to find only 4 cases of carcinoma of the small bowel in the records of 20,000 patients at the Polyclinic Hospital. In the same series he found 4 cases of sarcoma, one of which occurred in the ileum of an infant 14 months of age. A study of the records in the Presbyterian Hospital by Parsons (7) revealed 6 cases of small bowel carcinomata, excluding carcinoma of the terminal ileum at or near the ileocecal valve. A series of 82 tumors were reported from the John Hopkins Hospital by Raiford (8) in 1931. The tumors were located between the pylorus and the ileocecal junction and represented 6.5 per cent of all other gastro-intestinal tumors. In this group there were 18 in the duodenum, 14 in the jejunum (7 benign) and 43 in the ileum; location not reported in 7. Forty per cent of the tumors were asymptomatic. Ross (9) reported two cases of intestinal carcinoma in 1931, these being the only cases reported at the Melbourne Hospital between 1922 and 1931, during which time 70,000 out-patients were treated and necropsies performed on 75 per cent of patients dying in the hospital. Hinz (10) found only 18 carcinomas of the small bowel in a series of 584 cases of carcinoma of the intestinal tract. Mueller (11) reported from the Institute of Berlin 5,691 necropsies with 521 cases of carcinoma, 42 intestinal, and of these 42 only 3 were located in the small bowel. Maydl (12) reported 1,460 cases of carcinoma in 20,480 necropsies with 100 cases of intestinal carcinoma, 4 of which were carcinoma of the ileum. Zieman (13) reported 165 cases of carcinoma of the intestine from 21,624 necropsies; 6 were in the ileum. Hellstrom (14), in 1927, collected only 70 cases of carcinoma of the small bowel proven by operation from the literature. He reported 3 cases. In 1929 D'Allaines (15) was able to collect only 114 cases of carcinoma of the small bowel from the literature. Barnhart (16) found only 77 cases of carcinoma of the jejunum and ileum up to the beginning of 1931. From the above data it may be readily seen that the percentage of small bowel carcinomata is much less than the 3 per cent of the intestinal carcinomata which is usually referred to in the literature.

At the Edward Hines, Jr., Hospital from January 1, 1931, to July 1, 1936, a period of five and one-half years, carcinoma occurred in the small bowel six times as compared with 253 times in the large bowel and rectum and 183 times in the stomach. The incidence of carcinoma of the small bowel as compared to the large bowel in this series is 0.027 per cent. During this period of five and one-half years there were 39,444 admissions to the hospital.

SARCOMA

Staemmler (17) found only 33 cases of sarcoma among 54,000 necropsies reviewed. He reports the incidence of sarcoma of the intestines at necropsy as 0.06 per cent and carcinoma of the intestines at necropsy as 1 per cent. He further states that the proportion of sarcoma to carcinoma of the intestines as established at necropsy is about 1 sarcoma to 16 carcinomas, whereas in surgical practice based on statistics by German and Austrian surgeons, it is about 1 sarcoma to 100 carcinomas. Corner and Fairbank (18) collected from the literature 103 cases of sarcoma of the intestines. Sixty-three per cent of this group were located in the small bowel, the largest number being in the ileum and 37 per cent in the large bowel. Nothnagel (19), in 1904, reported 243 cases of intestinal sarcoma out of 24,358 necropsies. Smoler (20) found only

Submitted March 11, 1937.

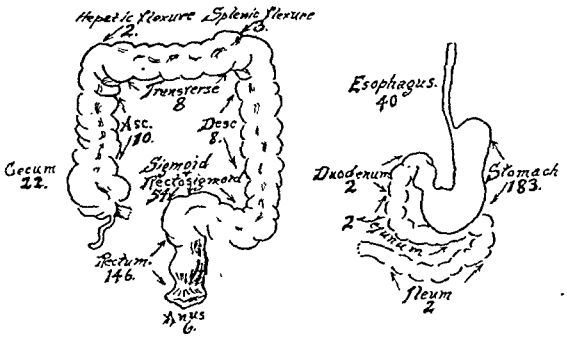

Fig. 1. Carcinoma of the gastro-intestinal tract at Hines Hospital from January 1, 1931, to July 1, 1936.

13 cases of primary sarcoma of the small bowel in 13,036 necropsies at the Prague Pathological Institute between the years 1883 and 1898. None of the cases were in the jejunum and 6 were in the ileum. Speece (21) collected 101 cases of sarcoma and directed attention to the frequency in which they produced intussusception. Sarcoma apparently occurs more frequently in the ileum than in the duodenum or jejunum, the reverse for the incidence of carcinoma. Ullman and Abeshouse (22) collected 125 cases of lymphosarcoma of the small and large bowel and reported 1 case making a total of 375 cases up to 1932. From the study of the 126 cases collected by them, they concluded that lymphosarcoma is twice as common in the small bowel than in the large bowel. The most common location was in the ileum.

In the group of 8 neoplasms reported in this paper taken from 39,444 admissions to the Edward Hines, Jr., Hospital, only one sarcoma was found, its location being in the jejunum.

As has been previously mentioned, Hartman (2) found only 44 cases of benign lesions of the small bowel as compared with 97 malignant neoplasms. In 1928 after making a complete review of the literature, Golden found only 17 reports of cases of non-malignant tumors of the duodenum. In 1924 Brown (24) after making a careful search of the literature found 19 cases of vascular tumors of the intestinal tract below the stomach. In this group were included all forms of vascular tumors, varying from capillary naevi to cavernous angiomas. He reported a case of cavernous hemangioma in the jejunum of a 12-year old girl. In 1917 King (25) was able to find reports of 119 benign tumors of the intestine, only 47 of which were in the small bowel. Only one benign tumor, a hemangioma of the jejunum, has been found at the Edward Hines, Jr., Hospital during the past five and one-half years.

Clifton and Landry (26) reviewed 45 cases of fibroma of the intestines. In 25 of these cases the tumor was located in the small bowel. The tumors were intraluminal in type in all but two cases. Adenomata are generally the most commonly found benign tumors of the small bowel.

AGE AND SEX

Carcinoma: Ewing (27) lists the average age as 46.5 years. The average age for the group of 6 cases of carcinoma of the small bowel reported in this paper was 49.1 years. Rankin and Mayo (1) found the average age of patients with carcinoma in their series of 55 cases to be 47.5 years. Primrose (28) reported a primary carcinoma in the small bowel in an octogenarian. Duncan (29) reported a scirrhous carcinoma in a patient 3.5 years of age. Rankin and Mayo (1) found the ratio with regards to the sexes in their group of 55 cases to be approximately 2 to 1; 37 males and 18 females. Other reports in the literature give a similar ratio.

Sarcoma: In a statistical study of 126 cases by Ullman and Abeshouse (22) the average age incidence was 33.19 years. The ratio for the sexes was 5 to 2, the males showing a greater predisposition for the disease. Corner and Fairbanks (18) found that the age incidence for sarcoma of the small bowel was between 30 and 40 years for the majority of cases. This type of tumor is found most frequently during the first, third and fourth decades. In the series of 59 cases of sarcoma of the small bowel listed by Libman (30) more than 50 per cent occurred between the ages of 20 and 40 years. The youngest patient was five days old.

Benign tumors: In the 35 cases of benign tumors of the small bowel reported by Rankin and Newell (31) the average age of the patient was 38 years, the youngest patient being 14 years of age and the oldest 70. Nineteen patients of the series were males and sixteen females. In the 20 cases collected by Brown (24), vascular tumors of the intestines, both large and small, the age of the patients varied from 2 months to 79 years. In 2 of the cases the age was not stated. The average age in the remaining 18 cases was approximately 41 years. Classification as to sex listed 10 females and 10 males.

SYMPTOMATOLOGY

Carcinoma: There are no characteristic symptoms associated with tumors of the small bowel. The most common symptomatology found in the majority of cases is that of intermittent partial obstruction. Occasionally the first symptoms manifested are the result of an acute obstruction. The usual picture is that of a series of partial obstructions which gradually become more severe. The slowly increasing encroachment of the tumor upon the lumen of the bowel produces the attacks of intestinal obstruction, as stated above, with abdominal pain which may have a paraumbilical or low abdominal location, vomiting, dehydration and finally collapse. The fact that patients may quickly recover from an attack of acute obstruction may be explained upon the basis of food substance which may become lodged temporarily in the constricted lumen of the bowel. As the obstruction increases the proximal bowel becomes dilated, the valvulae conniventes become prominent and the muscle fibers undergo hypertrophy. Fistulous communications may be established between neighboring coils of bowel with the more malignant types of adenocarci-

Fig. 2. Adenocarcinoma of the duodenum (Case No. 1).

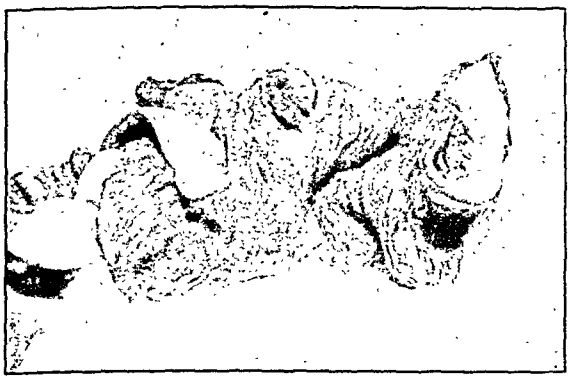

Fig. 3. Tumor of the ileum (Case No. 6).

noma. When the obstruction is situated high in the small bowel and is of the acute type, there is a rapid loss of fluid and solids by constant vomiting and death may occur rapidly from dehydration, demineralization and starvation. The sessile and intraluminal tumors are more likely to produce intussuception.

The most outstanding symptoms of intestinal obstruction are (1) abdominal pain, (2) vomiting and (3) constipation. Abdominal pain is present in practically every case and is the direct result of the vigorous peristalsis initiated to overcome the obstruction. Abdominal distension will be noticed in a large number of cases. Although visible peristalsis is generally mentioned, it is usually a late finding. A history of tarry stools is seldom given. A secondary anemia of varying degrees is usually found. If a mass is palpable, it is often tender and is not fixed in position, but is freely movable.

Sarcoma: The same type of symptoms may be found with the sarcoma group as with the carcinomata. The onset may be gradual and vague or it may begin suddenly as an acute abdominal emergency. Most of the cases of sarcoma reported have a gradual onset since the pathology of the tumors in the majority of cases is of the annular type. The polypoid type growth is more prone to produce intussuception. The alternating constipation and diarrhea found in some of the cases is the result of the stagnation of retained material in the paralyzed and distended loops above the obstruction. When the toxic products cause complete or partial emptying of the distended loop, a diarrhea may result.

Benign tumors: The symptoms of the benign group of tumors is very similar to that of the carcinoma and sarcoma groups. The pedunculated forms are more likely to produce intussuception. These tumors usually occur early in life and may be present for many years before producing symptoms or may not be discovered except during the course of an operation or at necropsy. The symptoms in the cases having encroachment of the tumor on the lumen of the bowel are usually chronic in nature and recur at irregular intervals whereas with the intussuception group the attack will be initiated by a sudden onset of sharp, colicky pain, nausea, vomiting and abdominal distention.

Although roentgenograms are very helpful in determining the presence of intestinal obstruction, the diagnosis is at times very difficult and quite often it is necessary to make examinations at intervals. A flat plate of the abdomen showing distended loops of bowel, especially when intra-intestinal fluid levels are present, is diagnostic of obstruction. In 1928, Case (32) reported that gas and fluid began to accumulate within six to eight hours after obstruction had been established. Roentgenographic examinations may be particularly helpful in ruling out lesions of the stomach, duodenum and colon.

TREATMENT AND PROGNOSIS

Carcinoma: When the tumor is removable, resection should be done restoring the continuity of the bowel with an end-to-end anastomosis. If the tumor is not resectable, a side-tracking procedure must be resorted to.

The prognosis is poor regardless of whether or not the growth is resectable. In the series reported by Rankin and Mayo (1) no patient had at the time of the report lived longer than three years and the average was one year.

The average length of life whether treated surgically or not of the group of six cases reported in this paper was fifteen months from the onset of symptoms. Only one patient lived forty-eight months after the onset of symptoms. Metastasis occurs early in the course of the disease.

Sarcoma: If it is at all possible to cure the patient, a resection of the involved bowel should be done. If the growth is too extensive, a side-tracking operation should be done as a palliative procedure. This may be accomplished by means of an entero-enterostomy, ileocolostomy or colostomy. Both the operable and inoperable cases should receive irradiation since this type of tumor is usually radiosensitive. Although many of the patients die within the first year after operation, there are reports in the literature of patients living more than five years following resection and irradiation.

Benign tumors: More conservative methods are employed in the surgical treatment of the benign group. They may be removed by means of an elliptical incision or by shelling out the lesion from the bowel. If the lesions are extensive, a resection may be done followed by end-to-end anastomosis. In Rankin and Newell's (31) series of 35 patients, all were operated without a single mortality.

Case No. 1. Reg. No. 56310, age 48, white male, was admitted 9-1-34. He stated he was in good health until five months previous to admission at which time he began

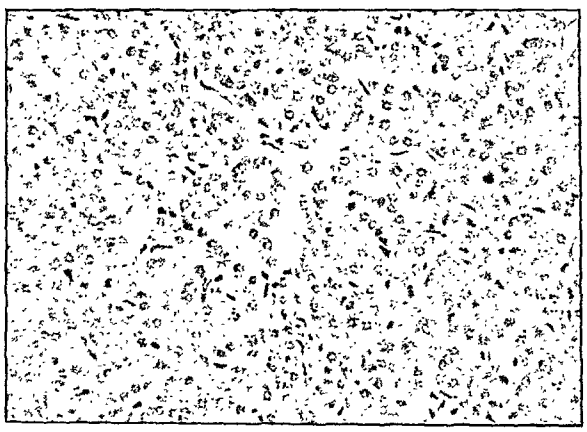

Fig. 4. Adenocarcinoma of the ileum (Case No. 7).

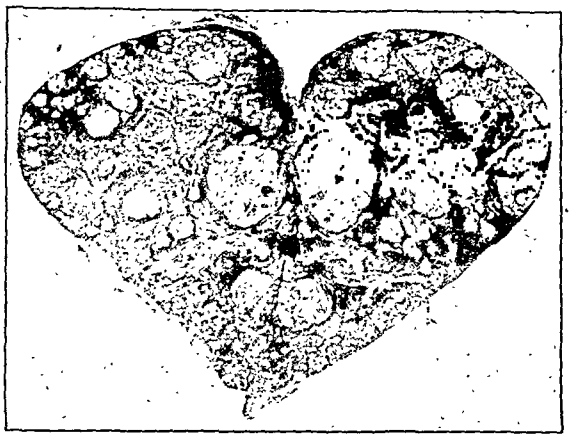

Fig. 5. Metastatic lesions in the liver from an adenocarcinoma of the ileum (Case No. 7).

to notice dull epigastric distress coming on when the stomach was empty and only partially relieved by food and soda. Associated with this was a gradually progressive loss of weight and weakness. Two months prior to admission he consulted a physician who made a diagnosis of duodenal ulcer and patient was placed on Sippy management. This relieved his distress but he continued to lose weight and to become weaker. Three weeks previous to admission he suddenly became icteric. In three days icterus became quite severe. The stools became clay colored and the urine was very dark. There was pronounced itching of the skin. There was no pain, nausea or vomiting associated with this. There was no history of blood in the stools. Weight loss, 55 pounds in five months.

Physical examination revealed a profound icterus of the skin, mucous membranes and sclerae. Patient appeared critically ill. There was tenderness on palpation in the epigastric region. There was a small mass in the right upper quadrant which was movable and smooth and was in all probability the gall bladder. The liver had increased in size.

Laboratory examinations: X-rays—G. I. series were not done because of the critical condition of patient. Erythrocytes 1,600,000, leukocytes 14,600, hemoglobin 40%; polymorphonuclear 92%. After transfusion of 500 c.c. citrated blood, erythrocyte count was 1,960,000; hemoglobin 50%. Urinalysis: albumin, positive, bile positive, many granular casts. Blood chemistry: urea 14.1 mgms., sugar 80. Wassermann and Kahn negative. Icteric index 27. Vandenberg, prompt direct. Feces positive for blood; parasites not found.

Clinical diagnoses: ulcer, peptic, active, severe; carcinoma, pancreas, undetermined; secondary anemia. The patient's condition was such that he did not respond to intravenous medication or blood transfusion sufficiently to enable him to be explored. He expired 9-10-34.

Necropsy revealed (1) ulcer, gastric with secondary hemorrhage; (2) adenocarcinoma of the duodenum, which was considered to have been primary in the duodenum on the basis of malignant regression of a duodenal ulcer, by the pathologist.

Case No. 2. Reg. No. 61759, age 52, colored male, admitted 6-4-35. Patient gave history of a mass starting in the left side of neck of about one year's duration. Patient complained of considerable difficulty in breathing, pain in the chest, difficulty in the passage of bowels, swelling of both legs and ankles, especially the right.

Physical examination revealed a critically ill patient. There was a slight icteric tinge to the sclerae. There was a slight ptosis of the lids. There was a very extensive mass in the left side of the neck which extended from the angle of the jaw filling the entire left side of the neck from the clavicle to the angle of the jaw and extending down on to the chest wall. Several discrete nodules were present on the surface of the mass. There were discrete nodules palpable in both axillae and both inguinal regions. The liver was enlarged on palpation. There was considerable edema of both lower extremities. On rectal examination there were discrete nodules filling the pelvis and the nodules were fixed to the pelvic wall.

Laboratory findings: Urinalysis was essentially negative. Wassermann and Kahn negative. Erythrocytes 4,660,000, leukocytes 7,100; hemoglobin 85%; icteric index 13; Vandenberg, prompt direct. X-ray of neck revealed a new growth, soft tissues of the cervical region. X-ray of chest revealed a heavy shadow of abnormal density which covered the region of the cervical, upper thoracic and left shoulder, giving the impression of an extrinsic lesion. There was no evidence of metastasis within the lung fields. Gastro-intestinal series were not satisfactory on account of the physical condition of the patient. Fluoroscopic examination of large intestine following barium enema revealed considerable deformity in the upper portion of the rectum. The deformity was very irregular and produced considerable constriction. The findings suggested a pathological process, probably a new growth. Definite bony changes were noticed involving the ischia and pubic bones. Histological diagnosis of biopsy removed from node, left axilla, revealed a colloid carcinoma.

Patient was given deep X-ray therapy to the mass in the neck producing very little change in its size. The patient died 7-18-35.

Necropsy revealed carcinoma of the duodenum with extension to adjacent structures and metastases to the liver, suprarenal glands and skeletal system.

Case No. 3. Reg. No. 44331, age 48, white male, admitted to the hospital 9-29-32. History dated back to the first week in May, 1932, at which time he suddenly developed an acute generalized abdominal pain two hours after eating. The pain was quite severe. The patient did not vomit or have any other gastro-intestinal symptoms. The pain continued fairly constant for about four days and then gradually disappeared. A local physician was consulted, but no diagnosis was made. The patient lost from ten to twenty pounds in weight in about two months. The pain suddenly recurred about July 15. The pain was similar in type to that of the original onset, but was not as severe. Since July, 1932, he had felt a tender mass situated near the umbilicus. There was no history of passage of blood per rectum.

Physical examination revealed evidence of considerable loss of weight. There was no cervical, supraclavicular or axillary adenopathy. There was an enlarged firm node in the right inguinal region. There were no definite abdominal masses palpable. Rectal examination revealed a very large firm, nodular mass which apparently had not originated in the rectum.

Laboratory findings: Urinalysis negative. Wassermann and Kahn negative. Blood count: erythrocytes 4,360,000; leukocytes 9800; hemoglobin 80%. Guinea pig inoculations of specimens from right and left ureters revealed no evidence of tubercle bacilli on necropsy. X-ray findings, gastro-intestinal tract, revealed no demonstrable evidence of the gastro-intestinal tract or gall bladder. X-ray of chest was negative. X-ray of genito-urinary tract was normal. Histological report of biopsy removed from right inguinal region revealed a metastatic adenocarcinoma.

Deep X-ray therapy to abdomen and right inguinal region was given affording the patient some relief from his pain and patient was discharged upon his own request 12-13-32 with a diagnosis of adenocarcinoma, metastatic, primary source not known. Patient had a recurrence of his symptoms and was admitted to another hospital where he expired on 2-16-33. Necropsy revealed a primary carcinoma of the jejunum with extension to the peritoneum

and regional lymph nodes and metastases to duodenum, liver, spleen and pancreas.

Case No. 4. Reg. No. 53060, age 43, male, white, admitted to the hospital 3-24-34. Patient stated that he noticed a small lump just above the umbilicus for the past 6 years. Also about the time he noticed this mass he began having cramping pains in his abdomen which occurred at irregular intervals. His appetite became impaired and he had frequent attacks of vomiting which would partially relieve the abdominal pain. He lost about 40 pounds in weight during the period two to three years prior to admission. The abdominal mass gradually increased in size. Five months previous to admission he was operated upon at a private hospital. At operation a mass involving the small bowel about eighteen inches from the pyloric end of the stomach was found. This mass was removed and an anastomosis of the small gut made, drainage introduced and the abdomen closed. Biopsy report from the National Pathological Laboratory, St. Louis, Missouri, was carcinoma of the small bowel (jejunum). Since operation patient had abdominal pain and nausea at frequent intervals. There was no history of passage of blood in the stool.

Physical examination revealed a fairly well nourished and developed white male, appearing chronically ill. There was a post-operative hernia present in his operative scar. There was a mass palpable to the left of the abdomen.

Laboratory findings: Urinalysis was essentially negative. Wassermann and Kahn negative. Blood count 4,500,000 erythrocytes; 10,000 leukocytes, 85% hemoglobin. X-ray examination, gastro-intestinal series revealed a normal gall bladder and normal stomach. Barium enema revealed a normal colon.

Because of recurrence of patient's symptoms and because of the palpable abdominal tumor, the patient was explored. A large intraabdominal tumor (retroperitoneal) was found. There were numerous adhesions between the liver and abdominal wall and between the omentum and abdominal wall and between coils of small intestine, producing partial obstruction. An anastomosis was made between a distended loop and a collapsed loop of small bowel. Patient did not react favorably following operation and died 8-15-34, approximately three months following the operation.

Necropsy revealed an adenocarcinoma of the jejunum with ulceration and perforation and regional metastases.

Case No. 5. Reg. No. 62391, age 43, white male, admitted 7-3-35. Patient gave a history of having had a moderate distention of his entire upper abdomen associated with a cramplike pain and marked tenderness of abdomen upon palpation. Onset was about six months prior to admission during which time he lost about 25 pounds in weight. There had been no nausea, no vomiting and no passage of blood per rectum.

Physical examination revealed a chronically ill patient in poor condition. Two large abdominal scars were noted which were the results of previous appendectomy and cholecystectomy done elsewhere. Abdomen was distended and patient complained of marked tenderness on palpation, making the examination unsatisfactory. However, no masses could be definitely palpated. Liver was not enlarged. There was an enlargement of the lymph nodes in the right axilla.

Laboratory findings: Urinalysis essentially negative. Wassermann and Kahn negative. Erythrocytes 4,150,000; leukocytes 13,000; polymorphonuclears 84%; hemoglobin 70%. Examination of sputum revealed no tubercle bacilli. Histological report of biopsy removed from right axillar revealed tuberculosis. Fluoroscopic examination of large intestine following barium enema revealed a normal colon. Examination of chest by X-ray revealed no evidence of metastasis.

Patient developed pneumonia while in the hospital and expired 9-10-35. Necropsy revealed a lymphosarcoma, primary in the jejunum with involvement of adjacent lymph nodes.

Case No. 6. Reg. No. 52769, age 62, white male, admitted 3-9-34. Patient stated that about five months previous to admission he began to have frequent pains, particularly in the lower half of abdomen. There was no history of vomiting or icterus. Patient had lost about 68 pounds in weight over a period of five months. There was no history of passing of blood per rectum. Prior to admission to hospital patient developed severe diarrhea.

Physical examination revealed a markedly emaciated senile white male, who appeared seriously ill. The liver was enlarged about two fingerbreadths below the costal margin. Patient complained of tenderness in the right upper quadrant on deep palpation. There was also a palpable mass in the right upper quadrant which was probably the result of metastasis to the liver.

Laboratory findings: Wassermann and Kahn negative. Urinalysis, albumin positive; coarsely granular casts present. Blood count: erythrocytes 4,200,000; leukocytes 23,000; polymorphonuclears 75%; hemoglobin 80%. Gastro-intestinal series revealed a pathological process situated near the pyloric end of the stomach. Upon fluoroscopic examination of the large intestine the examiner was unable to rule out a new growth.

Clinical diagnosis: Carcinoma, metastatic to liver, primary site unknown, inoperable. Shortly before patient's death he developed pneumonia and expired 5-15-34. Necropsy revealed an adenocarcinoma of the ileum with metastases to liver and regional lymph nodes and bronchopneumonia.

Case No. 7. Reg. No. 34699, age 42, white male, admitted to the hospital 7-23-31. He was admitted in a critically ill condition for treatment of gastric ulcer. He gave a history of having had a gastric ulcer for several years. He was previously hospitalized for three to four months for treatment of this condition at another hospital. On this examination he complained of severe cramping pain epigastric region of several days' duration. He stated he was quite restless and had vomited greenish material at frequent intervals. Pain was quite severe.

Physical examination revealed a critically ill patient who gave evidence of having lost considerable weight. There was vigorous active peristalsis present. Signs of intestinal obstruction were quite evident.

Laboratory findings: Urinalysis essentially negative. Wassermann and Kahn negative. Blood count: Erythrocytes 4,800,000; leukocytes 8,600; polymorphonuclears 64%.

Patient was explored several hours following admission. At the time of operation there was considerable bloody

Fig. 6. Hemangioma of the jejunum (Case No. 8).

fluid in the abdominal cavity. There was a spontaneous rupture of the ileum near its terminal portion. A mass was found in this same region. Because of the condition of the patient an enterostomy was done and the abdomen closed as rapidly as possible. Patient developed an acute generalized peritonitis, which had apparently formed before operation, and he died 7-28-31.

Necropsy revealed an adenocarcinoma of the ileum with perforation and metastasis to the liver and purulent peritonitis; surgical enterostomy in the jejunum.

Case No. 8. Reg. No. 51987, age 46, white male, admitted 1-30-34. Patient stated he was apparently in good health until six weeks previous to admission at which time he developed a pain in the upper part of his chest. The pain later left the chest region and settled in the epigastric region. Pain was dull in nature and constantly present. Food seemed to relieve the pain at times. He lost twenty pounds in weight during the previous fifteen days to admission as a result of the severe vomiting spells which he had during this time. There was no history of constipation or passage of blood per rectum.

Examination revealed an enlarged liver two fingerbreadths below the costal margin. There was a palpable mass in the right hypochondrium. Patient also complained of tenderness upon deep palpation over this region.

Laboratory findings: Urinalysis essentially negative. Wassermann and Kahn negative. Blood count: 4,600,000 erythrocytes; 15,200 leukocytes; 72% polymorphonuclears; 85% hemoglobin. Blood chemistry: N.P.N. 36.4 mgm. Feces positive for blood. Fractional gastric analysis normal. Flat plate of abdomen normal. X-rays of gastrointestinal tract apparently normal; gall bladder normal. X-ray of chest normal.

Patient was explored on 3-9-34. A small tumor was found in the jejunum about 10 cm. from the Ligament of Treitz. The small tumor was excised and the incision through the intestine closed in two layers, using fine chromic catgut and silk. Histological examination of section of small intestine removed revealed a cavernous hemangioma. The tumor was composed of blood vessels and channels having as their basic factor a stroma consisting of loose connective tissue. Patient was discharged symptom free.

CONCLUSIONS

1. The incidence of carcinoma of the small bowel is less than one-half of one per cent in this series.
2. Sarcoma is more frequently found in the small bowel than in the large bowel.
3. Sarcoma apparently occurs more often in the ileum than in the duodenum or jejunum, the reverse being true for the incidence of carcinoma.
4. There are no characteristic symptoms associated with tumors of the small bowel. The most common symptomatology found in the majority of cases is that of intermittent partial obstruction.
5. The majority of cases of benign tumor and of sarcoma occur between the ages 30 to 40 whereas carcinomata are more often found in patients from 40 to 60 years of age.
6. A flat plate of the abdomen showing distended loops of the bowel, especially when intra-intestinal fluid levels are present, is diagnostic of obstruction.
7. Roentgenographic examinations may be particularly helpful in ruling out lesions of the stomach, duodenum and colon.
8. The treatment of a malignant tumor should be by resection, if the tumor is operable, restoring the continuity of the bowel by end-to-end anastomosis. If inoperable, a side-tracking procedure must be resorted to. Post-operative irradiation should be given to sarcoma cases whether operable or inoperable.
9. The prognosis is poor for malignant tumors whether operable or inoperable.
10. Metastasis occurs early in the disease and involves adjacent structures first.
11. More conservative surgery should be employed in the treatment of benign tumors of the small bowel.
12. The prognosis is excellent for the benign tumor cases.

The Mechanism of Milk Clotting*

II. Role of Hydrogen Ion Concentration

By

I. NEWTON KUGELMASS, M.D.

NEW YORK, NEW YORK

THE course of clotting has been followed varying the pH of milk and the phenomena observed throughout the physiologic range of pH. The experiments were carried out at 37° C. in a thermostat and the pH measurements made with a quinhydrone electrode except in cases where the pH was varied with standard buffer solutions. The role of the individual components have been previously evaluated in the clotting process (1).

(1) Changes in the Hydrogen Ion Concentration During Clotting.

The pH of each of the clotting components was measured as a basis for comparison with the final pH

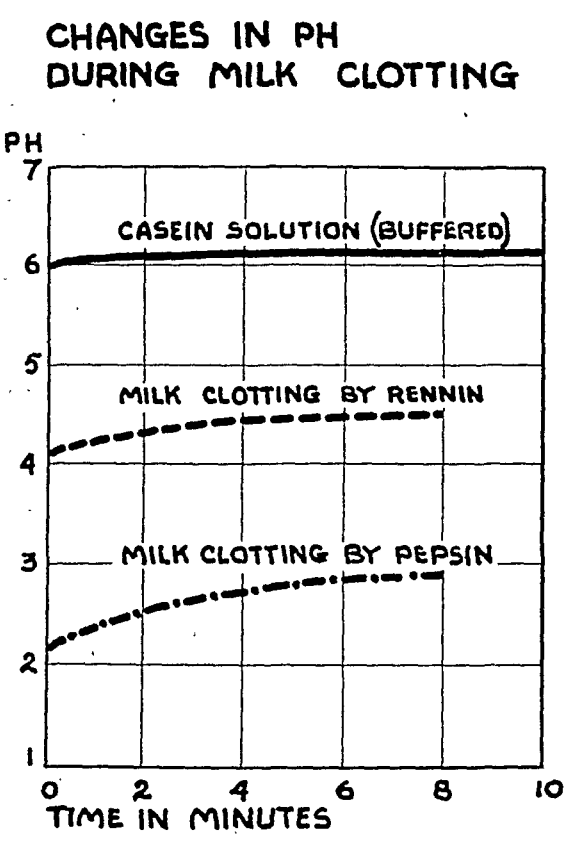

Fig. 1

of the mixture and the pH changes effected during clotting. Once the initial equilibrium cH values was established the changes in cH were followed potentiometrically at definite time intervals. An initial short range clotting period of the buffered synthetic clotting system showed no change in pH during coagulation. On measuring the cH during the clotting of the casein system without added buffer solution, the variation in cH was slight and indefinite. A cH study during the rennet clotting of milk also showed no change in cH

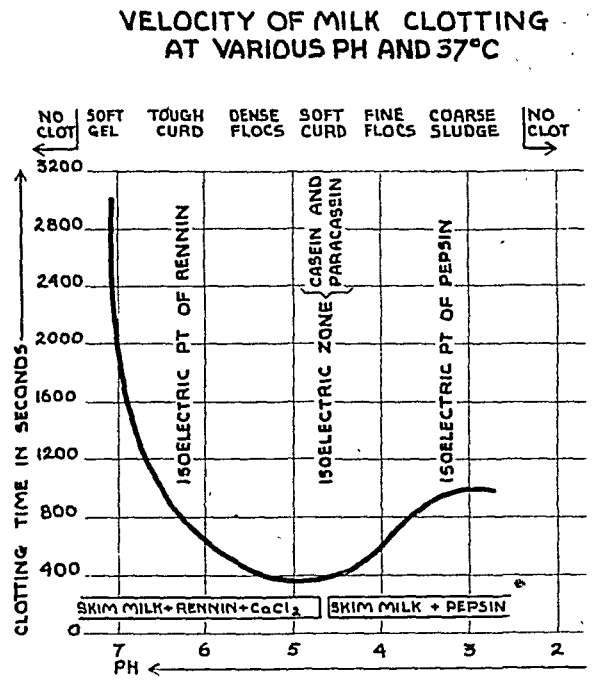

Fig. 2

at about pH 6.0 within the range of maximum rennet activity. But on studying similar solutions at more acid pH using pepsin, a small but definite diminution in cH maintained (Table I). Apparently the high buffer action of milk at about pH 6.0 obscures any change in cH during rennin clotting. But the low buffer value of milk at pH 2.0 does not interfere with the small cH change during pepsin clotting. The change in cH during clotting represents a continuous phenomenon (Fig. 1). The rate of diminution of hydrogen ions is great at the first intervals but gradually falls off an asymptotic limit. The paracasein formed adsorbs H in the process at least by pepsin clotting.

(2) Limits and Optimum of pH for Milk Clotting.

That alkalies prevent the clotting of milk is generally known. But the rate of clotting, the degree of clot formation and the character of the clot are greatly affected by pH. These factors are particularly

*From the New York City Children's Hospital.
This work was aided by grants from the Nutrition Research Fund and the Milk Research Council.
Submitted April 23, 1937.

significant for gastric digestion. Since milk may be precipitated by proteolytic enzyme or by an acid, both types of coagulation were studied. The pH of synthetic clotting solutions was maintained by standard buffer solutions, the pH of milk adjusted with HCl or NaOH and controlled potentiometrically.

Milk coagulates spontaneously at various pH zones of acidity. They pertain to skimmed or whole milk

TABLE I

pH change during clotting

Time (min.)	Casein Solution	Milk — Rennin	Milk — Pepsin
0	6.0	4.1	2.2
2	6.0	4.2	2.5
4	6.1	4.4	2.6
6	6.1	4.5	2.7
8	6.1	4.6	2.8
10	6.1	4.6	2.8

although the pH values are clearer for fat-free milk. Casein precipitates at its isoelectric point about pH 4.7 from both milk and casein solutions. On the acid side of this pH casein forms insoluble casein salts, the maximum precipitation appearing between 2 and 3 (Table 2). On the alkaline side of the isoelectric point casein forms relatively soluble metal caseinates. In the phosphate buffer solution no coagulation appears unless $CaCl_2$ is added to form calcium caseinate insoluble until about pH 6.5. Its solubility however, increases progressively with increasing pH. Addition of Ca++ is unnecessary below pH 4.7 because no calcium caseinate is possible since casein chlorides and the like are formed. The coagulation of a synthetic system at various pH media was observed at 37° C. The pH zone of coagulation was rather limited between 6.0 and 6.5, fine opalescence appearing above pH 6.5 and coarse turbidity below pH 6.0.

The rennet coagulation of skimmed milk showed a much wider pH range for clotting (Table 4). On the alkaline side of pH no clot formed. Paracasein has its charge increased and stabilized by OH as well as by other anions Cl, CO_3, HPO_4, $C_6H_5O_7$, citrates, etc. It is not due to precipitation of Ca++. Clotting was greatly prolonged near pH 7.0 but as the cH increased

TABLE II

Spontaneous coagulation of milk

pH Range	Buffer Solutions	Coagulation pH Milk	Coagulation pH Casein
1 —	Glycocoll — HCl	2.8	2.5
3.5 — 5.5	Acetate — Acetic	4.8	4.7
5.5 — 8.0	Phosphates	ppt. to 6.5 (added $CaCl_2$)	—

the duration of clotting rapidly diminished. The optimum zone is about pH 6.0 which coincides with the range for complete conversion of casein to paracasein. The clot assumed the form of a gel soft in consistency near pH 7.0 and firmer with increasing cH until about pH 5.0 when the coagulation became coarse, apparently the result of acid precipitation.

Since the maximum activity of rennin is about pH 6.0 it is not surprising that the acid nature of the coagulation becomes manifest at about pH 5.3 and failure of clot formation beyond pH 7.0 where rennin

TABLE III

pH and Rennet coagulation

5% Calcium Caseinate 25 c.c. 1% Rennin Solution 0.2 c.c. 0.2 N $CaCl_2$ 5 c.c.	
pH (Buffered)	Clot Time
5.8	turbidity
6.0	8′
6.2	7′
6.4	10′
6.6	16′
6.8	opalescence

is destroyed and calcium paracaseinate is soluble. The region between pH 6.0 and pH 5.0 is transitional for both rennin and acid precipitation respectively. The zone of rennin action is not an extension of the acid precipitation. Indeed the precipitation zone with rennin is much broader than with acid alone. Rennet makes the possibility of precipitation much more certain than with the narrow optimum for acid precipitation. The rennet precipitation optimum of paracasein is near pH 6.2 while the acid precipitation optimum is near pH 4.7. The rennet clotting optimum

TABLE IV

pH and milk clotting

Clotting System at 37° C. Skim Milk 25 c.c.			
1% Rennin 0.2 c.c. 0.2 N $CaCl_2$ 5. c.c.		Pepsin 1 c.c.	
pH	Clot Time	pH	Clot Time
5.0	300 sec.	2.0	
5.3	400	2.2	1000 sec.
5.7	420	2.5	950
6.0	460	2.7	900
6.2	600	3.0	850
6.4	850	3.2	810
6.6	1050	3.5	800
6.8	1300	3.7	700
7.0	1800	4.0	600
7.5		4.2	450
		4.5	400
		4.7	370

at about pH 6.2 yields practically 100% of clot while near the acid clotting optimum the rennet clot yield is nil. At about pH 5.0 half of milk is clotted with rennin.

Syneresis or clot retraction occurs with the rennin

clotted milk between pH 7.0 and 5.0. It becomes more marked toward the isoelectric point of casein for in more acid media the clot is less stable in dispersion. The greater attraction between the coalesced particles squeezes out the liquid between them, the rate of such contraction increasing with the concentration. The properties of milk curd will be considered in a forthcoming study.

The coagulation of skimmed milk below pH 5.0 was determined with pepsin (Table 4). The clotting time assumes a minimum at about pH 4.8 but increases with rise in pH. The clotting duration appears greatest at about pH 2.7. With increased cH however the rate of coagulation becomes increasingly faster. On the acid side of the isoelectric point of casein the clot was granular and no syneresis was observed. While clotting time diminishes at pH values below the broad maximum 2.5-3.0, clotting is inhibited below pH 2.0 (Fig. 2). Clotting time studies at higher temperatures indicate steeper gradients broadening at lower temperatures.

SUMMARY

Rennet clotting of milk is accompanied by no change in the hydrogen ion concentration but pepsin clotting shows an asymptotic diminution in the hydrogen ions due to their adsorption by paracasein. Milk coagulates spontaneously at various pH zones, insoluble casein salts being formed between pH 2.0 and 3.0, isoelectric casein at pH 4.7 and calcium caseinate at about pH 6.5. Optimum rennet coagulation is at about pH 6.0 coinciding with complete conversion of casein to paracasein. At about pH 5.3 acid precipitation is initiated and rennin activity practically ceases. The rennet zone is broad and the acid zone narrow; the optimum of the former is pH 6.2 and that of the latter is at pH 4.7. The rate of clotting with pepsin diminishes in more acid ranges until 2.7 when it increases again. At alkaline pH no clotting takes place.

The role of the hydrogen ion concentration in milk clotting has been considered more from the standpoint of digestion and absorption of milk from the alimentary tract rather than from its function in the actual mechanism of milk clotting (2). In this respect both hydrogen ion concentration and pH range affect the clotting of milk as they do the clotting of blood (3).

Editorial

SIDELIGHTS ON PROCTOLOGY*

AN examination of the written records of the past tends to induce a healthy attitude of humility in a medical man of any field. It is immediately found that fundamental medical methods and surgical procedures do not germinate spontaneously but are slowly evolved with the turn of the centuries, and that in the words of the prophet "All knowledge is but a remembrance and all discovery but a forgetting." Nowhere is this more evident than in proctology, where a lively interest existed on the part of the most ancient practitioners. Hundreds of years before Christ, the Egyptians recorded their findings in proctologic examinations; Hippocrates, born on the Island of Cos in 460 BC, left descriptions of fistulas and hemorrhoids and instructions concerning their treatment which would not be out of place in a text book of today; Aurelius Cornelius Celsus writing his "De Medicina" during the region of "Tiberius," included accurate descriptions of colitis and the dysentaries and recommended the use of the scalpel in the cure of fistula.

Records of this sort also induce a glow of pride in our historical heritage. In recent years through an orderly and wise process of evolution, proctology has identified itself as a subdivision of surgery and we have therefore come to have an impelling interest also in the story of surgery whose struggle for a place in the medical sun during the seventeenth and eighteenth centuries offers a rather curious counterpart of the travail through which our specialty has passed more recently.

In the 17th century the surgeon was still bound to the barber in a union which has become distressing, the United Company of Barber-Surgeons which had been chartered by Henry the 8th a century before, was not to be dissolved into its component groups until the 18th century. Denied the use of the title of Doctor by his medical confreres of the long gown, he was during this period of a tribe against whom every man's hand was turned.

In England, it was a Cavalier, a loyal follower of Bonnie Prince Charlie in his exile and "Surgeon in Ordinary to His Person" when he became Charles II, who was to lead the English surgeon into the promised land. This Richard Wiseman, like his great contemporary in the medical field, Sydenham, was primarily a soldier, like Sydenham he was a forerunner of modern methods and manners of thought. After completing his seven years of apprenticeship, he had served in the armies of Holland, of Spain, of Charles the 1st of England and later in those of his son. With the Restoration of the Monarchy, he became the first consulting surgeon of his time and at the age of 43, Master of the Company of Barber-Surgeons. His Surgical Treatises, which described his experiences in the diagnosis and treatment of a wide range of lesions including diseases of the anus, demonstrated that he was a man far ahead of his time and in England elevated surgeons from the tonsorial status to that of a respected profession. In France, the surgeon was in even greater disrepute, the itinerant and quack being often more highly respected. Late in the 17th century however an event occurred which has been said to have been more important to the prestige and consequent advance of surgery than all the teaching of the French master surgeon, Pare'. On November 18th,

*Address delivered at the Annual Dinner of the American Proctologic Society, Atlantic City, June 8, 1937.

1687, Louis 14th, the Sun King, was operated upon by his Surgeon in Chief Monsieur Felix de Tassy.

The royal patient had been afflicted with fistula for a year, during which courtiers and quacks extolled various remedies. The King sponsored a massive experiment, in which the most promising of these infallible remedies were applied to various of his subjects similarly afflicted. No one was cured after a year's trial and consequently permission was granted to the surgeon to incise the royal flesh. A curved and guarded scalpel was used, now known as the royal bistory; the operation resulted in a complete cure; the surgeon, his eight assistants and the boy who carried the hot water received altogether a fee of $73,000, a standard not exceeded until Mr. Lockhart-Mummery journeyed to far-off India to cure a Maharajah. The complaint became extremely fashionable in the Court and throughout France. It is said that Louis the 14th influenced medicine in three curious ways, his attack of typhoid fever gave immense vogue to the use of antimony, his anal fistula brought about the rehabilitation of French surgery, and the fact that his mistress was attended by Clement the royal accoucheur did much to further the cause of male midwifery.

From these beginnings has the art and science of surgery reached its present eminence and as surgeons we exult in its continued progress.

Proctology as a specialty was a product of the nineteenth century and it is good to feel that our craft is actuated by the same idealism and scientific honesty which motivates our confreres in the wider field. The constant flux in proctologic opinion, with increasing clarity of insight is apparent to one who peruses the pages of medical literature covering the diseases of the ano-rectum. It may interest you as it did me, to take a short journey, by way of contrast, through the Transactions of this Society and contemporaneous literature of 1913, a year I have selected because it marked my own passage through the first portals of medical study.

Dr. Joseph Matthews, the first physician in the world to limit his work to this field, was for the second time President of this body, succeeding Dr. Louis J. Hirschman. The problem of the proper bounds of the specialty was one of evident concern and the opinion was offered from the floor of this Society that while urologic and gynecologic lesions could well be disregarded by the proctologist, the structural uniformity of the intestinal tract, its exposure to the same agents of disease and the interdependence of all intestinal diseases rendered as logical the inclusion of the entire tract.

Dr. Jerome Lynch proposed a plan for blocking the abdominal sympathetic nerves which foreshadowed the work of Finsterer and Kappis; Dr. Dwight Murray offered a fourth report on the subject of pruritus ani, based on an enthusiastic belief in the relief to be obtained from the use of his streptococcic vaccine, while Dr. Hanes, acid and castor oil undiscovered, advocated surgical drainage and cauterization. Fistula enjoyed the same diversity of treatment afforded four hundred years before Christ when Hippocrates discussed the comparative merits of the scalpel, the ascharotic and the seton. Dr. Robins of Virginia and Dr. Riggs of South Dakota, called attention to the facility with which a flap of rectal mucosa could be slid down to cover the internal opening and suggest that all fistulae arise from thrombotic internal hemorrhoids. Mr. Mummery advocated incision but not excision of the fistulous tract.

Dr. Harvey Stone of Baltimore, entered a spirited defense of the Whitehead operation, although his records indicated that 37 out of 185 cases complained of "weakness of control of the bowel." Another author advocated electrolysis as a painless, safe method of treating all cases of internal hemorrhoids.

Several cases of rupture of the intestine from introduction of the new sigmoidoscope were reported and it was suggested that introduction under anesthesia presented perils as did the use of too vigorous inflation, made unnecessary by use of the position Dr. Hanes had suggested.

Amebic dysentery was a fruitful subject for discussion, as the exponents of appendicostomy or cecostomy (Dr. Jelks, Dr. Beach, Dr. Gant), were now hearing of the new specific, emetin, just discovered by Major Leonard Rogers of Calcutta, which had been found to have marvelous effect in the type of dysentery in which the parasites were demonstrated but not in the "bacillary" type.

The "Irritable Colon" of 1937 presented the same complexity of syndrome and multiplicity of treatment a quarter of a century ago under the names "myasthenia gastro-intestinalis," "membranous enteritis" and "colica mucosa."

Pilo-nidal sinus was discussed as an interesting anomaly by Dr. Krouse, who disagreed with the current opinion that the presence of hair was due to broken hair from the exterior being pushed into the sinus through its entire length and stitched the lining membrane to the skin, in another the tract was laid open and curetted, in a third the tract was excised on a probe and the parts approximated.

Dr. Dan Jones was already sounding the warning that rectal cancers came to surgery too late, and Dr. Jelks still hale and hearty in 1937, in 1913 gave a vigorous exhortation under the title "Crude and Careless Diagnostic Methods" which ended more or less as follows":

And now that life's end is near approached, our retrospection brings to mind the following verses:

> "Life is an experiment, whose proof is real
> That which you think, you live and feel;
> Think, feel, reap and learn to grow,
> For life is worth just how much you know."

The Oath of Hippocrates prescribes that the pupil shall cherish and support the Master who taught him the Art and regard as brothers the sons of his preceptor. In the confines of this small group are gathered all my preceptors as well as former fellow neophites in the art and science of our specialty and I should be ungrateful indeed if I failed to feel for this association an enduring affection as well as an honest admiration because of its thirty-eight years of service to the medical profession and to humanity.

These annual gatherings are to me refreshing opportunities for scientific rehabilitation and pleasant fellowship, the Society is to be especially congratulated upon the unusually large group of wives and daughters who grace the occasion. To these charming women who share so bravely our sorrows and rejoice

with us so sincerely in our successes I offer a toast in the words of Tagore:

O Woman, you are not merely the handiwork of God, but also of men; these are ever endowing you with beauty from their hearts.

Poets are weaving for you a web with threads of golden imagery; painters are giving you form over new immortality.

The sea gives its pearls, the mines their gold, the summer gardens their flowers to deck you, to cover you, to make you more precious.

The desire of men's hearts has shed its glory over your youth. You are one-half woman and one-half dream.

Curtice Rosser, Dallas, Texas.

ERRATUM

In the article "An Office Procedure for the Rapid Estimation of Pepsin and its Clinical Significance," by Drs. Barowsky, Tauber and Kleiner, appearing in the June issue, note the following correction. In all four tables under the headings "FREE HCl" the words "c.c. N/100 per c.c." should have read "c.c. N/10 per 100 c.c."

Book Reviews

Synopsis of Digestive Diseases. By John L. Kantor, Ph.D., M.D., 286 pages; C. V. Mosby Co., St. Louis, Mo.

THIS is a concise yet comprehensive and very informative review of the diseases of the digestive system.

The first part of the book is devoted to such important general considerations as classification of digestive disorders, diagnostic and therapeutic methods, and organic and functional inferiorities including the neuroses.

There then follows a more detailed consideration of the diseases affecting the various parts of the gastro-intestinal tract and its accessories such as the liver, gall bladder and pancreas. This section includes an adequate though not lengthy discussion of the etiology, pathology, symptoms, diagnosis, prognosis and treatment of the various organic disturbances of the digestive system.

The last few chapters are concerned with intestinal parasitic infestation and provide a very helpful review of the life history, mode of spread and the other general considerations of various intestinal parasites and the pathological changes they produce.

In the closing chapters there is a brief discussion of the more important extra-digestive diseases with digestive manifestations.

This small, well-bound book, although a synopsis of digestive diseases, is indeed a comprehensive review and should be welcomed by the general practitioner and the gastro-enterologist.

Hanes M. Fowler, Fort Wayne.

Take Care of Yourself. By J. W. Ephraim. New York, Simon and Schuster, Inc., 1937.

HERE is another book for the guidance of the unwary purchaser of cosmetics and the type of drug that is commonly found in the family medicine cabinet. Fortunately Mr. Ephraim spends little time in harrowing his readers' feelings and trying to scare them and horrify them over the dangers to life that lurk in many a proprietary drug or food. He spends most of his space on positive advice about the buying of drugs and cosmetics and about the care of the teeth, skin, hair, feet and bowels. There are chapters about shaving, sunburn, colds, indigestion, weight reduction, vitamins, antiseptics, "pain killers," sleep and "hangovers."

There is much good advice, and for a layman, Mr. Ephraim has done very well. The specialist can cavil here and there, and perhaps he will not be as optimistic about curing things as Mr. Ephraim is, but on the whole he will say the book is useful and helpful.

Ephraim is on surest ground in the last chapter in which he points out to consumers that they have themselves to thank for the fact that daily they are robbed and gypped and flimflammed. If they weren't so credulous and so easily influenced by false advertising it wouldn't pay the manufacturer to spend millions on attractive copy. When once the writer of this review suggested to an intelligent college graduate that instead of buying Countess de Pom Pom's rejuvenating facial food for five dollars a small artistic jar she buy exactly the same cream from Ephraim for 50 cents a large jar, she answered that although she didn't have much faith in the Countess and was willing to admit that she was being gypped, the expensive stuff gave her a certain feeling of satisfaction and hopefulness that the other did not, and so she would go on buying the fancy little jar — which shows again that human nature demands deception and that people will always pay well anyone who will cater to their wishful thinking.

W. C. Alvarez, Rochester, Minn.

Annual Abstracts of Proctologic Literature 1935-1937

By CHARLES E. POPE, M.D., Evanston, Illinois

LYMPHOGRANULOMA INGUINALE

Grossman reports 5 cases and Bacon in the same report discusses 94 cases studied at the Graduate Hospital in Philadelphia the past 4 to 5 years, stating that 46% showed positive Wassermans and 40 cases were treated with fuadin and tartar emetic but with discouraging results.

Hayes et al discusses the subject in complete and excellent fashion. Striking results were obtained in the inguinal adenitis cases, 14 cases becoming well with intravenous Frei antigen and marked general improvement occurring in other cases such as the fistulas and strictures.

From experimental observations *Hellerström* reports lymphogranuloma inguinale is an infectious disease due to probably an invisible unfilterable virus, 100% transmissible to apes and white mice but questionably to guinea pigs, is slightly glycerine resistant, stands cold temperatures, is lymphotrophic in nature, produces antibodies of virulicidal character, and may be demonstrated in the regional lymph glands in men shortly after infection. Animal inoculation has shown esthiomene to be etiologically synonymous with lymphogranuloma inguinale. The antigen used intravenously in 13 cases has proven of diagnostic value and therapeutic and theoretic interest.

Kondo reports a case of peritonitis with bloody serous fluid with retroperitoneal and mesenteric lymph node involvement in which the abdominal fluid injected into apes intracerebrally transmitted the disease and gave a positive Frei reaction. No bowel pathology accompanies. Meteorism, perirenal inflammatory reaction, a hematoma formation and a retroperitoneal phlegmon accompanied thought due to the above reason to the virus of lymphogranuloma inguinale.

C. Martin and *Bacon* review all phases of this disease in one of the most outstanding papers written. The article is practically a monograph and contains 371 references. They report the varied findings in 136 cases. They state "the disease is of interest by virtue of the fact that we realize that it is not new, that many cases of inguinal buboes have been and are manifestations of this disease, that inflammatory rectal strictures, which occur particularly in women are most frequently the result of a perirectal lymphongitis initiated by the specific virus of lymphopathia venerea, and that esthiomene and chronic elephantiasis or the combination of these as the genito-anorectal syndrome or the anorectal siphiloma are part of the same affection. Of considerable interest is the marked improvement of one case with inguinal adenitis to intravenous injection of the Frei antigen.

Purcell and *Finlaysen* report a rare case of lymphogranuloma inguinale following an intraurethral lesion.

Rainey and *Cole* report 41 cases of lymphogranuloma inguinale giving detailed findings in 23 cases. The Frei test was positive in all cases where inguinal adenitis, ulcerative proctitis, and rectal stricture were associated findings, but was negative in all of the control cases used. A positive Kahn in 28.5% was considered merely coincidental. 87% were negroes.

Vander Veer, Cormia and *Ullery* report 47 cases, 26 of which showed inguinal adenopathy and a positive Frei test and 21 cases which showed

IN CHRONIC BILIARY DISEASE, WHEN SURGERY IS CONTRAINDICATED

CONSERVATIVE medical management is today regarded as the most effective therapeutic approach in stone-free, chronic biliary disease. The extensive experience of many surgeons indicates that cholecystectomy not only fails to correct the characteristic epigastric distress and right upper abdominal pain, but frequently causes these symptoms to become more severe.

In the treatment of chronic cholecystitis, Taurocol (Plessner) has produced gratifying results. Its contained bile salts prompt more effective gallbladder evacuation, and tend to stimulate a greater production of bile by the liver cells. Cathartics overcome the frequently associated constipation; stomachic agents contribute to more rapid gastric emptying, thus relieving postprandial fullness and eructations. In consequence, Taurocol (Plessner) produces prompt relief of right upper quadrant pain and epigastric discomfort, and permits of a more liberal diet without distress.

Liberal sample and literature to physicians on request.

rectal stricture in which class 70% showed a positive Frei. 85% were colored patients.

Von Haam and *Lichtenstein* in a review and analysis of the case histories in the Charity Hospital believe that 20% of the 1285 rectal strictures present from 1911 to 1933 probably were lymphogranuloma cases. Seven local strains of the causation organism were isolated from inguinal buboes and successfully transmitted to experimental animals in a study of 154 definitely diagnosed cases. 86 were males and 68 females. 13% were white in the male group whereas only one white female was present. The age incidence was greatest between 20 and 30.

PILONIDAL CYSTS AND SINUSES

Breidenbach and *Wilson* review 288 cases from the surgical services of the Bellevue Hospital, N. Y. C., and favor complete excision. A follow up of 83 cases showed this method gave 94% cures. The authors believe this condition is one of a congenital faulty skin development.

Rogers and *Hall* review 181 cases of pilonidal sinus at the Massachusetts General Hospital. Where radical excision was done and partial or complete closure attempted poor results were experienced due chiefly to infection rather than retained tissue. Dye when used usually hindered the excision due to its not penetrating the sinus fully and staining normal tissue. The authors report a new method which permits ambulatory management. A mid-line post-sacral incision is made and a lateral under-cutting excision on either side is made of the sinus tract and tissue. The wound is packed with antiseptic soaked gauze and the wound is recauterized and dressed postoperatively from time to time. Healing occurred in 6 weeks. No extension occurred below the coccygeal fascia in any of their cases.

Gage reports a case showing embryonic neuroglia cells and fibrils extending into the sacral canal and therefore believes that the classification should include this type as well as the usual type with extension down to or near the periosteum of the sacrum. Demonstrates the sacrococcygeal dimple as being a caudal ligament attachment to the skin in agreement with Oehlecker, Ravdin and Johnston.

Ravdin and *Johnston* report a series of cases at the Hospital of the University of Pennsylvania. 44 cases were males and 9 females. Believes the sinus is embryonal ectodermal invagi-

ROENTGENOLOGY — RADIUM THERAPY — ELECTROSURGERY

ROENTGENOGRAPHY AND DIAGNOSIS

Branisteanu and *Moisuc* emphasize the importance of roentgenolic study of the intestinal mucosa. Normally the *plicae in the colon* are 5 mm. and their arrangement may be influenced by abnormal reflexes coming from diseased organs by way of motor fibers through the autonomic nervous system of the muscularis mucosa or by other reflexes. Normally they found a predominance of transverse plicae in the cecum, of oblique transverse plicae in the right half of the transverse colon and of longitudinal plicae in the descending colon.

Fiessinger and *Hutet* in a study of the normal colon in man state that the two extremities are constantly full due to the antiperistalsis and colonic mixing of fecal matter which gradually becomes of greater consistency low in the colon from its viscid state in the cecum. The sacculations may occur through normal tonic contraction or normal distention and are different in the spastic state. The study emphasized the considerable individual variation with time and bowel wall movement in any given case and emphasized the need for serial study.

Gershon-Cohen advises the routine use of the contrast air inflation roentgenogram and states that it is especially necessary in the diagnosis of early neoplasms, diverticulae, tuberculosis and inflammatory change of the mucosa.

Contrast enemas have gained importance abroad as well as in America. *Viamonte, Zdansky, Gershon-Cohen* and *Gillies* stress their importance.

Kuhlmann states that the colonray is most important in diagnosis and states that the tumor type cannot necessarily be identified in roentgenograms, whereas the infiltrating type can.

Pape emphasizes the importance of roentgenographic study in disturbances of motility in 224 pathologic cases studied.

Rother in an X-ray review of 546 cases of intestinal tuberculosis states that roentgen-examination is a more dependable diagnostic method than any other method. He stresses the importance of the fluoroscopic examination during the enema.

Zdansky states that transverse and longitudinal plicae of the mucosa must be accompanied by marked irregularity of contour to signify inflammatory swelling or lymphatic stasis. States that a comparatively frequent but usually disregarded finding in sigmoiditis is invagination, the same being confused with a circular stenosing tumor.

THERAPY

Chamberlain states that in general roentgen therapy of cancer is open to considerable improvement. The fractional treatment of Coutard and others is not necessarily as claimed to be the method of choice in all cases inasmuch as clinical experience plus a proper attention to the microscopic appearance of the biopsy specimen may lead to a better selectivity of cases. Preoperative irradiation is beneficial if it is followed by a sufficient delay for tumor regression. There is a decreasing emphasis on postoperative irradiation, however. Whether heavy radiation is beneficial requires further study.

Bensaude, Solomon and *Marchand* state that 50% irradiated fistulas are cured and 30% are markedly improved.

Your Medication
Made More Acceptable by

EFFERVESCENT PRODUCTS, Inc.
ELKHART, INDIANA

Seven cases of chronic fissure-in-ano were cured by 3 to 6 irradiations. Partial improvement occurred in 3 cases and a failure in one case. Pain subsided in all cases. State that acute hemorrhoidal thrombosis is markedly improved with the duration of symptoms lessened by X-ray therapy. Whereas pruritus ani is "cured" by X-ray state recurrences are frequent. Advise it also in condylomas and suppurative proctitis.

Cilley, Leddy and *Kirklin* estimated the amount of radiation received by various operators during the routine course of colon roentgenoscopy during a period of several years and found that although multiples of the so-called tolerance doses were received, no injury occurred.

Duffy states that roentgen radiation is less efficacious than radium irradiation and should therefore be supplementary. Advises roentgen therapy as a preliminary procedure to surgery. In inoperable cases advises 18 to 28 days external irradiation depending upon the patients ability to withstand the treatment. Cites two rare cases where complete disappearance of the primary tumor occurred. Metastases occurred 4 and 7 years later.

RADIUM

Bensaude believes radium should be used only where diffuse growths are beyond surgical aid.

Binkley in a review of advanced carcinoma of rectum cases treated by radon seed implantation and external irradiation states that 24 cases were clinically symptom-free, 213 cases showed a moderate or minimal improvement, 155 cases showed greater improvement and only 8.5% were unbenefited. 25 cases treated with heavy radiation therapy showed results comparable with radical surgery.

Boxing discusses adenomyoma of the rectovaginal septum and advises radiotherapy preceding surgery if intestinal obstruction occurs by reason of size and states they should not be considered malignant and may be repeatedly observed over a period of time.

David reports 7 severe radium burn cases and concludes that when radium burn results in the treatment of carcinoma of the rectum carcinoma may still be present in the tissue requiring radical resection.

Gordon-Watson states that carcinoma containing undifferentiated cells should be radiated as they are much less resistant than those containing differentiated cells; and tumors of the anus are radiosensative and should also be radiated. He, however, despairs of the cure of rectal and large bowel carcinoma by radium because of the inherent resistance of the tumor. He states further that experimental work seems to indicate that the time required to inhibit and disintegrate a number of carcinoma cells in different stages of activity is not less than 7-10 days. The uniform intensity of radium as compared to the diminishing intensity of radon is responsible for the permancy of cures. In the same article Maisin reports that in 32 patients 100% were healed after 3 months and 57% were living with healed cancer of the rectum after 16-20 months. The method of radiosensitization followed by Coutard's method of roentgen irradiation was used.

Lockhart-Mummery agrees with Gordon-Watson excepting that he does not believe adenocarcinoma is any less radio sensative than squamous celled carcinoma.

Schreiner reports on the successful irradiation of 8 cases of inoperable rectal carcinoma treated from 1919-1929. External irradiation combined with glass seeds and filtered radon were used.

An outstanding article is that of *Shedden* who concludes that with radium treatment in the properly selected case early growths can be destroyed, clinically inoperable cases can be rendered operable, and the worst and more advanced cases can be rendered more comfortable. States that the

Reducing Fecal Toxicity

Whenever the bowel loses its normal selectivity and the liver's ability to detoxify is overtaxed, a flood of toxic material enters the system

Soricin detoxifies at the port of entry—the bowel

Soricin is not a panacea—it is merely an effective means of decreasing toxic absorption from the enteric tract.

Soricin inhibits putrefaction and abnormal bacterial proteolysis.

The continued use of Soricin aids in desensitizing the patient who has become sensitized to the autolysates of his intestinal flora.

Specifically, Soricin is useful in the treatment and prevention of:

Bacterial hypersensitivity of the intestinal tract
"Irritable colon"
Intestinal toxemia
Allergic diarrhea
Urticaria
Non-ulcerative colitis.

Consequently, Soricin is of value in the relief of many symptoms such as headache, vertigo, anorexia and migraine.

SORICIN DOSAGE FORMS:

Soricin Capsules: Enteric capsules of sodium ricinoleate available in five-grain and ten-grain sizes.

Soricin Tablets: Enteric coated tablets each containing five grains of sodium ricinoleate.

ACTION:

Detoxifies in vivo Desensitizes Inhibits putrefaction Prevents toxic absorption

radio-surgical technic of Neuman and Coryn was reported on unfavorably at St. Marks and needs further study. Further research is necessary to determine the correct dosage and factors influencing the same. Whereas there are a number of 5 year cures the author believes that there are too few cures to warrant anything but surgery in operable cases.

Shepley advises preoperative irradiation.

ELECTROSURGERY

Bowing and *Fricke* report on 58 cases of rectal cancer treated between 1930 and 1933 by radium application and aided by surgical diathermy. Radical excision followed 37 cases. 27 cases appear free from recurrence. In 3 cases no evidence of carcinoma was seen in the surgical specimen removed, and in 3 others most of the cells were found destroyed.

Electrocoagulation has received more favorable attention and *Fansler* states that in cases unable to withstand radical surgery in inoperable obstructive growths, particularly where the growth produced distressing symptoms, and in early low grade malignancies where flat button-like 1 cm. or less sized lesions or tumor with a pedicle are present electrocoagulation is indicated.

Wadhams and *Carabba* performed 15 consecutive anastomoses of the intestine in animals successfully using a bipolar coagulation current of 1000 milliamperes.

Yoemans reviews the cancer cases seen at the New York City Cancer Institute during the past 10 years and states that the good results obtained by electrosurgery combined with radon seed implantation in apparently hopelessly advanced lesions is of great interest. Relief of pain is also obtained by chordotomy, and alcohol subarachnoid injection.

Knox Gelatine (U.S.P.) an Important Vehicle in GASTRIC DISTURBANCE DIETS

When advising a diet for gastric disturbances, remember that Knox Gelatine (U.S.P.) is a valuable vehicle. Knox Gelatine is not only an easily digested protein but blends with whatever foods are allowed into tempting salads and desserts.

In hyperacidity cases or in treating ulcers frequent meals are recommended. Jelled fruit juice or a bland, slightly sweetened gelatine dessert is a variant to the usual between meal beverage.

Knox Gelatine is scientifically made from selected long, hard, shank beef-bones — surpasses minimum U.S.P. requirements — pH about 6.0 — contains no carbohydrates — fat content less than 0.1% — odorless — tasteless — bacteriologically safe.

KNOX SPARKLING GELATINE

In daily menus and prescribed diets use Knox Gelatine

Recipe

Dessert with strained prune pulp.

PRUNE WHIP

(six servings)

1. Soak Gelatine in cold water about 5 minutes, using:
   1 envelope Knox Sparkling Gelatine
   ¼ cup cold water
2. Add to the following, stirring thoroughly:
   ¼ cup hot prune juice
   1 cup cooked prune pulp
   2 tablespoonfuls lemon juice
   ⅔ cup sugar
   ¼ teaspoonful salt
3. Cool. When mixture begins to thicken, *fold in:*
   2 egg whites, stiffly beaten
4. Rinse mold or dish in cold water, and fill with dessert. Chill. To serve, unmold and garnish with whipped cream, or serve with custard sauce.

TUBERCULOSIS OF THE COLON AND RECTUM

Augé reports a case where an amoebic ileocecal mass closely simulated tuberculosis.

Chisholm and *Gauss* write an excellent paper reviewing the findings in 71 proven or probable cases of anorectal tuberculosis. They find the incidence of anorectal complications in pulmonary tuberculosis to be 3 to 5 per cent. Diagnosis should be by guinea-pig injection of emulsion prepared from pus scrapings or tissue material, or else by suitable culture growth. The treatment should be surgical and proved most gratifying in 70 of the cases.

Gomez and *Rubio* have an excellent paper reviewing the clinical, roentgenologic, proctoscopic and necropsy studies of the large bowel in 500 patients with pulmonary tuberculosis. Air inflation enemas were used. Ulcerations hypertrophy of the ileum, edema of the submucosa, and proximal colitis granulosa were found.

Granet reviews 2086 cases of pulmonary tuberculosis and finds an incidence of 37% with intestinal tuberculosis. 86% showed cecal involvement. Only 2 out of 150 consecutive sigmoidoscopic examinations showed tuberculous ulcers of the rectum. Roentgenographic findings were correct in 43 of 49 autopsies. 95.4% of the intestinal cases had pulmonary cavitation.

Konjetzny describes an ulcerative ileitis of tuberculous origin resulting in narrowing of the lumen and tubular thickening of the wall.

Several authors checked on the Triboulet reaction in intestinal tuberculosis. *Robinson* and *Gruickshand* review 109 cases and found no diagnostic value. *Tisell* states it is of no value for early diagnosis.

Rother writes an extremely interesting paper and valuable partly because of the wealth of material studies. 546 cases were seen and their various findings described. The ileocecal region is of primary importance in the diagnosis.

Santy advocated heliotherapy and ultra violet radiation in the treatment of intestinal tuberculosis and would combine unilateral surgical exclusion with this rather than bowel resection by reason of the results seen in two series of 10 patients each.

Watson and *Hewitt* state that 10 years experience has convinced them of the efficacy of the quartz mercury vapor lamp. Supplementary treatment with diet (high vitamin-low residue) rest and fresh air is necessary. The associated pulmonary condition must not be too far advanced.

VICHY CÉLESTINS

THE WORLD'S MOST FAMOUS NATURAL STILL ALKALINE WATER

'Trisomin'

(MAGNESIUM TRISILICATE, LILLY)

● As shown by Mutch, synthetic magnesium trisilicate effectively neutralizes acid and displays a prolonged action in accomplishing this purpose. It is also a powerful adsorbent of alkaloids, putrefactive amines, bacterial toxins, and food poisons. Relatively large doses may be given by mouth since the compound is nontoxic. 'Trisomin' is not absorbed from the gastro-intestinal tract and alkalosis is not a probable side effect.

Tablets 'Trisomin' (Magnesium Trisilicate, Lilly), 7 1/2 grains, are supplied through the drug trade in bottles of 40 and 500.

Literature concerning dosage will be supplied to physicians upon request.

ELI LILLY AND COMPANY

Principal Offices and Laboratories, Indianapolis, Indiana, U. S. A.

"CONNOTATIONS." By H. J. Sims, M.D., Denver, Colorado.

Since Hunt and Taveau, in 1906, observed the vasodilator effect of choline esters, considerable attention has been given to aceteylcholine as the chemical mediator of parasympathetic nerve impulses.

In 1880, the pharmacologist, von Anrep, discovered the local anesthetic properties of cocaine. In 1884, Koller reported his experimental and clinical results in surgery of the eye. The term, "spinal anesthesia" was introduced by Corning in 1885. Bier, in 1889, first injected cocaine intraspinally.

Bastianelli, in 1890, reported three cases which presented symptoms similar to those now recognized as "liver deaths," a syndrome first described by Heyd.

Claude Bernard, in 1855, expressed the view that, in addition to the external secretions which are derived from the blood; the glands produce internal secretions which are derived delivered to the blood. To him belongs the origin of the term, "internal secretion."

Theophile de Bordeu wrote, in 1775, "Every organ serves as a workshop for the preparation of a specific substance which enters into the blood; and that such substances are useful to the body and are needed in order to maintain its integrity."

Metchnikoff (1845-1916) was a biologist and not a pathologist. He was engaged in zoological research when he discovered the mechanism of intracellular digestion in the mesodermal cells of lowly animals.

De Garcia, a singing master of London, is credited as having invented the laryngoscope.

The first thermometer for recording body temperature was used by Traube, in 1850. The thermometer was slightly over ten inches long and required thirty minutes under the axilla to register.

Reginald Fitz, in 1899, wrote, "Acute pancreatitis is to be suspected when a previously healthy person, or sufferer from occasional attacks of indigestion, is seized with violent pains in the epigastrium, followed by vomiting and collapse, and in the course of twenty-four hours, by a circumscribed epigastric swelling, tympanitic or resistant, with a slight rise in temperature."

Cooper, of England, in 1903, described acute dilatation of the stomach in a child eleven months old. The child previously healthy, while playing, suddenly seemed to stop breathing. He "made a noise in the throat" and died in a few minutes without a struggle or a convulsion. Autopsy showed a dilated stomach containing nineteen ounces of Mellins' Food. A stomach at this age should hold only about nine ounces.

Moor, in 1881, confirmed the theory that tuberculosis may cause cirrhosis of the liver.

Steatosis, which occurs so often in tuberculosis, was recognized by Andral in 1829.

McNeal is thought to have first recognized carcinoma of the bile ducts in 1835.

In 1821, Caindent advised the use of iodine in the treatment of syphilis. Wallace, of England, in 1825, is credited with the use of potassium iodine in syphilis.

Claude Bernard experimentally produced hemorrhagic pancreatitis by injection of bile and sweet oil into the pancreatic duct. The method by which diseased gall bladders predispose to pancreatitis was suggested by Opie in 1901. From his experimental work, he concluded that a gall stone lodged at the ampulla of Vater might convert the choledochus and the duct of Wirsung into a common channel.

Wren, in 1656, injected an infusion of opium into the vein of a dog and obtained narcosis. In 1823, Hale described the injection of castor oil into his own vein.

TRI-CALSATE

The BUFFERED *neutral antacid*

Extensive clinical experience proves the definite superiority of Tri-Calsate in the treatment of hyperchlorhydria and peptic ulcer.

Tri-Calsate is a powerful neutralizer of gastric HCl, yet does not cause a rebound in acidity nor alkalize the stomach contents. The buffering effect of its end salts protects against a harmful alkalosis, thus eliminating a major disadvantage of the alkaline antacids.

As no carbon dioxide is evolved during the reaction in the stomach, gastric distention and belching are eliminated.

Tri-Calsate is non-toxic and non-irritating. The probability of gastro-intestinal irritation is remote. The kidneys are unharmed. Patients like it because it is palatable and gives rapid relief without distressing systemic effects. Economical, too.

Available on prescription at your pharmacy or direct in 4 oz. and 18 oz. bottles.

Avoid the Vicious Circle of Alkali Neutralization

WISDOM is practical knowledge and it is acquired in the school of experience

First hand observation has taught physicians the world over that there is no better mineral oil emulsion than AGAROL. The wisdom of experience urges its use whether for the relief of acute constipation or for the treatment of habitual constipation. Effectiveness, palatability, convenience, every consideration favors Agarol.

The reasons why are briefly discussed in a folder, which we shall gladly send you with a liberal supply of Agarol. Please ask for it on your letterhead.

Agarol is available in 6, 10 and 16 ounce bottles.

AGAROL

WILLIAM R. WARNER & COMPANY, INC.
113 West 18th Street New York City

Hayden, in 1855, injected a solution of sodium chloride into the vein of a patient with cholera. Haford injected a solution of ammonia intravenously into a patient bitten by a snake.

Cotton, in 1917, gave the first report of cholecystitis due to B. aerogenes-capsulatus.

Riedel, in 1888, first called attention to enlargement of the right lobe of the liver in cholelithiasis.

The introduction of rubber gloves, as a surgical requirement was not enthusiastically received. Several types of elastic varnishes to cover the hands were suggested in preference to gloves.

Torsion of the fallopian tube was reported by Bland-Sutton in 1890.

Talma of Utrecht was the first to suggest establishing a collateral circulation by means of adhesions between the abdominal viscera and the parietes for the relief of ascites in cases of cirrhosis of the liver. The first operation by Van der Meude, in 1889, and another by Schelkly, in 1891, resulted in death. Lens, in 1892, repeated the procedure and the patient lived six months.

Vautrin, of Nancy, was probably the first to propose eversion of the tunica vaginalis in the treatment of hydrocele. Doyen claimed priority.

Mayer, in 1860, removed the first sarcoma of the uterus. Virchow made the microscopic report. In 1871, Kreegar was able to collect nine reported cases.

Schneck, in 1811, first recognized the difference between massive collapse of the lungs and pneumonia. Partial collapse of the lungs was described by Alderson in 1830. He recognized the condition in four fatal cases of whooping cough. The relationship of bronchial tube obstruction to atelectasis was noted by Traube in 1836. He believed conditions, other than mechanical, were more important factors.

Mendelssohn, in 1841, experimentally produced the condition in dogs.

Gardner, of the University of Edingburgh, advanced the opinion that a mucus plug obstructing the bronchi, represented the basic etiology.

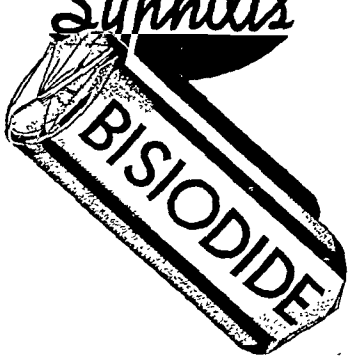
Bartels, in 1860, confirmed the findings of Gardner.

Pasteur, in 1886, described the clinical symptoms.

Sewall, of Denver, in 1921, was the first in America to describe the pathology.

Balliou, (1538-1616), physician to Henry IV, first described whooping cough in 1578. During his life time he introduced the term, "rheumatism."

Reply to a recent Editorial: "The Desirability of Measuring the Acidity of the Gastric Secretions Rather Than That of the Gastric Contents." By A. Galambos, M.D., New York.



Your Editorial, in the August issue, entitled: "The desirability of measuring the acidity of the gastric secretions rather than that of the gastric contents," from the pen of C. M. Wilhelmj, M.D., serves as an occasion to call attention to a paper of mine, which may readily answer the Editorial.

My paper, entitled: "Direct Examination of the Gastric Juice, a New Functional Test," appeared in the Archives of Internal Medicine, in the November issue of 1926 (Vol. 38, pp. 654-662) and deals, as its title indicates, with the question discussed by the Editor. The same question which has been brought up today, as a "desirability," has been discused and answered in the affirmative, 12 years ago by the writer of these lines.

I fully concur with the Editor, when he states: "that the acidity of the GASTRIC CONTENTS can not be used to study changes in the acidity of the GASTRIC SECRETIONS; the two are distinct entities and should be measured separately."

The Editor after discarding the use of histamin for such studies, concluded by recommending: "a better way of

Oral TREATMENT OF Syphilis

Bisiodide

An organic compound, being a synthesis of Bismuth (25%) and organic Iodine (58%). Indicated in all stages of Syphilis. Used concurrently with arsenicals in primary and secondary stages; exclusively in tertiary stages. Supplants intramuscular injection treatment.

BISIODIDE produces constant concentration of bismuth in all tissues.

Bisiodide is being used successfully by physicians, clinics and hospitals from coast to coast.

MUCILOSE

(STEARNS)

Supplies Non-Digestible, Bland Bulk

● When food bulk must be restricted —as in the treatment of obesity, in postoperative and other special dietaries—constipation frequently results.

For such a condition, the new development, Mucilose, is proving particularly useful because this specially prepared hemicellulose (vegetable gum) provides a much desired bland, lubricating bulk which is also non-digestible.

Mucilose—prepared by a special process from the Plantago loeflingii —is now available in two forms, *Mucilose Granules* and *Mucilose Plain.*

Both forms are as easy to take as a breakfast food.

RAPID CONTROL
of Gastroduodenal Hemorrhage in Peptic Ulcer

Impressive experimental evidence indicates that the most important factor in the control of gastroduodenal hemorrhage is the protection of the newly formed clot in the bleeding vessel. By raising the pH of the gastric contents above that at which pepsin is active, the protective clot is permitted to remain in situ, undigested.

In a recent series* employing the continuous drip method, 21 cases of severe gastroduodenal hemorrhage were successfully treated without mortality.

Creamalin — the distinctive colloidal cream of aluminum hydroxide —neutralizes 12 times its volume of N/10 HCl in less than 30 minutes. Within the stomach, it produces virtual anacidity, rendering pepsin inactive and insuring the safety of the protective clot. Creamalin produces no secondary rise in HCl secretion, and since it is amphoteric, cannot lead to alkalosis or change in blood pH values.

Because of the soundness of the underlying principle of Creamalin therapy in ulcer hemorrhage and the satisfactory results obtained by this method, Creamalin should be the therapy of choice when hemorrhage due to ulcer presents itself.

*Woldman, E. E.: The Treatment of Hematemesis and Melena by Continuous Aluminum Hydroxide Drip. Am. J. Med. Sci., 194: 333 (Sept.) 1937.

Reprints of this and other recently published articles dealing with Creamalin, together with sample, will be sent to physicians on request.

CLEVELAND CHEMICAL ASSOCIATES, Inc.

Creamalin
THE SUCCESSFUL ULCER TREATMENT

studying the acidity of the gastric secretions by putting some substance which is not destroyed or absorbed from the stomach in the fluid of the test meal and to determine the concentration of this substance in the gastric samples. When this is known, it is possible to say just how much of the fluid in the sample of gastric contents is fluid originally given with the test meal and how much is fluid of the secretions which entered the stomach. By dividing the acidity of the contents by the amount of fluid secretions which they contain, the true acidity of the gastric secretions can be obtained."

This recommendation as much as it is commendable and desirable, remains as a "pium desiderium" as long as the Editor fails to mention, what is this "better way," and what is "the substance, which is not absorbed or destroyed, etc." Whether or not the Editor knows of some such ways and means, or he merely wishes to express the desirability of having such methods at our disposition, can not clearly be seen.

At this point may I make reference to my above mentioned paper, which anticipated your questions and gave an "a priori" answer. I, likewise, have found desirable and important to have a method of obtaining and examining the DIRECT GASTRIC JUICE, instead of the GASTRIC CONTENTS in 1925. I have found, that "with the advent of the Rehfuss' tube we have a means that enables us to make examination of the gastric content by a fractional method and it becomes possible to make routine study of the fasting stomach, investigating the gastric juice—its secretion, concentration and amount, as well as its influence, psychic or otherwise—very much as may be done in animal experimentation by means of fistulas or the Pawlow pouch."

After comparing my method of providing for and obtaining unadulterated gastric juice for analysis or other purposes with other, more complicated and less applicable methods I concluded by recommending my simple method "its performance being even more simple than the administration and examination of a test breakfast."

In the method, advocated: "the Rehfuss' tube is introduced into the fasting stomach and its content withdrawn by means of a perfectly tight syringe. The tube is then left in place. As the gastric juice accumulates it is withdrawn at predetermined intervals—three, five, ten, fifteen minutes—and the quantity and total acidity of each portion is separately determined. Any special examination, microscopic or otherwise, can be performed at the same time on any or all of these samples.

Insofar as my examination of the literature has extended, no such test has heretofore been recommended, either to complete the functional food tests in common use, or as a substitute for them, when it is desirable to obtain pure gastric secretion, unadultered by food, a procedure, which, as has been pointed out by Compton, would open up a wide field of study in relation to gastric function."

When the Rehfuss tube remains in the stomach, the presence of its tip will excite and maintain the process of gastric secretion. The acid-concentration and the amount of the gastric juice widely varies according to the underlying conditions. The method best adapts itself for conditions with concomitant hyperacid or hypersecretory disorders. In such states huge amounts of gastric juice can be obtained, with high concentration of its HCl content. The highest concentration is observed as a rule after the first 5 or 10 minutes. After a period of continuous secretion of ca. 30 minutes, a respite sets in, which is followed again by the resumption of a renewed secretory period. After a second secretory activity of 30-60 minutes duration, an inhibition of the gastric secretion sets in, sometimes for a period of hours.

The method as described and illustrated by various curves, showing the variations under pathological conditions, as well as also the normal variations with the same individuals, under normal conditions, is very plain and simple. It requires only a Rehfuss tube, which will on fasting be introduced in the stomach and kept in situ, for the required period of examination or observation. The samples received at any required interval, give fairly accurate record of the actual gastric secretion. The juice received is the unadultered, pure gastric juice, and not the food containing gastric content, as is generally used for examinations and tests.

For further informations I wish to refer the reader to the original article. I must remain content at this time to have called attention to an actually existing method of approach to the problem in question.

APPENDICITIS

Blood counts were recorded on 6,601 cases; of these, 65 showed a leukopenia of which 59 were in the chronic group. Five deaths occurred in this group. In 3,086 cases there was a leukocytosis of 5,000 to 10,000 with 59 deaths; in 2,265 cases there was a leukocytosis of 10,000 to 15,000 with 43 deaths; in 1,031 cases a leukocytosis of from 15,000 to 25,000 with 124 deaths; and in 174 a leukocytosis of 25,000 to 50,000 with 49 deaths. It was also found that the mortality rate decreased with the elevation of the mononuclear cells and vice versa.

Francis D. Murphy, Milwaukee.

NEW! • *PRACTICAL!* • *DEPENDABLE!*

PRACTICE of MEDICINE

By JONATHAN CAMPBELL MEAKINS, M.D., LL.D., Professor of Medicine and Director of the Department of Medicine, McGill University. 1343 pages, 505 illustrations, 35 in colors. Price, $10.00.

The book on practice that IS different—built around the physiologic appeal to the study of diseases, profusely illustrated in black and white, and colors—something no other book on practice has done. 505 illustrations, including 35 color plates. Pictures teach in medicine as well as in surgery, gynecology and obstetrics. Why have books on practice not been illustrated? This never was thought of until Meakins did it. That's enough to prove that Meakins "Practice of Medicine" is different—and brand new.

It is not only a descriptive account of individual diseases but also an attempt so far as our present knowledge goes to be a practical treatise on disease processes in general and how these may be corrected along rational lines. Treatment is also handled along rational lines and the reasons explained as far as possible.

"This textbook represents what the physician of today is expected to know and what the modern medical student is expected to learn. It is told in a brief, simple manner that is adequate for this purpose and attractive to the reader. It is richly illustrated with pictures that help much to visualize the contents. In short, an excellent one-volume practice of medicine."—Journal of the Ohio State Medical Association.

THEORY and PRACTICE of PSYCHIATRY

By WM. S. SADLER, M.D., Chief Psychiatrist and Director, the Chicago Institute of Research and Diagnosis; Consulting Psychiatrist to Columbus Hospital. 1231 pages. Price, $10.00.

A stream of patients flows into the offices of general practitioners of medicine every day needing psychiatric treatment. These conditions must be recognized and the proper methods used in treating them if medical practice is to serve society adequately. To neglect—overlook—and fail to meet the needs of such patients will drive many of them to seek relief from the irregular practitioner. This situation challenges the general practitioner. It calls for serious thought on his part and sincere effort to meet a condition that is growing daily more and more serious. We invite general practitioners who have this situation to deal with to look into the possible help to be obtained from Sadler's "Theory and Practice of Psychiatry." It may possibly give you just the help you need to successfully treat these cases.

This new work in the field of mental hygiene embraces the entire field. It discusses mental mechanisms, the unconscious and the subconscious, the significance of dreams, and other attitudes. It includes a discussion of symptomatology, diagnosis and prognosis of mental disease entities, and includes a description of methods of examining.

BALTIMORE, MARYLAND

IN PREGNANCY AND LOW-CALORIE DIETS

Boxes of 25 and 100 Capsules

and wherever vitamins A and D are required with minimum added calories

RESTRICTED diet regimens, as for the obese, know no season for vitamin therapy. Because of the frequent drain on the mother's stores and the added requirement of the fetus, the need for vitamins A and D is increased during pregnancy. Yet it is in just such cases that there may be an aversion or intolerance to fats. In the obese, who studiously avoid butter, cream and other good sources of vitamin A, the deficiency should be made up. This can be done in a convenient and highly acceptable manner by prescribing Mead's Capsules of Oleum Percomorphum, which combine a high potency of both vitamins A and D.

Each 10-drop capsule supplies natural vitamins in amounts not less than 13,300 A units and 1,850 D units (U. S. P.). Every capsule represents more than 5 teaspoonfuls of cod liver oil* in vitamins A and D. These vitamins, moreover, are in the same ratio as in cod liver oil.*

*U. S. P. Minimum Standard.

For physicians who prefer Mead's Viosterol in Halibut Liver Oil, 3-minim capsules containing not less than 8,500 vitamin A units and 1,700 vitamin D units (U. S. P.) are available.

Adrenal Cortex and Intestinal Absorption*

By

PROF. DR. F. VERZAR
BASEL, SWITZERLAND

THE editors of this Journal have been kind enough to ask me for an account of recent work in my laboratory. For ten years I have worked with my collaborators on the question of absorption from the intestine. We made it our task to study especially those cases of absorption which seem to be directly opposed to the established laws of diffusion osmosis and filtration which ordinarily govern the process of absorption (1).

Such a case is, for example, the absorption of certain sugars. Glucose and galactose, the sugars which play a special rôle in metabolism, are absorbed especially well, in fact three to four times more quickly than are other hexoses of equal molecular weight, such as mannose and sorbose, or pentoses, such as xylose, arabinose and ribose (2). While the latter sugars are absorbed in accordance with the laws of diffusion, the former are not. The absorption of the latter is greater the greater the concentration of the solution, while with the former sugars, no matter what the concentration the same quantity is always absorbed in a given time, and this represents the maximum amount which can pass through the membrane (3).

To explain this difference a special activity of the intestinal mucosa was postulated. It could be shown that this activity was particularly strong in the jejunum, in comparison with the lower parts of the small intestine (4), and that it could be influenced by the pH (5) of the intestinal contents, and inhibited by low temperatures (6) and by iodoacetic acid (7). This last fact gave us a hint as to what the process might be. We know from the influence of this substance on muscle metabolism that it interferes with oxidation-reduction processes connected with the resynthesis of hexose phosphoric acid during the recovery process in the muscle. We therefore supposed that a similar transformation of glucose (and galactose) might occur in the cells of the intestinal mucosa, and that this process might be stopped by iodoacetic acid. Such a synthetic process in the mucosa would maintain a high diffusion gradient between the sugar in the intestinal lumen and that in the mucosal cells by constantly transforming the sugar which diffuses into the mucosal cells into another substance. This might be the explanation for the rapid absorption of these sugars.

I do not want to refer to all the details of older work, but I may say that it was not by accident that we one day postulated, as a working theory, that the adrenal cortex might influence this synthetic process (8). We know that the muscular weakness, so well known to all who have studied the effect of destruction of the adrenal cortex, is caused by a lack of the restoration processes in the muscle. We had shown an elongation of the contraction curve of a single muscle twitch in adrenalectomized frogs and rats (9), and we had also shown a lack of carbon dioxide and lactic acid formation (10), so that it was logical to test the effect of extirpation of the adrenals on the activities of the intestinal mucosa.

It was immediately seen that the activity was abolished by adrenalectomy, and that glucose was then absorbed with about the same velocity as xylose. An injection of cortical hormone restored the rate of the glucose absorption to four times that of xylose (11).

We next showed that fat absorption was also destroyed by adrenalectomy and was restored by the giving of cortical hormone (12). Further, lactoflavin, or provitamin B_2, which in the normal animal probably has to be transformed in the intestinal mucosa to flavin phosphoric acid (vitamin B_2) to give the so-called "yellow breathing ferment" of Warburg, is not phosphorylated if the adrenal cortex is removed (13).

Our work on intestinal absorption thus brought us to studies on the function of the adrenal cortex. In studying absorption from the intestine one has a good opportunity to study the activities of a single cell layer, such as is found in the absorbing epithelium of the intestine. These studies showed us that in adrenalectomized animals a series of syntheses (esterifications) are lacking, namely the phosphorylation of glucose, the synthesis of fat, which probably goes via the phospholipids, and the phosphorylation of lactoflavin. Since such processes are not only of importance for absorption but also for other metabolic activities, the disturbances in a cortico-adrenalectomized animal are very complicated. The lack of the restoration processes in the muscle is easily explained by the inhibition of phosphorylation. A new step was the discovery that the wandering of fat from the fat depots to the liver is only possible in the presence of the cortical hormone (14).

Furthermore, disturbances in carbohydrate metabolism cause important secondary disturbances in osmotic conditions, so that water and sodium metabolism are also disturbed. Then the inability to synthesize the allimportant "yellow breathing ferment" must influence the whole intermediate metabolism of an animal in the most fundamental way.

Recently we were able directly to show that adrenalectomized rats and cats lose the capacity of transforming lactoflavin into flavinphosphoric acid in the liver (15). It was also shown that adrenalectomized rats could be kept alive with flavin phosphoric acid from liver or yeast, and that all the absorption disturbances could be healed with this substance (16). Thus the metabolic disturbances in adrenalectomized animals may be largely due to the inability to synthesize the "yellow ferment."

Unexpectedly we were pushed into questions of more practical importance through these experimental results. The question inevitably arose whether in

*From the Physiological Laboratory of the University of Basel, Switzerland.
Submitted May 26, 1937.

human pathology any symptoms are known which might be caused by a disturbance of the activity processes in the intestinal mucosa, and whether the adrenal cortex plays any part in these disturbances.

By chronic poisoning of a young animal with iodoacetic acid (a poison whose action is in many ways comparable with lack of adrenal cortex), we were able to produce an illness which reminded us in all its details of Gee-Herter's disease or the celiac disease of children. The animals stopped growing, they had an enlarged abdomen, steatorrhea, osteoporosis and hypochromic anemia (18).

Now, celiac disease in children seems to be identical with the so-called "nontropical sprue" or "idiopathic steatorrhea" of adults, a disease to which attention was called about five years ago, and which is now found everywhere in Europe (19). A great loss of strength with bulky stools containing large quantities of fat are characteristic of this disease, and in the later stages a darkening of the skin develops, as in Addison's disease. A study of these cases often reveals a history running back ten years or more of slight unexplained intestinal disturbances. I am convinced that many such cases of uncertain origin are cases of disturbances of the special activity process in the intestinal mucosa due to insufficient production of the adrenal cortical hormone.

I should like to suggest that these milder illnesses, of which the cause is unknown, the Gee Herter's disease in children and "nontropical sprue" in the adult, should all be looked on as possibly "adrenocortical disturbances of absorption," or since the adrenal cortex is called the "interrenal body," one might preferably speak of "interrenal disturbances of absorption," or "interrenal steatorrhea."

We may note that it is only accidentally that doctors first notice the steatorrhea in these illnesses. Glucose absorption is also disturbed in all these cases, but the sugar does not appear in the feces because it is fermented in the large intestine by bacteria.

These cases often respond marvelously to liver extracts (as Castle has shown), and to such yeast extracts as contain undestroyed flavinphosphoric acid. The liver extracts contain this substance. Yeast extracts on the contrary often do not contain this easily destroyed substance. At present it is unfortunately impossible to give patients adrenocortical hormone in quantities, which, judging from animal experiments, could be expected to be effective.

In cases of steatorrhea, a primary disturbance of absorption should be diagnosed only if one can be sure that the work of the digestive enzymes and intestinal motility is normal. However, one must not suppose that sugar or fat are not absorbed at all in these cases. Even total adrenalectomy abolishes only some special processes whose function it is to speed up the absorption of certain substances. The absorption of fat and glucose still continues but at a much reduced rate.

One must not expect every patient with Addison's disease to show disturbances of absorption with steatorrhea. Pigmentation in this illness seems to be the result of a hypofunction of the adrenal medulla while disturbances of absorption and loss of strength are the result of disease of the cortex. It is true that in the later stages of "nontropical sprue," the adrenal medulla also seems to become affected and pigmentation results. One might think of Addison's disease as starting in the adrenal medulla and Gee-Herter's disease and "nontropical sprue" as starting in the cortex. Many cases are now known in which Addison's disease seemed to change into sprue and vice versa (20).

It may be that hypofunction of the adrenal cortex is to be found in the absence of characteristic anatomical changes. Perhaps there may be only a decrease in the volume of the organ. Unfortunately there have been as yet, but few postmortem studies made to answer this question.

The physiologists' work must generally be uninfluenced by practical considerations, in order that he may investigate his problems as fundamentally as possible. But it is rather fortunate if, as in this case, one is forced to connect theoretical results with the experiences of the clinician.

The Physiological Control of Gastric Acidity*

By

CHARLES M. WILHELMJ, M.D., REX W. FINEGAN, M.D.

and

FREDERICK C. HILL, M.D.

OMAHA, NEBRASKA

DURING the past six years this laboratory has been engaged in a detailed study of the physiological factors regulating gastric acidity, particularly in an attempt to evaluate the relative importance of the various mechanisms involved. In the present summary technical details and descriptions of the various control experiments will be omitted and only the general conclusions will be given.

GENERAL METHODS

Two types of test meals were used in the various phases of the work. *A tenth normal hydrochloric acid test meal* with and without histamine stimulation was used to study the factors responsible for the lowering of the acidity of the gastric contents and the amount and composition of the non-acid secretions which may enter the stomach. *A specially prepared 2 per cent Liebig's extract test meal* was used to study the gastric secretory curves under various conditions. Both types of test meal contained 15 mg. of phenol red per liter, and the determination of the per cent of phenol red in the gastric samples enabled us to say just how much of the fluid in the gastric samples was fluid of the test meal and how much was fluid of the various secretions which entered the stomach. It was thus possible to study the acidity of the secretions entering the stomach as well as the acidity of the gastric contents. It was also possible to estimate in the total fluid secretions entering the stomach the size of the two fractions representing the acid secretion and the non-acid secretions. The latter is sometimes spoken of as the diluting fluid.

I. THE STRENGTH OF THE ACID SECRETED BY THE STOMACH

We believe that it is now well established, due largely to the work of Hollander (1, 2, 3, 4), that the strength of the acid secreted by the stomach is practically a physiological constant. In dogs the value for the pure acid secretion is approximately 0.170 normal (600 mgm. of acid chloride per 100 c.c. of secretion). This value remains constant, uninfluenced either by the amount of acid secreted or by the acidity of the material already in the stomach. Since hydrochloric acid of this strength is damaging to living tissues, it is fortunate that the acidity of the mixed gastric secretions, under normal conditions, seldom reaches this value. This paper deals with the various factors which bring about the necessary dilution and neutralization.

II. DECREASE IN ACIDITY DUE TO DILUTION AND NEUTRALIZATION

Over 220 fractional gastric analyses have been made on 34 normal dogs, while using the 2 per cent Liebig's extract test meal. In about 90 per cent of these analyses the gastric secretory curve showed a striking uniformity. The characteristics of this commonly seen normal curve are as follows: The quantity of total fluid secretions entering the stomach, per 100 c.c. of gastric contents, increases progressively from the beginning of the experiment until the stomach empties. The composition of the total fluid secretions shows rather constant variations during the different phases of the secretory curve. The quantity of acid fluid is low at the beginning but rises rapidly so that near the middle of the curve there is usually more acid than non-acid fluid present in the gastric contents. Near the end of the curve, just before emptying occurs, the secretion of acid fluid becomes much slower and the curve may actually fall off. With this there is an abrupt and marked relative increase in the amount of non-acid fluid entering the stomach. The acidity of the total secretions entering the stomach shows corresponding changes; the curve rises rapidly at first but near its middle or end there is a cessation of the rise, or more commonly, an abrupt fall. Coincident with the terminal increase in the inflow of non-acid fluid and the fall in the acidity of the total secretions, bile appears in the gastric samples.

One of the first questions which we attempted to answer was: What is the source of the non-acid fluid which gushes into the stomach just before emptying occurs? Is it of intragastric or duodenal origin? Experiments were first performed on whole stomach pouches isolated from the duodenum. When fractional analyses, using the Liebig's extract test meal, were performed on juice from these pouches, the secretory curves were strikingly different from those obtained in the intact stomach connected to the duodenum. The increase in non-acid fluid failed to occur as the pouch emptied; in fact this secretion often decreased to zero, apparently as a result of this the acidity of the secretions rose progressively during the experiment and finally reached the value of the pure acid secretion or even surpassed it. From this it appeared that the marked increase in non-acid fluid, so characteristic in the intact normal stomach, is not of intragastric origin but must be due to regurgitation of fluid from the duodenum.

Certain hypothetical objections were brought up against these experiments on whole stomach pouches and in order to meet them a series of experiments were performed on dogs before and after performing the Mann-Williamson operation of "surgical duodenal drainage." In this operation the duodenum is detached from the stomach and the upper end closed, the lower end is drained into the terminal ileum, and the jejunum is brought up to the stomach to take the

*Departments of Physiology and Experimental Surgery, Creighton University School of Medicine.

Submitted May 30, 1937.

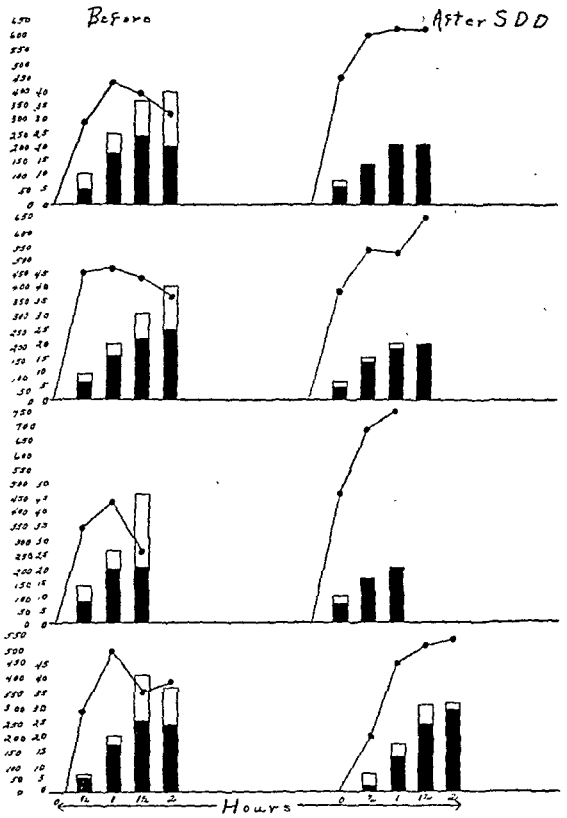

Fig. 1. Shows the average gastric secretory curve obtained with four dogs *before* and *after* the Mann-Williamson operation of "surgical duodenal drainage."

The height of the rectangles shows the total amount of fluid secretions entering the stomach per 100 c.c. of gastric contents. The *black* portion indicates the fluid of the acid secretion and the *white* portion the fluid of the non-acid secretions. The line represents the acid chloride concentration of the total secretions entering the stomach.

The scale increasing by 5 represents the fluid of the secretions per 100 c.c. of gastric contents, and the scale increasing by 50 represents the acid chloride per 100 c.c. of secretion entering the stomach.

Samples were removed from the stomach every half hour.

place of the duodenum. Following this operation the average secretory curves were exactly the same as those found in whole stomach pouches. The acidity of the secretions entering the stomach after operation was always markedly higher than before operation; the non-acid fluid was very small in amount, and it tended to *decrease* even to zero rather than to *increase* as the stomach emptied (Fig. 1).

In further experiments on whole stomach pouches a tenth normal hydrochloric acid test meal was used and it was found that the isolated stomach had very little ability to reduce the acidity unless the amount of acid present was very small. A more detailed study showed that the amount of non-acid fluid secreted by the isolated stomach was small in amount, that it was secreted at nearly a constant rate, independent of the rate of acid secretion, and that marked and abrupt increases did not occur.

The results of the above experiments were clear-cut and definite, and showed clearly that regurgitation of duodenal secretions is a normal event, occurring as the stomach is emptying, and that the primary effect of regurgitation is to prevent further rise, or more commonly, to lower the acidity of the *total secretions* entering the stomach.

A detailed study was next made of the *duodenal* secretions and it was found that the alkalinity of the mixed secretions might vary from 0.01 to 0.07 normal, apparently depending upon the amount of pancreatic juice which was mixed with the bile and succus entericus. The average value in nearly one hundred analyses was found to be 0.04 normal alkali. From this it is evident that the efficiency of the duodenal *secretions in lowering the acidity* of the gastric secretions depends more upon dilution than upon neutralization.

III. THE PHENOMENON OF ACID INHIBITION

The second factor in the physiological control of gastric acidity is one to which we have given the name "acid inhibition." This mechanism acts *in the stomach* to control the intragastric chemical phase of acid secretion and *in the intestine* to control the intestinal phase of acid secretion.

(a) Intragastric acid inhibition. When the acidity of the gastric contents rises above a certain threshold value progressive inhibition of acid secretion occurs and at certain concentrations acid secretion may be totally inhibited. This mechanism is entirely an intragastric one and apparently does not involve the vagus nerves since it occurs in the vagally denervated whole *stomach isolated from the intestine.* The exact level of acidity at which inhibition begins varies in different animals but it is usually not marked until the acidity of the gastric contents approximates 60 units (0.06 normal acid). Above this value inhibition is progressive so that in all animals the acid-forming cells appear to be markedly or completely inhibited by tenth normal hydrochloric acid.

This mechanism appears to be the second bulwark of defense to prevent an excessive rise of the acidity of the gastric *contents.* Should duodenal regurgitation fail to keep the acidity of the contents below a certain value, acid inhibition will then operate to decrease the rate of acid secretion. After the Mann-Williamson operation, and in whole stomach pouches there was evidence that this mechanism operated to decrease the rate of acid secretion as shown by the progressively slower rise in the acidity of the gastric contents toward the end of the experiments (Fig. 1). It is interesting and important to note that when histamine is administered (1 mg. subcutaneously), this mechanism does not operate and marked secretion occurs even when the stomach is filled with 0.170 normal hydrochloric acid. This shows that histamine is qualitatively or quantitatively (or both) different from the normally occurring secretogogues present in food, and it emphasizes the danger of using histamine to study *normal regulatory mechanisms.*

(b) Intestinal acid inhibition. The intestinal phase of acid secretion by the stomach is apparently due to the absorption from the intestine of digestive products which, when they reach the stomach by way of the blood stream, act as secretogogues. It was found that when acid passed into the intestine, inhibition of the intestinal phase of acid secretion occurred, but that the presence of acid in the *stomach did not* inhibit this phase of acid secretion.

The mechanism of acid inhibition is not known, but it is possible that enterogastrone (Ivy) may be concerned in the inhibition of the intestinal phase by acid in the intestine. It seems unlikely that a humoral mechanism is concerned in the inhibition of the intragastric chemical phase by acid in the stomach.

Further studies showed that when the intragastric chemical and intestinal phases coincided, the resulting stimulus to secretion was usually too potent to be inhibited by acid in the stomach and intestine. The degree, then, of acid inhibition depends upon the relative strengths of the *secretory and inhibitory* stimuli.

Acid inhibition is thus seen to act within the stomach to prevent an excessive rise in the acidity of the gastric contents and in the intestine to stop the intestinal phase of acid secretion after the stomach has emptied. Acid inhibition could theoretically control gastric acidity independently of duodenal regurgitation but when both mechanisms are in operation simultaneously it is difficult to determine which plays the more important role. It is possible that the relative importance of the two mechanisms may vary in different persons so that in some individuals duodenal regurgitation may be the primary factor responsible for the control of gastric acidity while in others acid inhibition may be the controlling mechanism. It is also possible that certain types of hyposecretion and hypersecretion may be due to changes in the threshold for acid inhibition in the stomach or intestine.

The effect of acid inhibition on the psychic or cephalic phase of acid secretion was also studied. It was found that this phase is often of such great potency that it is not inhibited by the presence of acid in both the stomach and intestine. Thus the secretory energy of the cephalic phase often approaches that of the simultaneously combined intragastric and intestinal phases and approximates that of histamine stimulation. This is important in showing that the cephalic phase may often be responsible for a degree of hypersecretion or hyperacidity which could not be attained by either of the other two phases alone. The cephalic phase may thus often be correctly termed the "outlaw" among the phases of acid secretion.

IV. THE ROLE OF THE PARS PYLORICA IN ACID SECRETION

Whether or not some stimulus from the pars pylorica serves to augment the secretion of acid by the fundus and thus plays a role in the intragastric chemical phase of acid secretion is a much debated question. One group of clinicians and experimental workers believe that after a Polya or Billroth type of operation, the lowering of gastric acidity can be entirely accounted for by the increase in the amount of duodenal secretions which enter the stomach, while another group believe that the lowering of gastric acidity is more marked than could be accounted for by the presence of duodenal secretions.

We have studied this question using new methods of analysis and calculation which allowed us to determine the amount of duodenal secretions which entered the stomach after Polya and Billroth II operations and found that the decrease in the acidity of the gastric secretions was usually definitely greater than could be accounted for by the diluting and neutralizing effect of regurgitating duodenal secretions.

In some animals however, removal of the pars pylorica failed to produce the usual decrease in the secretion of acid, and our evidence now suggests that this may be due to the fact that in these animals the cephalic or vagal control over acid secretion was unusually marked. In fact, our evidence at the present time suggests that it may be possible to divide animals into two groups, *first*, those in which gastric acidity is greatly influenced by stimuli arising in the pars pylorica and *second*, those in which the acidity is much under the control of cephalic or vagal influences. In the case of the first group, removal of the pars pylorica may produce a marked lowering of acidity while in the second group it may fail to do so, and in these animals a double thoracic vagotomy may have to be performed before the production of acid can be lowered.

It is possible that cases of gastric hypersecretion in man may be similarly grouped, and if this be true, then removal of the distal third of the stomach might be resorted to to control hypersecretion in one group and vagotomy performed to control it in the other group. At present we are subjecting this theory to experimental proof and are attempting to develop methods for recognizing the animals that are to be put into each one of the two groups.

V. WATER ABSORPTION FROM THE GASTRIC CONTENTS

Our evidence indicates that in most normal dogs small amounts of water are constantly being absorbed from the gastric contents but this is hard to show because the quantity of non-acid fluid regurgitating from the duodenum is much in excess of the amount of water absorbed in the stomach. However, when the non-acid fluids from the duodenum are prevented from entering the stomach, as in the case of whole stomach pouches or after the Mann-Williamson operation, the absorption of water may be easily detected; some of the non-acid fluid will disappear as the experiment progresses and as a result the gastric contents will be concentrated and the acidity will rise above the value for pure acid secretion from the parietal cells (Fig. 1).

This phenomenon of absorption and concentration is in some way related to the composition of the normal gastric contents since it does not occur when a tenth normal hydrochloric acid test meal is used. In some dogs water absorption is much more pronounced than in others, and it is in no way related to or dependent upon the degree of dehydration of the animal as a whole. When marked water absorption is associated with a decrease in duodenal regurgitation, a marked degree of hyperacidity may result. It may well be now that there is a clinical type of *hyperacidity* due to an excessive absorption of water from the gastric contents with or without an associated decrease in duodenal regurgitation. This could only be detected by adding phenol red to the fluid of the test meal and determining the amount of total fluid secretions entering the stomach, together with their acidity.

SUMMARY

The physiological control of gastric acidity depends upon the following factors:

1. Strength of the acid secreted.
2. Regurgitation of non-acid secretions from the duodenum.
3. Inhibition of the intragastric chemical phase of

acid secretion due to the presence of acid in the stomach and of the intestinal phase of acid secretion due to the presence of acid in the intestine.

4. The intensity of the stimuli arising in the pars pylorica and the degree to which, in a given animal, they influence the intragastric chemical phase of acid secretion.

5. Vagal or cephalic influences.

6. Absorption of water from the gastric contents.

The relative importance and the interrelations of these factors are briefly discussed.

Anoxemia Used as a Means of Analyzing the Structure and Functions of the Nervous System of the Bowel*

By

WALTER C. ALVAREZ, M.D.†

ROCHESTER, MINNESOTA

SEEING that the several tissues of the body lose their functions at different intervals after the stoppage of the circulation, it occurred to me that this differential death rate might be used as a sort of dissecting needle in physiologic studies, and some eight years ago, when I came to distrust more and more all conclusions based on the assumed actions of drugs, I turned to the use of anoxemia as an aid in unraveling the structure and functions of the nervous system of the bowel.

I first searched the literature for information as to the ways in which the various neurones in the body, as well as the several parts of a neurone, die. A review of this literature has been published elsewhere (5). Suffice it to say here that in mammals', including man, synapses, some of the sensory nerve endings in the central part of the nervous system, and perhaps some ganglion cells, cease functioning within a minute or two after the circulation stops. There is probably a descending gradient of susceptibility from the ganglion cells in the cortex, through the medulla and down to the end of the cord. Consciousness and most reflexes disappear immediately after the stoppage of the heart. After from five to ten minutes the damage done to the nerve cells of the brain becomes irreparable. Some of the nerve fibers and the motor nerve endings in the central nervous system are much hardier, and will function for an hour or two when left in the uncooled animal. Fifteen minutes after stoppage of the circulation in a limb, sensations of touch, pressure, vibration, and position begin to go, and after from thirty to forty-five minutes all that can be felt is warmth and burning pain. With these changes, there is a loss of electric response in the A and B fibers (Clark, Hughes and Gasser).

In the autonomic part of the nervous system, and particularly in the sympathetic division, all parts of the neurone are more resistant to anoxemia than are the corresponding parts of the neurones in the brain and spinal cord. Reflexes persist for from ten to twenty minutes after the stoppage of the circulation, and ganglion cells can be resuscitated after periods of time ranging up to twenty minutes. Stimulation of the vagus nerves continues to slow the heart for about forty minutes, while stimulation of the sympathetic nerves accelerates the beat for a few minutes more. In the intestine, the nervous system, if left in contact with blood, will survive for six hours or more after the stoppage of the circulation; without blood, irreversible changes take place in about three and a half hours.

THE WAY IN WHICH THE INTESTINE OF THE RABBIT LOSES ITS FUNCTIONS AFTER THE DEATH OF THE ANIMAL OR THE STOPPAGE OF THE CIRCULATION.*

PERISTALTIC RUSH

I have long known that in the dying rabbit, the first function of the bowel to be lost is that of peristaltic rush; it disappears immediately. In twenty years I have seen only a very few examples of what looked like a normal rush in the intact bowel left in a dead animal with the abdomen open in a bath of warm aërated saline solution.

At first glance it would seem that any function that disappears so promptly after the stoppage of the circulation must be dependent on a synapse as sensitive as are those in the higher parts of the central nervous system. In favor of this view is the fact that the injection into the animals of a little nicotine usually puts an end to the rushes. But against the view are a number of observations. One is that the synapses in the sympathetic division of the nervous system appear usually to retain their function for from ten to twenty minutes after the stoppage of the circulation, and from Cannon and Burket's experience, one would expect the synapses in Auerbach's plexus to be even more resistant than are those elsewhere in the abdomen. Perhaps confirmatory of this view is my observation (4, 8, 9) that the synapses that presumably exist between the vagus nerves and the neurones in Auerbach's plexus retain their function for from ten to twenty-seven minutes after the death of the animal. The evidence in favor of the view that such synapses exist has been summed up elsewhere (7).

It seemed probable, then, that the immediate stoppage of rush waves which is usually observed when

Submitted July 21, 1937.

*In the experiments herein described the rabbits were anesthetized with urethane. The distal part of the spinal cord was pithed and the abdomen was opened under a bath of warm Locke's solution. The technic used in starting and recording rushes has been described elsewhere (Alvarez) (6).

the heart ceases beating is due to inhibition, and this view was strengthened by two observations. One was that with the stoppage of the rushes, there was, at times, a stoppage also of the rhythmic contractions of the muscle. This took place even when the saline bath was aërated. That it was due to inhibition was indicated by the fact that the rhythmic movements promptly reappeared when the bowel was cut away from the mesentery. The other observation was that if, instead of sacrificing the animal, I stopped the circulation in the bowel by clamping the abdominal aorta or the superior mesenteric artery, the rush waves often stopped for a few minutes, only to reappear, much as the rhythmic contractions did. The rushes could be elicited then for a few minutes until, perhaps, with loss of function in some synapse, they stopped, never to reappear.

When the intestine was left attached to the mesentery of the dead animal the rushes never reappeared, perhaps because by the time the inhibition had worn off, irreversible changes had taken place in the synapses. This inhibiting effect may come by way of the nervous system or it may come through the blood from other parts of the dying body. The latter theory is probable because the inhibition was often absent when the stoppage of the circulation was effected by clamping the mesenteric vessels, and it could then be produced sometimes by removing the clamp and letting the blood flow in again. It is interesting to note here that Carnot and Glénard (24, 25) found that a segment of bowel would survive better if they washed out the blood vessels. Interesting, also, is Nolf's (41) conclusion that, in the chicken, the stoppage of the movements of the gizzard which follows asphyxia is due to stimulation of a nervous center which produces inhibition. Somewhat similar observations on the behavior of the arrectores pilorum muscles of dying animals were puzzled over years ago by Langley (37, 38).

That some form of inhibition of the intestine is removed after the death of the animal was suggested by a number of observations. Thus, I found that the tonic effect of electric stimulation of the vagus nerves on the muscular contractions of the bowel was easier to demonstrate immediately after death than it was in the living animal. Similarly, the short distance conduction of an electrically produced disturbance was more easily demonstrated in excised than in intact bowel. Other investigators have made similar observations.

Difficulties in differentiating normal and abnormal rush waves: Unfortunately, as I (6) have pointed out elsewhere, definite conclusions as to the length of the interval between the death of an animal and the cessation of rushes are hard to draw because so much depends on the experimenter's opinion as to the normality or abnormality of each wave seen. The problem would be much simpler if inspection of the graphic records could decide the matter, but often this does not help much. The difficulty lies not only in the defects in the methods of recording, but also in the fact that some of the rushes observed in apparently healthy bowel are atypical or perhaps as abnormal as those seen in nicotinized or dying bowel. Usually the dying or nicotinized bowel empties itself poorly after a rush, but bowel that appears to be normal will often do the same thing, and bowel that has long been anoxemic may seem to empty perfectly (Fig. 1). Sometimes the main abnormality of a questionable rush is its fast rate, or its tendency to combine the characteristics of both a "systole" and a rush.

I regret that for some time I used recording devices, attached to the longitudinal and circular muscle, which did not facilitate the differentiation of normal and atypical rushes, or rushes mediated by some mechanism other than the normal nervous one. Eventually I devised a satisfactory "distention recorder" described elsewhere (6).

The study of peristaltic rush is made particularly difficult by the fact that there appear to be a number of ways in which the intestinal contents can be made to travel through the bowel. Actually, a column of fluid rushing down the bowel with good momentum can be made to pass through 100 cm. or more of dead bowel or even through a length of glass or rubber tubing. When some of this fluid reaches normal bowel at the further end of the inert segment, it commonly starts a new wave which proceeds normally on toward the ileocecal sphincter. Other ways in which the rushes can travel will be described later in this paper.

Rushes seen after clamping the abdominal aorta: In a series of sixteen experiments, the aorta of the rabbit was closed just below the diaphragm, usually with the help of a snare made with a metal tube and a piece of tape. In every case the bowel was rendered pulseless and either blanched or scanotic. In a few of the experiments I observed the immediate inhibition of rushes which is so characteristic after the death of the animal. Usually, after a few minutes, they could again be elicited. In animals which showed but few rush waves before the clamp was applied, it was hard to start any after the circulation was stopped, while in robust animals with a very active bowel to begin with, an hour or two of anoxemia sometimes did not do much harm. These differences in individual rabbits added greatly to the difficulties of interpreting the results of experiments.

Some rushes started spontaneously, but most of them were produced by squirting fluid into the duodenum according to the technic described elsewhere (6).

So far as my assistant and I could tell from the appearance of the rushes, they were normal for from twenty to thirty-five minutes after the stoppage of the circulation. This interval agrees fairly well with that representing the usual survival time of synapses in the sympathetic nervous system and also of those synapses which are believed to connect the ends of the vagus nerves with the neurones of the myenteric plexus. After half an hour of anoxemia, the graphic records of rushes often looked fairly normal, but the waves themselves commonly did not look right to the experienced observer. Some seemed to go too slowly, others too fast, others too weakly, and others seemed to be mixtures of systoles and rushes, usually running caudad but sometimes orad. Actually the records often indicated that a series of short waves had arisen simultaneously in several parts of the bowel and had traveled caudad or orad.

Very puzzling was the fact that in one rabbit with the aorta clamped, after good rushes had run for thirty minutes, questionable ones continued to appear for three hours or longer; in one animal, what looked like a normal rush was recorded three hours and thirteen minutes after the bowel had first been rendered pulseless and cyanotic. In another animal,

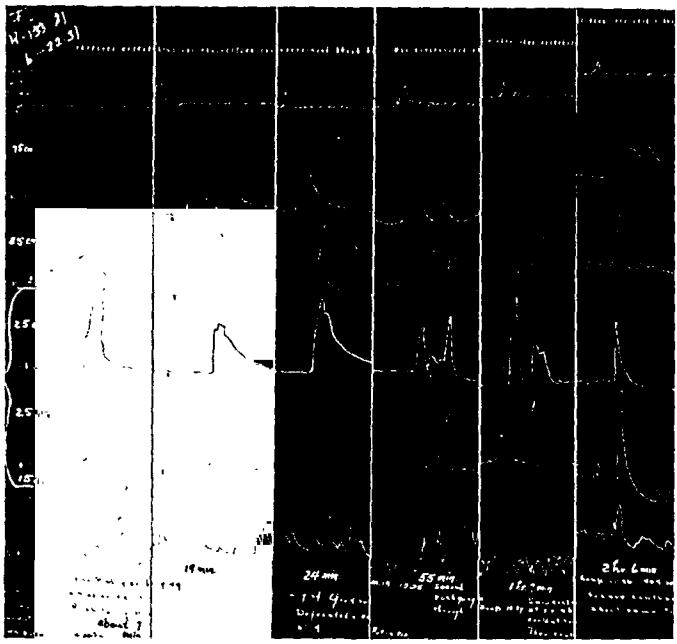

Fig. 1. Showing the change from a wave to a systole produced by anoxemia: *a*, record of a normal rush coming seven minutes after the segment indicated by the brace had been cut away from its mesentery; *b*, twelve minutes later a wave progressed normally until it reached the anoxemic segment and there it traveled rapidly; *c*, five minutes later a rush went through the anoxemic segment even more rapidly; *d*, thirty-one minutes later the anoxemic segment contracted as a unit the moment a rush reached its oral end, and contracted systolically again thirty-two seconds later; *e*, twelve minutes later, or sixty-seven minutes after the segment lost its blood supply, it failed to conduct a rush; instead, the caudal end contracted at almost the moment when the rush left the duodenum 160 cm. away, and originated a wave which ran orad until it met the descending rush, and *f*, after two hours and six minutes of anoxemia the contraction of the anoxemic segment was typically systolic; in the bowel orad and caudad to the abnormal segment rushes still traveled normally.

after the circulation of the bowel had been shut off for about an hour, first by clamping the aorta and later by cutting through the root of the mesentery, an apparently normal rush was seen. It is hard to know what to think about these observations. Either synapses survived unusually long because some trickle of blood continued to come in through collateral channels or else I was mistaken in my opinion as to the normality of the rushes, or perhaps synapses are not so important in the mechanism of peristaltic rush as I think they are. Good examples of the changes in the appearance of rushes which come with anoxemia are to be seen in Figures 1 and 2.

In eleven animals the clamp on the blood vessels was removed after varying intervals of time to see if the rushes would become normal again. In no instance did they seem quite normal when the anoxemia had lasted over half an hour. One must not conclude from this that changes in the nerves are irreversible after this length of time because experiments of another type showed that they are reversible. The experiments to which I now refer resembled those of Cannon and Burket in which clamps were applied under aseptic conditions so as to stop for several hours the circulation of the bowel. Later these clamps were removed, and the animal was allowed to recover. In one such experiment, to be described later in more detail, rushes which appeared to be normal were seen traversing a long segment of bowel which, three weeks before, had been kept pulseless and purple for twelve and a half hours!

Rushes seen after clamping the superior mesenteric artery: In nine animals, the superior mesenteric artery was clamped, and the results obtained were very much like those seen after clamping the abdominal aorta. If there were good rushes before the artery was clamped these generally continued for about thirty minutes, and after that they were atypical (Fig. 2).

Rushes after clamping the mesenteric vessels to a segment of bowel: In thirteen animals the mesenteric arteries supplying a segment of jejunum or ileum approximately 140 cm. in length were clamped for varying periods of time. In every experiment most of the segment became cyanotic, but some blood continued to trickle into the ends adjoining the normal bowel.

Again, in the more healthy animals in which there were good peristaltic rushes before the vessels were clamped, waves continued to pass normally through the cyanotic segment for from eight to thirty-seven minutes. Then there usually came a change; the bowel often became beady as it does after it has been

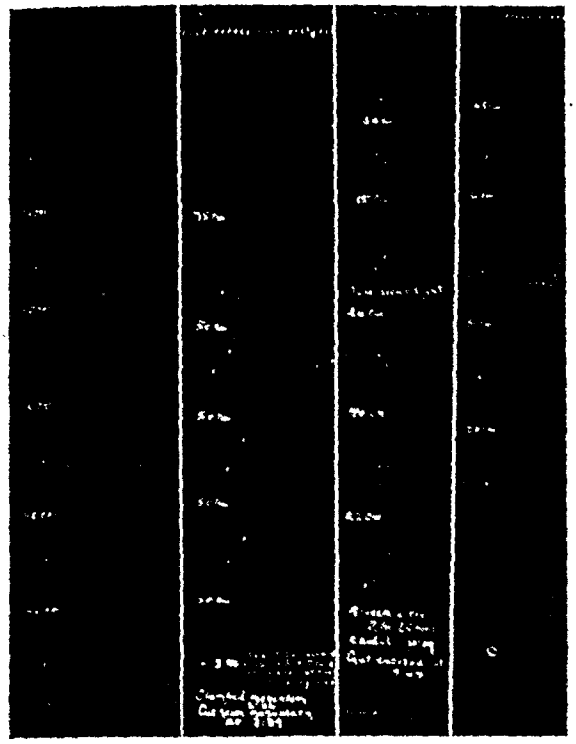

Fig. 2. *a*, a slow rush wave; *b*, a fast traveling disturbance in the same bowel forty-six minutes after the mesenteric vessels were clamped and three minutes after the bowel was cut away from the mesentery; to the observer the disturbance looked like a normal rush in the first 125 cm. of bowel, but what happened caudad to this point was not so clear, the record showing that the contraction was systolic in type and that it began as the wave left the duodenum; *c*, 145 minutes after the bowel had been separated from the mesentery a disturbance was made to travel orad the length of the bowel; that this was not due purely to an advancing column of fluid is shown by the fact that about midway the lumen of the bowel was closed with a ring of tape; in addition to the traveling wave, there was an immediate response of the bowel 92 cm. orad to the point stimulated; and *d*, rarely seen wave of inhibition running down the bowel.

poisoned by nicotine, and the rushes then became shallow and discontinuous. Such atypical rushes often continued for a long time. In one animal, they were still going through with some signs of a following wave of contraction four hours after stoppage of the circulation. In this particular experiment, the rhythmic contractions had ceased, but the long-distance nervous paths, to be described later, were still functioning well, as shown by the fact that some segments of the injured bowel were "anticipating" the arrival of the rush waves with an increase in tonus and activity.

After the first half hour of anoxemia, rushes entering the upper end of the cyanotic segment sometimes faded out and failed to reach the distal end. Whenever they did reach it, they always went on caudad with a normal appearance in the normal bowel. So long as the rushes could get through the cyanotic segment they usually traveled there with a normal rate. Sometimes they went through abnormally fast.

The removal of the clamp and the restoration of the circulation after an interval of from twenty to thirty minutes resulted after a time in the return of perfectly normal rushes.

In some cases the root of the mesentery was cut between clamps, and in one such case records of rushes looked normal one hour later. They looked fairly normal to the observer, but they decelerated instead of accelerating in speed, as they should normally have done.

At times, the observers could see a change in the character of the rushes after the first thirty minutes, but examination of the graphic records did not help in determining what was wrong with them. In one experiment the records of the rushes looked normal for an hour and forty-seven minutes after the tying of the arteries. When the rushes could no longer get through an anoxemic segment they seemed to enter it and go normally for a distance of perhaps 20 cm. They could do this perhaps because near the end of the handicapped segment there was still some inflow of blood.

Rushes seen after cutting segments of the bowel away from the mesentery: In ten rabbits segments of bowel were cut away from the mesentery after ligation of the vessels supplying the region. The blood remaining in the bowel was forced out by tonic contraction of the blood vessels, so that the wall became blanched and often beady. When the segment was less than 65 cm. long, rush waves continued to run through it as if nothing had happened; when it was from 65 to 170 cm. long, the waves commonly got through but they were abnormal in one way or another. Sometimes when they looked normal to the observer they appeared to be abnormal on the record (Figs. 1 and 2).

In a number of experiments most of the small bowel was cut away from the mesentery, leaving only the blood supply of the duodenum intact. The plan was to start rushes in this first part of the bowel and see how far they would go. In most of the rabbits so prepared rushes could not be started, but in one rabbit some very interesting observations were made: Eight minutes after nearly all of the jejunum and ileum (235 cm.) had been separated from its mesentery, an apparently normal rush went through and another followed two minutes later. After this there were no more.

Rushes seen after removing the whole small bowel from the body: In a series of eighteen experiments the whole small bowel was removed quickly and placed in a tank of warm aërated Locke's solution. Recording devices were attached at intervals along this bowel, as in the experiments with intact animals. When fluid was squirted into the oral end of such excised bowel, there seldom appeared anything that could be mistaken for a normal rush wave, at least during the first hour or two. During this interval the fluid injected usually worked its way slowly toward the caudal end, leaving the bowel constantly distended. When contractions appeared here and there they usually progressed for some distance caudad, but there was no coördinated rush traveling a long distance.

Rarely, there seemed to be exceptions to this rule, and what looked like normal rushes would appear, usually in the first few minutes after the death of the animal. Once this may have been because the mesenteric artery was clamped as the animal was dying, thus cutting off the access of inhibiting substances to the bowel.

One day Dr. Berkson and Mrs. Bennett, who were working with me, saw several spontaneous and apparently normal rushes traversing about 50 cm. of bowel which had been out of the animal and in oxygenated Locke's solution for about one hour. The contractions of the muscle were powerful and the waves seemed to advance continuously. In the case of one such wave which I watched closely the successive segments of bowel traversed by the disturbance emptied themselves promptly and efficiently, which is a good sign of normality. Evidences of normality could be seen also in the graphic records made of this rush which appeared nearly three hours after the death of the animal. In another instance the records made nearly three hours after excision of the bowel showed what looked like good rushes with signs of "anticipation," or an increase in the tonus and activity of the bowel far out ahead of the crest of the wave.

In two other experiments waves were still traveling caudad six and a half hours after the gut had been removed from the body. Some of these were almost normal in appearance, not only to the observer but to the analyzer of the graphic records.

Difficulties in the appraisal of these late appearing rushes were multiplied because of the fact that after from one to three hours of anoxemia, long-distance conduction usually improved so markedly that there appeared many systoles (Fig. 5) or mixtures of systoles and short rushes (Fig. 3) which often seemed to the observer to be fast rushes. Perhaps the greatest uncertainty in all this work arose in the fact that often, long after the rush waves had apparently stopped or had become decidedly abnormal, along would come one in which no fault could be seen.

This occasional long persistence of what looked like rushes in excised bowel was hard to reconcile with the observations made with the anoxemic bowel left attached to the mesentery. A few things seem certain from the experiments recorded in Figs. 3, 4 and 5: one is that some of the nervous pathways for the long-distance type of rapid conduction must be in the bowel itself; another is that these conduct in either direction, and another is that they are remarkably immune to anoxemia. It seems probable also that the more sensitive nervous mechanism which presides over normal rushes resides in the bowel; the polarity which causes waves to travel more easily in one direction is certainly resident in the wall of the bowel.

The importance of the advancing column of fluid: As I have already said, yet another difficulty in the way of saying when normal rushes stop is to be found in the fact that there are a number of ways in which rushes can be kept going. In another paper I hope to show in more detail how the mere advance of a column of fluid through the bowel may serve to maintain or keep going what looks like a rush. The importance of this mechanism is shown by the fact that in bowel handicapped by anoxemia, rushes seldom got past a point where the lumen had been occluded by a ring of tape drawn just tight enough to prevent the passage of the intestinal contents. In normal bowel, such obstructions seldom had much effect because the wave could travel through the muscle to pick up a new column of fluid on the other side of the ring (2).

The importance of the advancing column can be seen also from the following experiments: In the first one, excised bowel was cut across and the lumen was

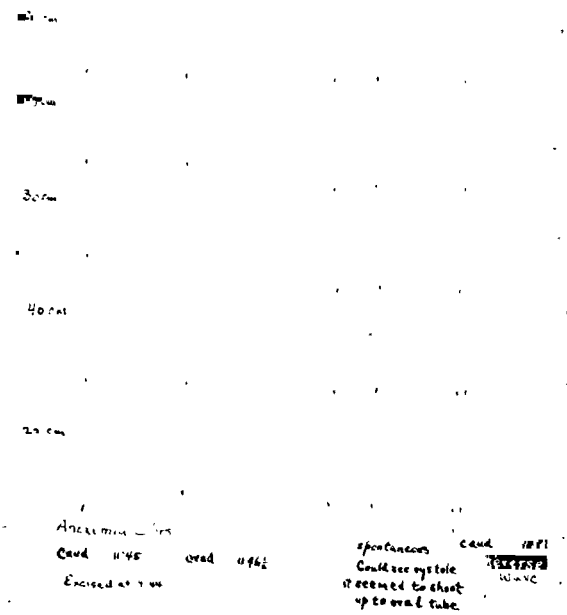

Fig. 3. Types of activity in excised whole bowel, kept in warm oxygenated Locke's solution for about two hours: The first stimulus, applied at the caudal end, appears to have spread orad as a faint ripple for 62 cm. The second stimulus, applied at the oral end, produced two disturbances, one of which shot almost instantly 75 cm. to the fourth recording segment from the top; the other, a wave, spread rapidly to the caudal end of the bowel. Next came two spontaneous disturbances, the first of which apparently originated at the caudal end and shot almost instantly 107 cm. orad. To the observer it looked like a rapid wave. The next disturbance appears to have begun in the middle and spread both ways. Then a stimulus was applied to the caudal end, producing what seemed to be a wave running orad for at least 107 cm.

restored with a short segment of glass tubing, any rushes that appeared then ran on without hesitation, in spite of the fact that there could have been no preparation of the segments caudad to the cut. In the second experiment, the bowel, attached to its mesentery, was cut across and the end was left open so that when a rush arrived the fluid ran out into the bath. Under these circumstances a wave never went on down the distal part of the bowel. In the third experiment the wall of the bowel was crushed with a hemostat in eight places, distant about 5 cm. one from the other. When rushes continued to go normally through this series of segments held together only by narrow bands of dead tissue, it was apparent again that the moving column of fluid within the lumen must be an important factor in keeping the wave going.

Important as this moving column of fluid is, however, it apparently must be assisted by the gradient or the "polarity" of the gut or whatever it is that causes the waves to move caudad in every short length of intestinal muscle. Were it not for this it should be

as easy to make waves run orad as it is to make them go caudad, simply by injecting fluid into the caudal end of the bowel, intact or excised. Actually, on attempting this, in both normal and anoxemic bowel, I found that with one squirt of fluid into the ileum, a wave could be forced orad for only about 80 cm.; there it usually faded out, and then the fluid was driven back caudad. Two mechanisms seemed to be working against the success of the experiment; one, the "long-distance conduction" which caused contractions to appear some distance ahead of the reverse waves, and the other, the gradient which caused each one of these contractions to spread caudad as a wave (Fig. 3).

Poor emptying of the anoxemic bowel: One important point to be noted about all of the atypical rush waves in anoxemic or nicotinized bowel is that the injured muscle usually did not contract well so as to clear the liquid contents out of successive segments (see Fig. 1, Alvarez) (7). Since there is much evidence to indicate that smooth muscle does not lose its faculty of contraction until anoxemia has lasted for several hours, one must suspect that the poor emptying of the abnormal gut is due to some failure either in the nervous pathways which transmit stimuli from the mucous membrane to the overlying muscle bundles, or else to interruption in the short conducting paths which cause many muscle bundles to contract together in a coördinated way. Actually, a number of investigators have found that cocainization of the mucous membrane of the bowel tends to disorganize peristalsis in the treated segment.

Reverse peristalsis after anoxemia: In several instances the shutting off of the circulation from a long segment of bowel brought with it a tendency to reverse peristalsis, but it seemed clear that the gradient in the bowel had not been much altered because contraction rings appearing here and there usually traveled caudad. Because some of the gradients tend to be reversed in pregnant animals (Alvarez and Hosoi) (11), I tried adding the reversing effect of anoxemia to that of pregnancy, but without much success in reversing the direction of rushes. They would not run orad very far even when fluid was squirted into the lower end of the ileum.

Peculiar, fast rushes: In some animals with an anoxemic bowel I saw a type of disturbance new to me. This appeared to be a very fast rush with a rate of travel varying from 30 to 65 cm. a second. Usually in the normal rabbit the rate varies from 3.5 to 6.5 cm. a second, but occasionally in the ileum a rush will traverse 25 cm. in a second.

SURVIVAL OF NERVES AND NERVE ENDINGS

After having obtained some idea of the survival time of what I assumed to be synapses in Auerbach's plexus, the next problem was to see how long the nerve fibers and their motor endings would function after the death of an animal. Only a study of action currents would enable one to determine the survival time of a nerve fiber if this time should happen to be longer than that of the motor ending. Hence now when I say "nerve" I mean the fiber together with that series of mechanisms which carries the nervous impulse over into a contraction of the muscle (Rosenblueth and associates) (46, 47).

Years ago Elliott concluded that the myoneural junction depends for continuance of life on the nucleoplasm of the muscle cell, not of the nerve cell; and actually, in the bowel, I have found the nerve endings to be very hardy. Time and again, what I call "long-distance effects" appeared in segments so poisoned by anoxemia that they gave no response to direct faradic stimulation. These endings and the fibers were immune also to doses of nicotine large enough to kill the animal, and they were immune to atropine.

Conduction over short distances: The first form of nervous conduction studied was that which is brought about through stimulation of the bowel with an interrupted electric current. Hosoi and I (12) found that in rabbits the constant current, or a single shock or a pinch, produced a contraction which did not spread along the bowel. The disturbance produced by an interrupted stimulus spread at most about 15 cm. orad and 20 cm. caudad, and considerable evidence was gathered to show that this conduction took place along short nervous pathways. These pathways did not seem to be injured by nicotine. According to Fleisch a similar type of conduction in the guinea-pig was blocked by dilute solutions of nicotine. Fleisch and Wyss blocked it also with atropine and cocaine. Raiford and Mulinos (44, 45), using denervated exteriorized segments of colon in dogs, were able to block conduction between the mucosa and the overlying muscle with atropine, and they obtained blockage also by cocainizing the mucosa.

Immediately after the bowel was excised and put into warm Locke's solution, some form of inhibition disappeared and short-distance conduction could be demonstrated more easily than when the bowel was attached to the mesentery in the living animal. This was observed also by Fleisch and Wyss, using guinea-pig bowel.

When I kept the bowel in warm aërated Locke's solution this short-distance conduction disappeared usually after about 100 minutes, but sometimes it lasted for from three to five hours (4). This interval could be doubled by filling the bowel with oxygen. In one such experiment, conduction was unimpaired after six and a half hours, when the observers left the laboratory. Such survival times are compatible with the idea that this type of conduction is mediated by nerve fibers.

Puzzles still remain, however, because from what is now known of the great dependence of smooth muscle on nerves for all but the slowest type of transmission of a stimulus, it would seem that so long as segments of bowel a few centimeters long are contracting, nerves must be at work. If this is true, then there must be two types of nerves conducting over short distances: one that loses function after some 100 minutes of anoxemia, and the other, one that survives for hours or perhaps for as long as the muscle survives. In support of this view may be the fact that degenerative section of the splanchnic nerves which commonly seemed to destroy the conducting paths with a survival time of 100 minutes did not prevent short segments of bowel from contracting in a coördinated way.

That there can be complete failure of conduction between muscle fibers, with such incoördination of activity that the many contractions and relaxations cancel out and have no effect on the length of even a short segment of bowel, was shown by me years ago while I was studying young alligators. Puzzled because with the usual heart levers I could not detect the slightest sign of activity in segments 2 or 3 cm.

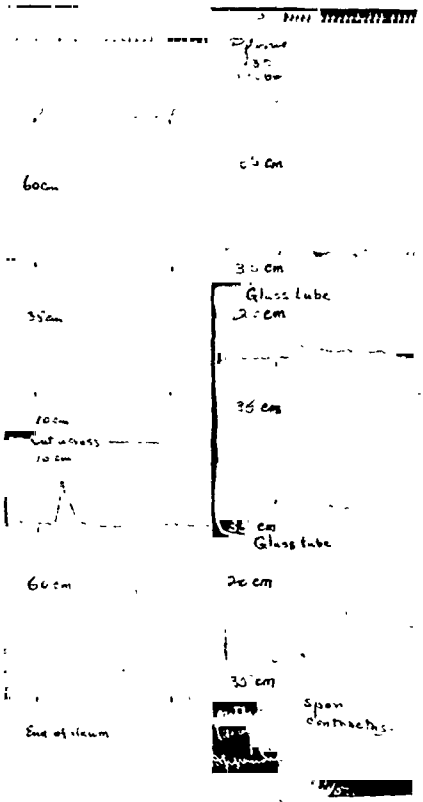

Fig. 4. Showing that some of the long nerve tracts are in the mesentery; *a*, in spite of the fact that the bowel was cut across, the ileum was inhibited when the duodenum was stimulated and *b*, similarly, with the bowel cut across in two places, a rush in the duodenum promptly affected the lower ileum. The record shows that the stimulus was not transmitted by the column of fluid because this did not get through the separated segment 90 cm. in length.

long, I looked with a microscope and found that the trouble was that every muscle fiber was busily contracting and relaxing, but each was out of step with its neighbor. Probably in these animals, as in the elasmobranch fishes, and to some extent in mammals, the power to conduct appears from time to time suddenly and for no known reason in smaller or larger portions of the enteric nervous system. One of the greatest needs today in the field of intestinal physiology is light on the nature of the mechanism which at intervals hooks this conducting system together and makes it work.

In twenty-seven rabbits studied with the technic used by Hosoi and me (10) for stimulating the bowel, the first function of the bowel to disappear was usually conduction orad of the disturbance produced by faradic stimulation. Conduction caudad lasted longer, perhaps because it is easier for impulses to go in that direction with the gradient. The local response to the faradic current disappeared next; then the rhythmic contractions, and finally the ability to respond to a slowly interrupted galvanic current.

If Nolf's (42) idea of a chain of neurones along the bowel was applicable in the case of the rabbit, one might expect to find, after a half hour of anoxemia had injured the synapses, a sudden, step-like shortening of the distance over which conduction could take place. Actually, in scores of experiments, Hosoi and I failed to observe any such change, and we failed to see it also after applying nicotine. This drug impaired the responses to stimulation, but we could not see that conduction failed segmentally as Nolf found it to do in the chicken. Also, much against Nolf's idea of a chain of conducting neurones in the myenteric plexus is my observation that in the rabbit, degenerative section of the splanchnic nerves almost wiped out what I call "short-distance conduction" throughout the small bowel, and degenerative section of the vagus nerves often shortened the distance over which such conduction could be demonstrated in the lower part of the small bowel (16). These observations indicated that, in the rabbit, much of this type of conduction is effected by fibers belonging to the *extrinsic* nervous system; Nolf believed it to be effected by *intrinsic* nerves. Fig. 12 in an article by Borchardt showed that conduction caudad was good in a denervated segment of bowel. Borchardt found also that denervation of the bowel did not interfere with the transmission of stimuli between the mucosa and the overlying muscle. According to Langley and Magnus, degenerative section of the mesenteric nerves had little effect on conduction in the bowel.

I have records showing what I call "long-distance conduction" in rabbits with both vagus nerves cut and degenerated, and I have others showing it in the bowel from animals with both vagus and splanchnic nerves cut on the day of the experiment. Unfortunately, I cannot now find any records throwing light on this point in animals with the splanchnic nerves cut and degenerated.

Few of my observations seem, then, to fit well into Nolf's attractive theory of a chain of neurones down the bowel. Perhaps this theory applies only in the case of the chicken. It is conceivable, however, that in the bowel of the rabbit, neurones about 35 cm. long, instead of being arranged like the links of a chain, overlap like the fibers in a rope. It may be, also, that there is no transmission across synapses except when a rush gets started. Against Nolf's idea that valve-like synapses between the neurones in the chain prevent reverse peristalsis is the fact that reverse waves of some kind can often be seen in the rabbit and cat. Their guiding mechanism may perhaps be very different from that of the normal caudad-directed waves.

Rapid conduction over long distances: Years ago I reported the fact that, almost coincident with the start of a rush down the duodenum, there were changes in the level and appearance of records being made of the activities of the jejunum and ileum (15). There was some increase in the tonus and activity of a segment of bowel here and there, or one rhythmic contraction was either lessened or increased in amplitude, or one or two such contractions were blocked, or the interval between two contractions was shortened or lengthened. Similarly, defecation sometimes paralyzed the whole small bowel for a few seconds.

It seemed obvious that the stimuli which produced these effects so promptly must be transmitted through nerves. Occasionally, these long-distance effects, as I call them, can be elicited by a faradic stimulus, but the best way in which to demonstrate them is to start a rush wave in the upper bowel. Interestingly, these effects commonly tend to skip one segment of bowel

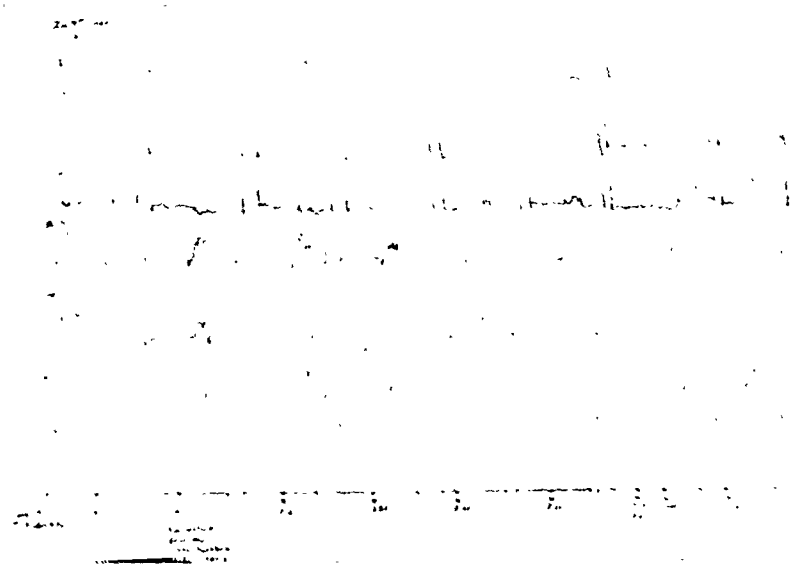

Fig. 5. A series of systoles in 130 cm. of excised bowel lying in warm oxygenated Locke's solution. Each contraction was produced by the injection of water at the oral end. The animal was sacrificed at 9:51 a. m. and the experiments here recorded were performed between 2:40 and 4:25 p. m., or from four hours and forty-nine minutes to six hours and thirty-four minutes after the bowel had lost its circulation.

to affect others near by. Possibly, one region is ready and another is not. In favor of this view is the fact that the presence of active rhythmic contractions in a segment seems at times to block the reception there of long-distance stimuli.

When I began to study the anoxemic bowel I soon noticed that the long-distance effects came out strikingly after the bowel had been without its circulation for a few hours. Then, after peristaltic rushes, short-distance conduction, and perhaps even the rhythmic contractions had failed, the long-distance conduction came to the fore, and the hardy nerves involved seemed to take over the direction of activities in the gut. It was interesting to note that the same thing happened in many of my animals when the nervous mechanism underlying peristaltic rush was put out of action by nicotine (7).

The most striking manifestation of the long-distance type of conduction I have called a "systole" because of the almost simultaneous contraction of the muscle in many parts of the small bowel. Often these systoles are associated with a series of small rushes (Fig. 3).

The fact that the mechanism that produces these manifestations is so highly resistant to anoxemia and to nicotine suggests that it consists of long nervous paths unbroken by synapses. That these paths must be present in both bowel and mesentery was shown by the persistence of long-distance effects in both excised bowel (Figs. 3 and 5) and normal bowel cut across in one or more places (Fig. 4). Fig. 3 shows that these nerves conduct in either direction, orad or caudad.

Function in these long pathways tended to fail after from five to seven hours of anoxemia, but my impression was that in healthy and active animals, or in intestine filled with oxygen, it could be maintained much longer. Thus, on several occasions, powerful systoles were being observed in the bowel some six or seven hours after the death of the animal when, because of the closing of the laboratory, the experiment was brought to a close.

Just as with short-distance conduction, so also with the long-distance type, there was considerable evidence to indicate that impulses would continue to travel caudad for some time after they had ceased going orad.

Rapid conduction by means of "water waves": I have reasons for believing that, at times, when a stretch of bowel is full of fluid, a type of long-distance conduction is effected by a stimulus transmitted through the fluid to receptors in the mucosa or the muscle. Occasionally, long-distance effects seemed harder to demonstrate when, in order to eliminate the possibility of transmission through fluid, I closed the lumen of the bowel here and there with a snugly applied ring of tape. That usually the transmission was through nerves and nerves alone was shown by experiments such as that recorded in Fig. 4. It was shown also by experiments in which the bowel was stimulated electrically or by suddenly distending a balloon in the duodenum.

LIGHT THROWN BY ANOXEMIA ON THE ACTIVITIES OF THE INTESTINAL MUSCLE

There are reasons for believing that if the excised bowel were to be kept in a stream of warm oxygenated Locke's solution, perhaps with dextrose added, the rhythmic contractions would last for days, to be stopped only by the advent of bacterial and autolytic decomposition. In some of my experiments in which the solution was changed every hour or two the contractions stopped in from five to six hours, but on several occasions they were going well after eight hours when the observers had to leave the laboratory.

In some experiments in which enough boric acid was added to the Locke's solution to make a 0.05 per

cent solution, the rhythmic contractions lasted longer than usual.

Usually, after the death of the animal or excision of the bowel, the rate of rhythmic contraction was slowed. Because approximately the same amount of slowing was usually produced by cutting both the vagus and the splanchnic nerves and allowing them to degenerate, and because after such denervation death of the animal or excision of the bowel did not cause much more lowering in the rate, it seemed that the extrinsic nerves of the bowel must contribute something to speed up the rate of the rhythmic contractions (16).

Curiously, I did not see much slowing of the rate immediately after the extrinsic nerves were cut. The big change came after degeneration of these nerves, and particularly after degeneration of the splanchnic nerves. Curiously, also, the slowing did not appear in all animals operated on. Castleton saw slowing when in dogs he denervated a loop of bowel which had previously been transplanted out under the skin.

Practically all of the available evidence now indicates that the rhythmic contractions of the bowel can keep going in the absence of any nervous impulse, but that in the normal intact animal the nerves play some part in the pace-making process just as they do in the case of the potentially automatic heart of Limulus (Heinbecker and Bishop). This nervous help seems to be needed most in the distal end of the ileum where Auerbach's plexus thins out (17). It is curious that this aid should come from the extrinsic nerves of the bowel, but perhaps it comes from some of those many fibers in Auerbach's plexus which disappear after degenerative section of these nerves. It is curious also that on warming to 38° C. excised bowel that has been in the icebox for twenty-four hours, the rate of rhythmic contraction will sometimes return almost to normal (1). This is hard to explain.

Much light on the nature of the relationship between the nerves and the rhythmic contractions of the bowel will probably come some day from further investigation of the fact that good "action currents" can be obtained from temporarily quiet stomach or bowel (13), or the fact that while epinephrine and atropine stop the contractions, they leave the electrogram unchanged (Alvarez and Mahoney (14), Berkson (18), and Castleton); or the fact that while nicotine and curare wipe out the electrographic changes, they leave the contractions more powerful than before (Berkson (19, 20), Puestow). Curiously, large doses of cocaine and ergotamine had no effect on either the myogram or the electrogram.

The recent work of Heinbecker indicates now that, in the cardiac nerve cord of Limulus, the comparatively slow potential alteration, the rate of which corresponds to that of the heart, arises in the large unipolar ganglion cells. The future alone will tell if similar conditions are present in Auerbach's plexus, and if the currents derivable from the active bowel are produced, as it now appears, in the ganglion cells rather than in the muscle.

After studying the problem off and on for years I still do not understand why the rhythmic contractions sometimes stop within a few minutes after the death of the animal and at other times go on unchanged. This stoppage was observed sometimes after clamping the mesenteric vessels. When this happened it could not be due to anoxemia because, when the bowel is cut away from the mesentery, it goes on contracting rhythmically for hours. In some of the experiments in which the aorta was clamped for a time the stoppage came immediately after the clamp was removed, indicating that some inhibiting substance arrived with the returning blood. A sudden slowing when the circulation failed in the dying animal was seen even in animals sacrificed by an overdose of nicotine. In them the rate had already been slowed by the drug.

Not infrequently irritability and conduction (over short distances) disappeared at the beginning of a period of anoxemia, only to reappear later when the rhythmic contractions stopped. This sort of thing added greatly to the difficulties of drawing conclusions, and necessitated much repetition of experiments.

THE REMARKABLE ABILITY OF THE NERVES OF THE BOWEL TO RECOVER AFTER LONG PERIODS OF ANOXEMIA

Nolf (42) concluded from experiments with nicotine that in the bowel of the chicken there is a second stage of neurones in the myenteric plexus, situated between the longitudinal nerve chain and the muscle fibers. I was particularly anxious to identify and study these second-stage neurones. Granted that they exist, I hoped to find some way of putting them out of action, because if they could be destroyed in any short segment of bowel, there are reasons for believing that, like the muscles in some lowly forms of life which contract into a hard knot whey they are cut off from their ganglion, the muscle in the bowel would contract spastically and permanently (3). Such a disturbance could easily account for some of the spastic contraction rings which cause obstruction, particularly in the bowel of children. I did much work with the hope of finding some neurotoxin or some amount of anoxemic injury that would destroy this hypothetic second-stage neurone without injuring the muscle, but I did not have any success. If such neurones exist in the rabbit they must be about as hardy as is the muscle.

In one series of experiments, resembling those of Mall, Cannon and Burket, and Scandola, Mrs. Bennett operated on rabbits under ether and clamped, for from four to twelve hours, the arteries supplying a segment of bowel. The circulation was then restored, the abdomen closed, and the animal allowed to recover. After from two to three weeks it was again anesthetized, and the bowel was studied in the tank with my usual technic. It was then found that peristaltic rushes went through the previously anoxemic segment without any demonstrable abnormality. These experiments showed, perhaps even more conclusively than did those of previous experimenters, that the intrinsic nervous system of the bowel is about as resistant to anoxemia as is the muscle in which it is embedded. In this way it seems to differ from nervous tissue everywhere else in the body.

There is one possibility, however, and this is that nerve fibers everywhere survive as long as does muscle; what looks like a failure of conduction in the nerve fiber may be only a failure of the muscle to respond to the exciting substance that is formed at the ends of the nerves. Against this assumption is the finding that, with anoxemia, two of the components of the electric response of a nerve to stimulation disappear (Clark, Hughes and Gasser). It would be in-

teresting to see if such changes could be observed in the case of the intestinal nerves.

Berkson (21) studied anoxemic bowel at various intervals up to three days to see if at any time while the muscle was still contracting well the rhythmic currents would disappear as they did under the influence of nicotine, but he could not get any clear-cut results. The impression was that the currents became irregular and weak as the contractions became irregular and weak, which perhaps supports the evidence suggesting that ganglion cells in the bowel are about as hardy as is the muscle. Dr. Kernohan, the neuropathologist, examined for me sections of the myenteric plexus from bowel that, three weeks before, had survived several hours of anoxemia, and found the ganglion cells so edematous and abnormal that he doubted if they could be functioning. Nevertheless the motor functions of the bowel seemed to be normal.

COMMENT

The most interesting discovery here reported is that of the long conducting paths. So far as I know, no one has pointed out their unbroken nature, or their tendency to take over the control of the bowel after anoxemia has injured the functions of the synaptic nervous system. Neither has anyone discussed in the light of modern neuro-humoral theory the gradual release from inhibition which can be demonstrated in the bowel after stoppage of the circulation or section of the extrinsic nerves. The facts of observation suggest that the inhibitor may be a chemical substance such as was demonstrated by Finkelman. After the death of the animal it may gradually be destroyed or it may diffuse out of the tissues.

Anyone who will look through a microscope at a well stained specimen of the myenteric plexuses will realize in a moment how almost impossible it is for the histologist to unravel the structure of that maze of fibrils. One might as well try to map the electrical systems of New York City after looking into a few manholes. The physiologist will probably then have to find for himself the answers to the many questions that he is inclined to ask about the nervous system of the bowel. Perhaps the pharmacologist will be able to help but some doubt must always remain as to what his drugs really did to nerves and muscles.

In my own experiments, atropine, cocaine, strychnine, lead and botulinus toxin seemed to be without effect on the peristaltic rushes.

The results of my work on rabbits agree fairly well with some conclusions of Henderson (1933), who worked mainly with guinea-pigs. Unfortunately, I do not know how closely one can compare the fast rushes in rabbits with the slower waves which are obtained on distending the intestine of the guinea-pig. The waves in the guinea-pig appear to resemble those that I learned years ago to produce in the rabbit by obstructing and distending a segment of bowel. They travel slowly and do not much resemble rushes. I called them "obstruction waves."

Henderson found that under adverse conditions, the traveling waves observed in the bowel of the guinea-pig stopped some time before the rhythmic movements did. He found also, as did Bayliss and Starling long ago, that nicotine interfered with the traveling waves but not with the rhythmic movements. He noticed that contractions of the intestinal muscle produced locally by a pinch did not spread along the bowel, and he concluded, as I have done, that when there is rapid spreading of an impulse this must be mediated by nerves. Henderson saw also that the moving column of fluid might help in producing a peristaltic type of wave.

Hukuhara (1933) (35, 36), using rabbits, found that peristalsis continued for about thirty minutes after stoppage of the circulation. In the guinea-pig it lasted for from thirty to forty minutes.

In agreement with my findings were those of Finkleman who, while studying excised small bowel and mesentery of the rabbit found that electric stimulation of the nerves on a mesenteric artery would sometimes, for a few minutes, produce contraction of the bowel; after that it produced inhibition for four hours or more. This suggests that a synapse between preganglionic fibers and the intestinal plexuses soon lost its power to function, while the postganglionic fibers and their endings in the muscle survived for some time.

SUMMARY

An attempt has been made to throw light on the structure and function of the enteric nervous system by measuring the intervals between the stoppage of the circulation and the disappearance of the several motor functions of the bowel. The tissues were kept at a temperature between 37° and 38° C., and whenever the bowel was separated from its blood supply the surrounding medium was aerated or oxygenated. The animal used was the rabbit.

In the autonomic nervous system impulses continue to pass through ganglions for from ten to twenty minutes after the death of the animal; vagus nerve endings in the heart stop functioning after about forty minutes, while the accelerator nerves continue to work for a few minutes longer.

With the bowel left in connection with the mesentery, peristaltic rushes cease the moment the circulation stops. This stoppage is produced by inhibition, perhaps humoral in origin. When the aorta or superior mesenteric artery was clamped or the bowel was cut away from the mesentery, rushes continued to travel during intervals as long as thirty-seven minutes.

Peristaltic rushes appeared to be dependent largely on a nervous synaptic mechanism, which probably did not survive for more than forty minutes after the circulation was shut off. The mechanism was severely injured by nicotine but seemed to be unaffected by atropine, cocaine, strychnine, lead, and botulinus toxin.

The synapses between the vagal and the enteric neurones continued to conduct for from ten to twenty-seven minutes after the stoppage of the circulation.

If normal peristaltic rush is dependent on a synapse highly sensitive to anoxemia, then the rushes which were sometimes observed an hour or more after the death of the animal must have been maintained by supplemental mechanisms. One of these is the moving column of fluid in the lumen of the bowel. That another important one is the "polarity" of the muscular wall or the gradient of forces was shown by the fact that waves in anoxemic bowel could not be made to run orad nearly as far as they ran caudad. Unfortunately, at times it was hard to tell atypical from

typical rushes even with the help of recording apparatus.

Apparently normal rushes were observed occasionally when the whole bowel was excised and kept in Locke's solution, showing that the directing mechanisms are located in the gut itself.

There appear to be at least four conducting systems in the small bowel of the rabbit. First, there are the fine nerve fibrils (histologically demonstrated) that presumably enable thousands of muscle fibers in a short segment of bowel to contract as a unit so as to produce the to-an-fro swaying movements. These fibrils are highly resistant to anoxemia and to the action of nicotine. Second, there appear to be short tracts which mediate conduction over distances averaging 15 cm. They are resistant to moderate doses of nicotine and they survive the loss of the circulation for about 100 minutes. They are injured by degenerative section of the splanchnic nerves. Third, there are long pathways, running the length of the bowel and also through the mesentery. The fact that they are immune to the action of nicotine and highly immune to anoxemia indicates that they are unbroken by synapses. Fourth, there are pathways, apparently broken by synapses, which have much to do with the peristaltic rushes. They are sensitive to nicotine and to anoxemia.

In health, the intestinal muscle is constantly held in check by some inhibiting influence, possibly a chemical one. This influence begins to fade out when the animal dies, or when the bowel is removed from the body; much is lost after about thirty minutes of anoxemia, and still more is lost during the next hour or two. As the inhibitor disappears, the bowel tends more and more to respond in a systolic way to impulses arriving by way of the long, unbroken nerve tracts. Normally the muscle responds only slightly to these impulses.

Nerve endings in the bowel were highly resistant to anoxemia and nicotine.

Segments of bowel kept cyanotic and pulseless for from four to twelve hours appeared to be functioning normally three weeks later. Rushes passed through them in an apparently normal manner.

The intestinal muscle continued to contract rhythmically after anoxemia had apparently put an end to the functions of the nervous system. The rate of contraction became slowed as soon as the circulation failed, and it was slowed after degenerative section of either the vagus or the splanchnic nerves, or of both sets together. The normal rate of rhythmic contraction seemed to be kept at a high level by influences coming from the extrinsic nerves of the bowel. These influences seemed to persist until the sectioned nerves degenerated.

Studies on the Gastric Hunger Mechanism*

II. The Inhibitory Effect of Dextrose Solutions

By

IDA A. MANVILLE, M.D., Ph.D.

and

WALTER R. MUNROE, B.S.

PORTLAND, OREGON

IN the first published report of these studies, Manville and Chuinard (1) showed that dextrose is capable of inhibiting gastric secretion as well as motility. Lim (2) demonstrated fat also to be inhibitory to these gastric activities. While it is well recognized that dextrose can inhibit the motility of the stomach, the evidence in regard to a similar effect on secretion is not yet commonly accepted although Miller and his associates (3) as long ago as 1920, reported that concentrated glucose was capable of depressing gastric secretion. The inhibition of gastric motility probably depends on a humoral mechanism (4). The vagi are not essential as Templeton and Quigley (5) observed inhibition of motility of a Heidenhain pouch and Quigley and Halloran (6) reported inhibition of motility in a vagotomized animal. The present study was undertaken to further the observations of Manville and Chuinard (1) and extended to include the effect of dextrose on secretion induced by various types of stimuli.

METHODS

Dogs with ileogastrostomies were used. Under ether anesthesia, the abdomen was opened, the ligament of Treitz identified and a segment of jejunum about six inches long and supplied with blood from a primary arcade of the superior mesenteric artery was chosen. This segment was resected and an end-to-end anastomosis of the small bowel performed. The distal end of the resected segment was attached to the edges of an opening on the anterior surface of the stomach near the greater curvature. The proximal end was sewed to all layers of the body wall in the operative incision. With this sort of a fistula, dogs have been kept alive and healthy for as long as five years. At autopsy, the gastric mucosa and the mucosa of the fistulous tract are grossly normal.

Before each experiment, food was withheld for twelve to thirty-six hours. A preliminary period of gastric lavage was always observed. The purpose of this was to cleanse the stomach of any residue and to determine whether or not there was active secretion (stimulation) of gastric juice and active motility. Experiments were not conducted unless gastric motility, tonus and secretion were absent or constant at a low level. The dogs were trained to lie quietly during the experiment. Through the fistula, a rubber tube was introduced on the end of which was a light rubber balloon. The outer end of the tube was connected to a chloroform manometer whose float recorded pressure variations on a smoked drum. A catheter with the closed end perforated by a number of openings also was inserted through the fistula. Between operations, the outer end of the catheter was kept closed with a clamp. At five minute intervals, the clamp was removed, the gastric contents aspirated and 50 c.c. of the wash solution were introduced. Tap water and five, ten, twenty and twenty-five per cent dextrose at body temperature were used as wash solutions. The pH of the aspirated gastric contents was determined colorimetrically and a 10 c.c. portion was titrated with N/40 NaOH to determine free and total acid. Topfer's reagent and phenolphthalein were used as indicators. The amount of gastric contents aspirated was recorded as "c.c. returned." Variations in this, coupled with the record on the smoked drum, gave information concerning gastric motility and tonus. The titration values of the gastric contents gave information about the relative amount of HCl secreted during the five-minute period the sample was in the stomach.

For the acidity (secretory) curve, results were charted by plotting cubic centimeters of alkali used against time. For the motility curve, the cubic centimeters returned were plotted against time. The motility curve was inverted in all the graphs and the distance above the ordinant considered an indication of motor activity—the higher the curve, the greater the motility or tonus.

Gastric activity was stimulated by starving for 24 hours; by injection of histamine; pilocarpine HCl, or by injection of insulin.

The method of determining gastric secretory activity used in this work is open to some criticism. The examination of stomach contents at the end of a period of time is not a true indication of the secretory activity of the stomach during that period, but is rather an indication of the end result of all additions to and subtractions from the stomach contents during the interval between aspirations. Additions to the gastric contents may be made via the fistula, swallowing, regurgitation from the duodenum as well as secretion from the gastric mucosa. Subtractions from the stomach may take place via the pylorus; leakage from the fistula, which is usually unimportant; vomiting with which we have not had to contend; and absorption from the stomach which is usually not considered important. However, the principles involved in this method and the difficulties with which we contended are the same as those used and met by other investigators in clinical and laboratory practice. The results may, therefore, be considered comparable.

EXPERIMENTAL

The action of physiological doses of histamine is to produce a large amount of gastric juice of high

*From the Department of Physiology and the Department of Medicine, University of Oregon Medical School, Portland, Oregon.
Submitted May 21, 1937.

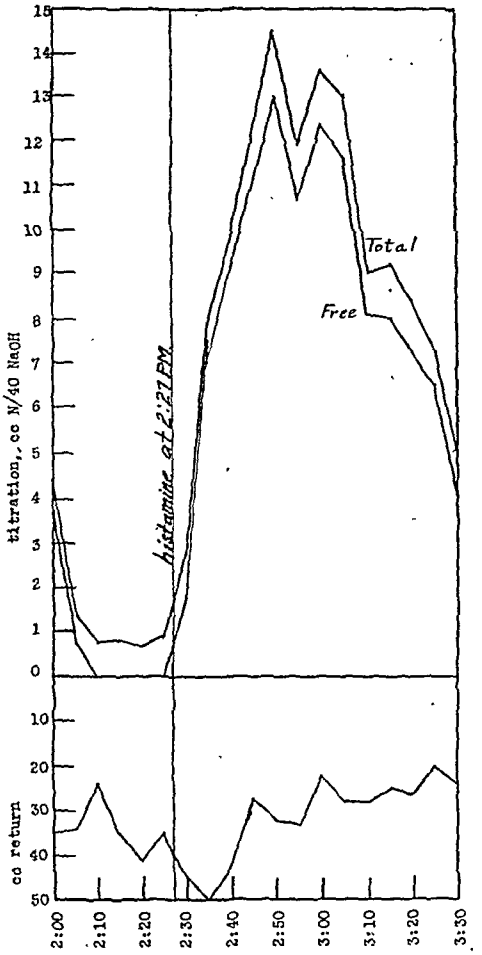

Fig. 1. *Joe, 3/19/36. One mg. histamine at 2:27 p. m.* Water wash used throughout.

acidity. Others (7) have shown that histamine has no power of stimulating pepsin secretion, or of producing any effect on gastric motility (8).

In one series of experiments, gastric secretion was stimulated by the intramuscular injection of one mg. of histamine. When a water wash was used, the secretion induced by histamine reached its maximum in about 35 minutes. When ten per cent dextrose was used as a wash, the maximum secretion was reached much later, the titration values were much less and the maximum secretion tended to be a plateau rather than a peak. For the sake of brevity only typical experiments will be presented.

Histamine stimulation and water wash. Protocol I,

Water wash used throughout. One mg. histamine given at 2:27 P. M. Ten c.c. of gastric contents titrated with N/40 NaOH. Titration values are c.c. of NaOH used.

Joe, March 19, 1936. Fig. 1, Table I. Joe is a healthy, very active young male dog weighing about 13 kg. At the start of this experiment (2 p.m) the stomach was empty and quiescent. There was some residual acidity but as soon as this was washed out, the gastric secretion was seen to be very low, there being no free and very little total acid. One milligram of histamine (ergamine acid phosphate, Burroughs Wellcome) was injected intramuscularly at 2:27 p.m. resulting in an almost immediate rise in both free and total acid. The acid value of the gastric contents rose rapidly and

Water wash used until 11:00 A. M. when 10% dextrose wash was started. One mg. histamine given at 11:07 A. M. Titration same as Table I.

reached its highest point 22 minutes after injection of histamine. When the experiment was discontinued

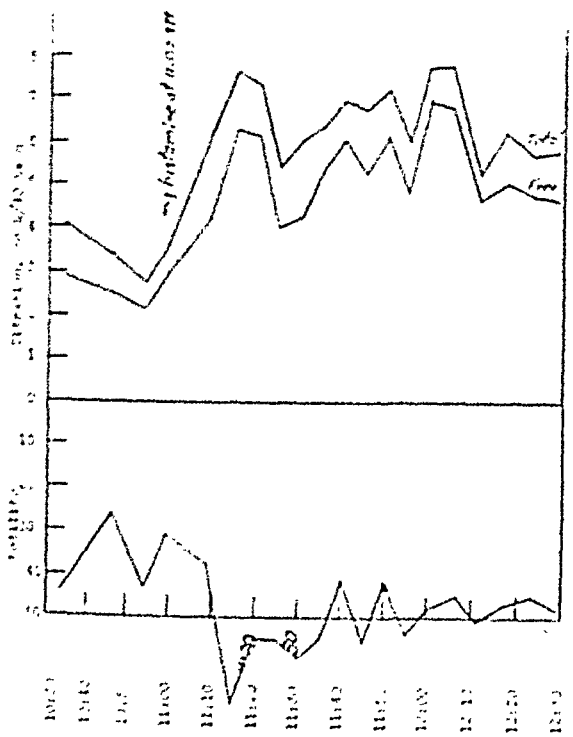

Fig. 2. Joe, 12/6/35. Water wash until 11:00 a. m. One mg. histamine given at 11:00 a. m. and 10% dextrose wash started. Note the effect of the dextrose on motility.

one hour and three minutes after histamine stimulation, the acid values were still high but were coming down. The acid values did not fall as fast as they rose. The pH which was initially above 4.0 fell rapidly to less than 1.0 which is the lower limit of the colorimetric pH set used. This experiment shows very well the effect of histamine in stimulating the secretion of HCl. Histamine has very little if any, effect on the motor activity of the stomach since the tracing shows no significant variations and the returns from the stomach show a marked uniformity. The increase in gastric tonus associated with the shivering caused a slight increase in the emptying ability of the stomach. It is probable, furthermore, that water is incapable of altering the motility of the stomach.

Histamine stimulation and ten per cent dextrose wash. Protocol II, Joe, December 6, 1935, Fig. 2, Table II. This is the same animal as described in Protocol I. Before histamine stimulation there was some acid secretion but it was occurring at a constant rate. One milligram of histamine was given at 11:00 a.m. and 10% dextrose was started as the wash solution. The histamine resulted in a stimulation of gastric secretion. The acid values rose slowly and the high point of the curve was reached at 12:07 p.m., 67 minutes after histamine stimulation. At 11:15 a.m., 15 minutes after histamine stimulation, the free acid value was 6.3 and the total acid value was 7.65. The pH was 1.2. These are to be contrasted with a free acid value of 13.0, a total acid value of 14.5 and a pH of 1.0 twenty-three minutes after histamine stimulation with water only as the wash solution. The preceding protocol showed that histamine alone or histamine and water have very little, if any, influence on gastric motility. In this experiment, there was a

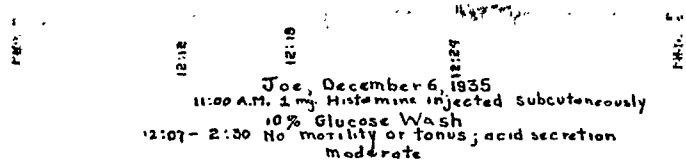

Fig. 2

definite drop in gastric tonus which allowed all the wash solution to return in five minutes. The conclusion, therefore, was reached that the drop in tonus was due to the 10% dextrose which was used as the wash solution. The typical action of dextrose in the upper gastro-intestinal tract seems to be that of inhibiting tonus, gastric motility and secretion.

Comment. Figure 3, (Table III) an average curve, shows definite inhibition of histamine stimulation by 10% dextrose. It is noteworthy that this concentration of dextrose did not completely inhibit the secretory effect of histamine. The method by which histamine stimulates gastric secretion is apparently through vasodilation, thus allowing a freer flow of blood to the glands of the gastric mucosa (8). If this explanation for the effect of histamine can be entirely accepted, then dextrose in the upper gastro-intestinal tract must act either by inhibiting vasodilatation or by preventing gastric motility and secretion in a manner analagous to the action of atropine on the submaxillary gland after stimulation of the chorda tympani. It should be noted also that the fluid removed from the stomach washed with dextrose was greater than the amount introduced. Very little of the sugar solution, therefore, could have reached the duodenum. This point will be commented upon later.

Pilocarpine HCl stimulation and water wash. Protocol III. Pinky, April 23, 1936. Fig. 4, Table IV. Pinky is a young, active male dog, weighing about 13 kg. This animal had an ilio-gastrostomy in November, 1935, and has remained in excellent health since. He is very cooperative. At the beginning of this experiment (10:49 a.m.) due to moderate tonus, the stomach was emptying rapidly but there was no secretion. The preliminary water washes apparently decreased the tonus during the first 21 minutes without increasing the secretion. Two milligrams of pilocarpine HCl

Average of experimentally using histamine as the secretory test stimulant. Time is measured from histamine stimulation. 65 time is the time that the histamine was given.

were given at 11:11 a.m. This increased the rate of emptying as well as the secretion of HCl and mucus. Within five minutes the animal was freely discharging serum from the nose and within ten minutes he was quite salivated. Thirty-seven minutes after pilocarpine stimulation, the gastric secretion had reached its maximum. At the peak, the free acid value was 9.5 and the total acid value 12.0. The sharp dip in the secretory curve just before the peak is due to the fact that during the preceding five minute interval the animal swallowed a quantity of saliva (the sample was one-half saliva—usually the saliva drained freely from the side of the mouth). The acid values were still high, but were falling rapidly when the experiment was discontinued at 12:12 p.m., 61 minutes after pilocarpine stimulation. The zone between the free and total acid values was greater than in the histamine experiment thus denoting an increased amount of buffering material.

Pilocarpine HCl stimulation and ten per cent dextrose wash. Protocol IV, Pinky, December 20, 1935.

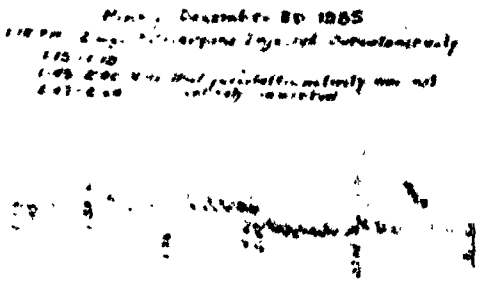

Fig. 4

Fig. 5, Table V. At the start (12:45 p.m.) the stomach was quite tonic, but not motile and there was very little secretion. Plain water was used as a wash until 1:14 p.m., at which time a wash of 10% dextrose was instituted and two mgs. of pilocarpine HCl were given. In spite of a slight initial secretion and the stimulatory effect of the pilocarpine, the secretion of acid never reached a high figure. The acid value of the samples never rose above 4.3 and this high point was reached at 1:18, four minutes after pilocarpine stimulation. Thirty-seven minutes after pilocarpine stimulation, the total acid value was 1.5 with a 10% dextrose wash as contrasted with 12.0 when a water wash was used. Moreover the acid value reached 3.5 at 2:25 p.m., 71 minutes after pilocarpine stimulation. Dextrose of this concentration was only partially effective in decreasing the emptying time of the stomach. The action of pilocarpine on the salivary glands likewise was not completely inhibited.

Comment. Reference to Fig. 6 (Table VI), average curves, shows definitely that 10% dextrose solutions are capable of greatly inhibiting the secretion resulting from pilocarpine HCl stimulation. Whether or not complete inhibition could be obtained by properly balancing the stimulatory effect of pilocarpine against the inhibitory effect of dextrose was not determined. In only one of the experiments using pilocarpine stimulation and 10% dextrose as an inhibitor was the total inhibitory effect of glucose on gastric motility

apparent. Pilocarpine acts by stimulation of the myoneural junctions of the cranio-sacral autonomic system (9). It acts first upon the vagus by stimulating both gastric secretion and motility. Ten per cent dextrose solutions are capable of more effectively inhibiting the secretion induced by pilocarpine than the motor activity resulting from this type of stimulation. The inhibitory effect of dextrose on mucus secretion is as apparent as on acid secretion as can be seen by comparing the width of the zone between the curves for free and total acid.

Insulin stimulation and water wash. Protocol V. Pinky, September 16, 1936. At the beginning of the experiment there was no secretion of free acid and the total acid values were at or below 0.6 c.c. of N/40 NaOH. There was no motility and the tonus was insufficient to expel much of the wash fluid into the

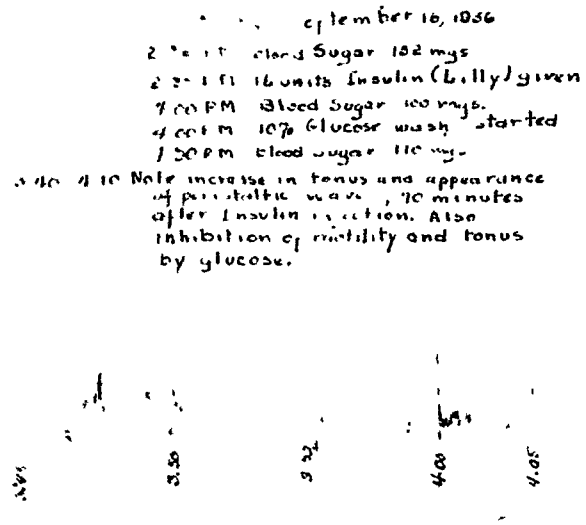

Fig. 5

duodenum. After washing the stomach four times and finding no evidence of gastric activity, a sample of blood was taken for a blood sugar determination and 16 units of insulin were given subcutaneously (2:35 p.m.).

The blood sugar was found to be 123 mg. per cent. The next forty minutes were entirely devoid of any evidence of gastric activity. At 3:10 p.m. the acid values began increasing. Tonus and motility also began improving at this time as shown by the graphic record of the decreasing returns of wash water. From 3:10 p.m. to 4:10 p.m., there was a steady increase in the output of acid until the maximal amount of 16.8 c.c. free and 21.8 c.c. combined acid were reached. Up until 3:50 p.m., however, there was no increase in tonus or motor activity—at least not enough to affect the return of wash water. Forty minutes after secretion began increasing, there was a definite and marked increase in the emptying power of the stomach. At 4:00 p.m., the blood sugar was 100 mgs. per cent. Five minutes later (4:05 p.m.) and thereafter ten per cent dextrose solution was used for washing out the stomach. For the next five minutes the glucose was without effect since the stomach emptied as rapidly as before and the acid secretion reached its highest level. Immediately thereafter, however, acid production began subsiding so that at the end of the experiment (4:45 p.m.) the values were 1.8 c.c. of free and 2.4 c.c. of total acid. There was no effect on motility or tonus until 4:35 p.m. or 25 minutes after acid secretion began diminishing. At the end of the experiment nearly half the wash solution was recovered. Thus dextrose inhibits the gastric motor and secretory activity induced by insulin. There is, however, a dif-

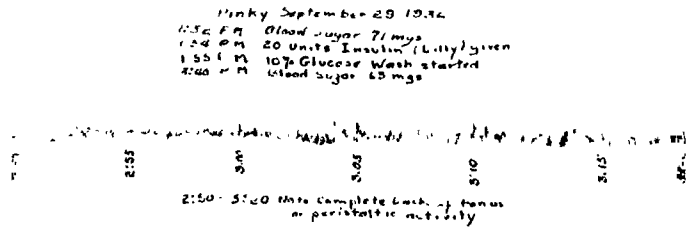

Fig. 6

ference in the time of appearance of the two effects—secretion being more easily influenced than muscular activity. This confirms the findings published in the first report.

At the end of the experiment the blood sugar was found to be 110 mg. per cent. About 235 c.c. of ten per cent dextrose solution entered the duodenum before any inhibitory effects were noted. Altogether approximately 324 c.c. of the sugar solution entered the duodenum to account for the slight rise in blood sugar. It is interesting to note the definite presence of gastric secretory and motor activity with a blood sugar of 100 mgs. per cent and a complete subsidence of these activities with a blood sugar only 10 mg. per cent higher. This is further confirmation of the statements made in the first report.

Insulin stimulation and ten per cent dextrose. Protocol VI. Pinky, September 29, 1936. Fig. 8, Table VIII. In this experiment, 20 units of insulin were administered subcutaneously and a ten per cent dextrose wash used throughout. Three preliminary washes between 1:30 p.m. and 1:45 p.m. showed no acid production, no motility (peristalsis) and very little tonus. The blood sugar at 1:52 was 71 mgs. per cent. The

Sixteen units of insulin were given subcutaneously at 2:35 P. M. Water wash was used until 4:05 P. M. when it was replaced by ten per cent dextrose.

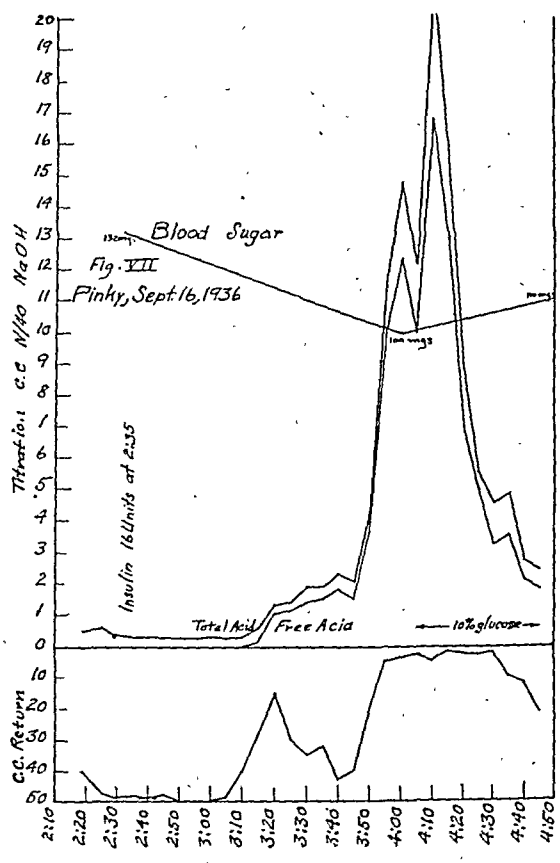

Fig. 7

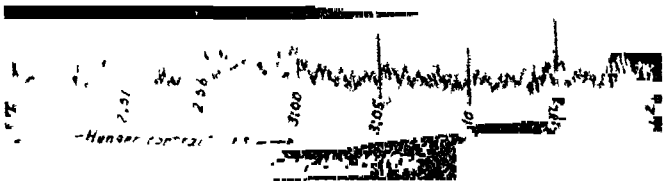

Fig. 7

insulin was given at 1:54 and the sugar wash instituted at 1:55 p.m. During the entire experiment there was no evidence of gastric stimulation of any sort. Although a total of 1,000 c.c. of ten per cent dextrose solution were placed in the stomach, only approximately 91 c.c. entered the duodenum. The nine grams of dextrose thus obtained were insufficient to effect the blood sugar which at 3:40 p.m. was 63 mgs. per cent. Aside from showing the inhibitory effect of dextrose on gastric activity induced by insulin, this experiment shows the lack of gastric motility when the blood sugar is at a low level. Thus the stimulatory effect of 20 units of insulin is not as effective in the presence of dextrose in the stomach as is 16 units when given alone.

Comment. (Fig. 9, Table IX). It is well known that insulin is a powerful stimulant to both gastric motor and secretory activity. The use of insulin in non-diabetic malnutrition is based largely on this effect. The first report of this series sets forth clearly the effect of insulin on both of these gastric activities. Presumably insulin acts through stimulation of the vagus. It is not clear whether this stimulation is central or peripheral although what little evidence we have seems to indicate a peripheral action.

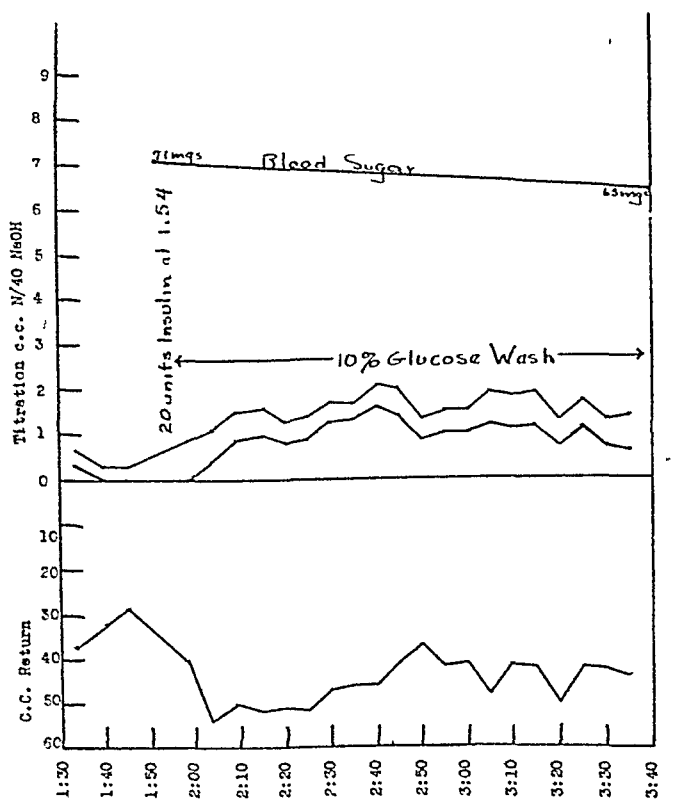

Fig. 8. Pinky, 9/29/36. Twenty units of insulin at 1:54 p. m. Ten per cent dextrose started at 1:54 p. m.

In this group of experiments the animals were given 16 to 27 units of insulin subcutaneously. It will be noted that 20 and 27 units of insulin produces a more effective stimulus than a dose of 16 units. As previously reported, insulin produces a definite increase in gastric secretory and motor activity. It should be noted (Fig. 9 and Table IX) that the inhibitory effect of dextrose was exhibited in the face of a larger stimulating dose of insulin than that used in the experiment where plain water was used as the wash solution. The maximum effect of insulin insofar as secretion and motility of the stomach is concerned occurs in from 45 to 60 minutes after its administration.

Spontaneous hunger contractions. Protocol VII. Pinky, January 14, 1936. Fig. 10, Table X. In this experiment, the graphic record of gastric motility can be divided into six periods: Period I (2:45-3:00) in which hunger contractions were present but no secretion of acid; Period II (3:00-3:20) in which acid was being secreted but little motility evident; Period III (3:20-3:31) reappearance of hunger contractions with a diminution in the acid secreted; Period IV (3:31-3:46) inhibition of motility, tonus and secretion as the result of a twenty per cent dextrose wash; Period V (3:46-4:06) under the influence of water wash the reappearance of tonus and motility with very little increase in secretion of acid; Period VI (4:06-4:16) twenty per cent dextrose solution again used as wash with complete inhibition of motility and

Twenty units of insulin were given subcutaneously at 1:54 P. M. Except for the three washes prior to insulin administration, ten per cent dextrose was used as wash throughout.

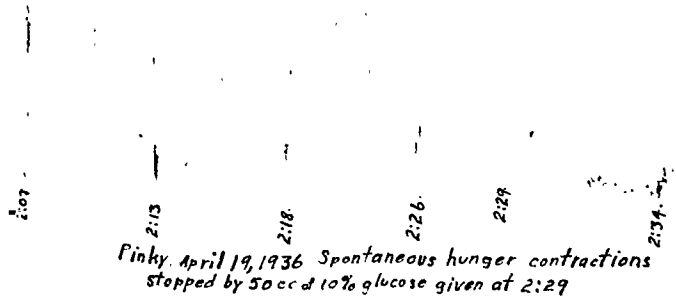

Fig. 8

tonus. Twenty per cent dextrose solution is thus inhibitive to psychic secretion as well as hunger contractions. When muscular activity of the stomach during hunger is in evidence, there may be only slight evidence of secretory activity. Vice versa, when muscular activity is absent, secretion may be occurring. A twenty per cent dextrose solution inhibits both.

Protocol VIII. Pinky, April 19, 1936. Fig. 11, Table XI. At 1:55 p.m., this animal's stomach was exhibiting powerful hunger contractions. The first wash fluid showed no free or total acid. The stomach was emptying so completely in five minute periods that the wash water was run in and out again with no intermediate pause. No free acid was found and very little total. At 2:29 and 2:34 p. m., fifty c.c. of ten per cent dextrose solution was used as a wash water. Five minutes later motility and tonus were almost completely inhibited. Acid production still was almost nil.

Apparently, then, there may be a complete dissociation between gastric motor and gastric secretory activity in that an actively motile stomach which is

emptying rapidly may not be secreting acid, or from the motor standpoint, an actively secreting stomach may be quiescent.

Dissociation of gastric motor and secretory activity. Frequently in the course of the experiments herein described, there was noted what appeared to be a complete dissociation of gastric motor and secretory activity. That is, a motile stomach exhibiting powerful peristaltic waves would not be producing acid, or, at other times, a quiescent stomach would be found actively secreting acid.

The experiments described in the seventh and eighth protocols show the absence of active secretion when hunger contractions were occurring. The data obtained from "Joe" (Table 12, Fig. XII) showed marked secretory activity during complete absence of motility. Furthermore, a ten per cent dextrose wash did not completely inhibit this activity while a stronger solution (25%) exerted the usual inhibitory effect.

Water wash was used until 2:29 P. M. from which time ten per cent dextrose solution was used.

In protocol VIII a wash of ten per cent dextrose was sufficient to inhibit hunger contractions. The data in Table XII show ten per cent dextrose solutions had only slight effect on psychic secretion. Only when the cencentration was increased to 25 per cent did a marked inhibitory effect appear. In the experiments where histamine and pilocarpine were used as gastric excitants, it was observed also that ten per cent dextrose was not completely inhibitory. Gastric activity provoked by twenty units of insulin was completely inhibited by a ten per cent dextrose wash. It seems, therefore, that the amount of histamine and of pilocarpine used were more effective stimulants than the quantity of insulin administered. This difficulty, however, should not detract from the conclusion that dextrose solutions are definitely inhibitory to both types of gastric activity. One of the difficulties encountered in these experiments was the balancing of the inhibitant against the stimulant. Since ten per cent dextrose inhibited psychic (hunger) contractions but not psychic (appetite) secretion, one would be inclined to

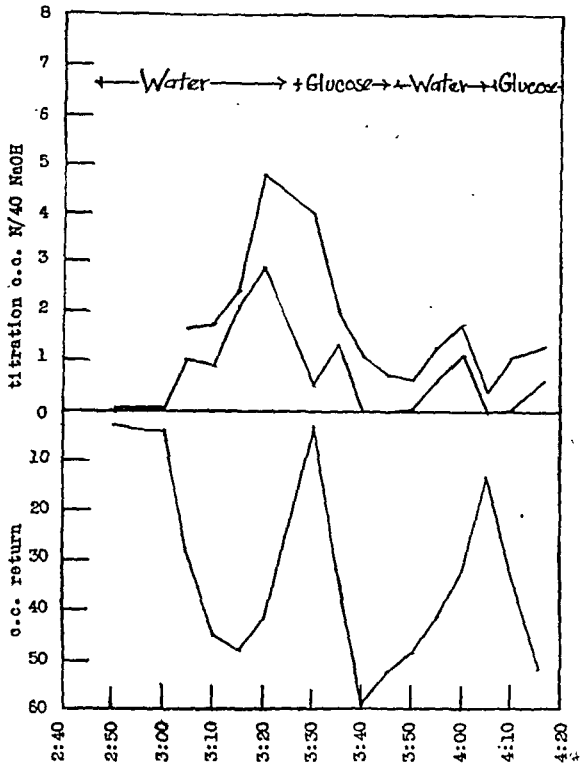

Fig. 10. Pinky, 1/14/36. Spontaneous hunger contractions alternating with secretory activity. Inhibitory effect of 20% dextrose on both types of activity. Motility and secretion do not necessarily occur together.

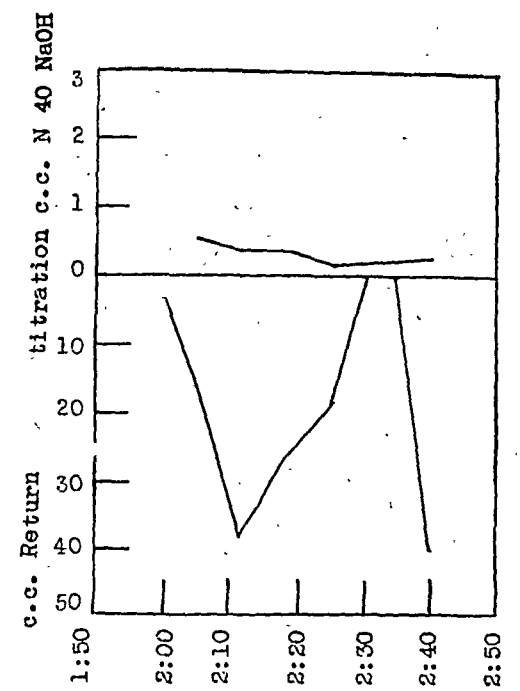

Fig. 11. Pinky, 4/19/36. Spontaneous hunger contractions stopped by 50 c.c. of 10% dextrose given at 2:29 p. m.

conclude that the secretory stimulus is greater than the motor.

Upon the introduction of dextrose solutions into the stomach, there occurred a slight delay before the inhibitory effects were noted. This latent period has been explained as being due to the time required for the glucose to reach the duodenal mucosa where it may bring into existence an inhibiting chalone. Evidence is presented in this paper which may make necessary a revision of this view. In Protocol VI, for example, the stimulatory effect of twenty units of insulin was completely held in abeyance by the ten per cent dextrose solution. Both tonus and peristalsis were at such a low ebb that in the entire experiment only 91 c.c. of the dextrose solution failed to be recovered. We realize that this latter statement is not strictly true since the secretory activity of the stomach, fluids swallowed (saliva) and material regurgitated from the duodenum were not considered. It will be noted that bile was present in the aspirated contents. The low amount of total acid titrated and the narrow margin between the figures for free and for total acid (buffer material) indicate very little alkaline or mucoid material present. Therefore, it may be assumed that the 91 c.c. of ten per cent dextrose that was not recovered represents a fairly close approximation of the quantity of sugar required to exert an effective inhibition. Data of a similar nature are provided in Fig. 12 and Table XII. During the

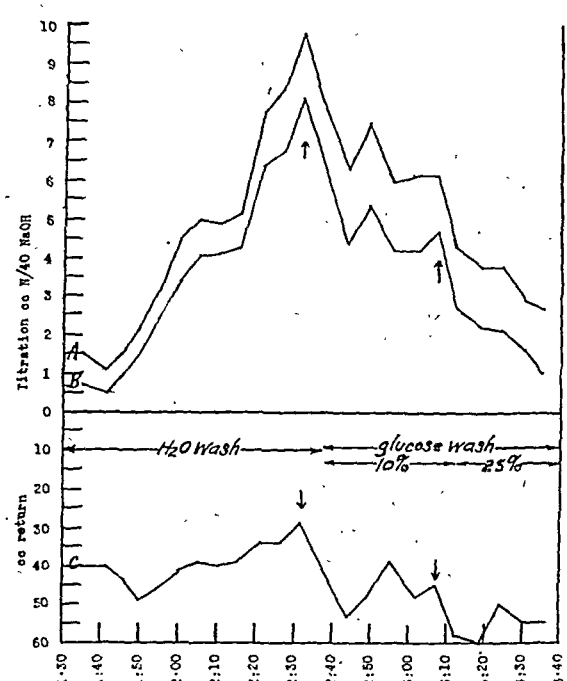

Fig. 12. Joe, 4/30/36. No stimulant used. This experiment shows the dissociation of gastric secretory and motor activity.

23	3:31	3:36	55	+	1.0	2.6

Water wash was used from 1:30 P. M. to 2:31 P. M. Ten per cent dextrose wash was used from 2:38 P. M. to 3:07 P. M. Twenty-five per cent dextrose wash was started at 3:08 P. M. and used to the end of the experiment.

thirty minutes in which the ten per cent dextrose solution was used, there was a net loss of 27 c.c. or 2.7 grams of sugar. While there was a definite inhibition of secretion, the effect was far from being complete. During the following twenty-five minutes in which twenty-five per cent dextrose was used there was a net gain of 28 c.c., indicating a very small sugar loss, yet inhibition was complete.

We are thus faced with a situation where it seems apparent that a twenty or twenty-five per cent solution of dextrose is a more effective inhibitor than a ten per cent solution. Furthermore, the effectiveness of inhibition depends a great deal upon the strength of the stimulus. Nor does it seem to be dependent upon the amount of dextrose entering the duodenum. Can it be that some of the inhibitory effect is mediated through a gastric mechanism? Undoubtedly this angle of the problem will have to be handled with a much more precise method of procedure.

The inhibition of gastric secretory and motor activity by sugar brings up the question as to how long the inhibitory influence of the glucose solution would last if it were left in the stomach. Our experience indicates that the period of inhibition persists for approximately thirty minutes.

The practical implications of these findings are obvious. The inhibitory effect of dextrose solutions on the human stomach should be determined. On the assumption that there is a gastric residue of 50 c.c., the ingestion of five grams of dextrose would produce a ten per cent solution in the stomach. If there is a twenty-five c.c. residue, a twenty per cent solution would result. The administration of this quantity of dextrose every half hour should, on the basis of the experiments herein described, keep the stomach quiescent. On the Sippy regime, the dextrose only need be given every hour.

SUMMARY

1. Evidence is provided confirming previous observations that dextrose solutions (ten, twenty, twenty-five per cent) placed in the stomach inhibit hunger contractions and that the appearance of gastric motility is not always associated with a drop in blood sugar.

2. Gastric motor activity induced by pilocarpine and insulin are also inhibited by introducing dextrose solutions into the stomach.

3. Gastric secretion provoked by histamine, pilocarpine, insulin as well as psychic secretion also is inhibited by dextrose.

4. Further evidence is presented of a genuine dissociation between the secretory and motor activity of the stomach.

5. The clinical application of these results is discussed.

Peptic Ulcer Therapy

By

M. B. LEVIN, M.D.
BALTIMORE, MARYLAND

IN previous work on gastric digestion (1), reference was made by the author to a method of treating peptic ulcers, based on experimental findings in which potential or active alkalis were employed just before as well as after feedings. It was pointed out that complete neutralization of gastric digestion depended on the presence of potential or active alkalis for immediate neutralization of the pepsin-HCl or pepsin-HCl pancreas-bile combination. In such alkalized mixtures digestion of muscle fibers was completely absent. When an interval of 15 minutes or longer was allowed before such neutralization was carried out, complete inhibition of peptic digestion of the meat fibers did not occur.

The usual methods of peptic ulcer treatment, as given by von Leube (2), Lenhartz (3), or Sippy (4), advocate at least a half hour interval between the time of feeding and the administration of neutralizing substances, when these are employed. Such treatment does not prevent digestion of the gastric or duodenal content, and probably interferes with healing of the ulcer to some extent. When alkalis are administered before as well as after feedings, to the point that digestion of meat fibers, as demonstrated by our method of stool examination (1), is decreased to 10 to 30 per cent, rapid relief of symptoms (within 72 hours after proper dosage) and apparent healing of the peptic ulcers has been noted. Sufficient time has not elapsed to determine the permanency of these results, since these patients have all been treated within the past five years.

In this group of cases, ambulatory treatment has been employed except where active hemorrhage has necessitated two to three week periods in bed. Since continuous gastric analysis could not be maintained for the demonstration of complete inhibition of gastric digestion by titration methods, recourse was had to frequent stool examinations.

Simultaneous experiments on gastric digestion *in vitro* revealed that the majority of acids tested activated pepsin to varying degrees in its digestion of muscle fiber. Neither nitric nor sulfuric acid, in concentrations producing the same pH as hydrochloric acid, were as effective in promoting digestion with pepsin alone or with the combination of pepsin pancreas-bile, as was the latter acid. Phosphoric, lactic, acetic, boric, salicylic, benzoic, oxalic, tannic, tartaric, citric, and the other acids tested all activated peptic digestion to some degree, and were active also in combination with the pepsin pancreas-bile mixture. Salicylic acid was markedly more active *in vitro* in the pepsin pancreas-bile combination than anticipated from the hydrogen ion concentration. This finding should be kept in mind as a possible explanation of the starting point of some peptic ulcers in humans.

With these findings as a basis, the diet was so arranged that during the first three to eight weeks all foods containing appreciable acid, such as tomatoes, fruits and buttermilk, were eliminated. Other cooked and raw vegetables were permitted. Meats, eggs, fish, fowl, crustaceans, bi-valves, curd or cottage cheese and milk, American or Swiss cheese, were permitted in normal quantities. Bread, tea, coffee and milk in normal quantities were also allowed. Cereals or pureed foods were reduced to a low level in order, so far as possible, to prevent intestinal fermentation.

After the three to eight weeks period, tomatoes, raw or cooked, were permitted along with adsorbent ant-acid powder (to take care of the additional acid) in quantity sufficient to keep muscle fiber digestion down to or below 30% as estimated by stool examination. Gradually, fruits were added to the diet, and in the milder cases, after twelve weeks, the adsorbent ant-acid powder was reduced ½ dram weekly. The 30% level of digestion was maintained during this period. When necessary to achieve this level, the patient was kept on the adsorbent powder for a longer period before the next reduction was made.

Fresh tincture of stramonium was employed before meals and maintained just below the dryness or blurred vision stage during the entire period. Usually the stramonium was administered 10 drops t.i.d. A.C., the object being to have three normal sized meals with no feedings between, an increase of one drop at each meal until the pharmacological effects were obtained. The use of stramonium for this purpose, as compared with belladonna, has been found more successful in the author's experience, possibly because of the greater hyoscyamine content and consequent antispasmodic effect. It was not necessary to carry stramonium medication to the stage of complete dryness to obtain this result, as is required with belladonna. This has been fluoroscopically confirmed on several occasions.

In the severe ulcers of long-standing, it was felt advisable, while employing the ambulant treatment, to continue the therapy outlined for a period of four to six months. The results thus far obtained have justified this prolongation of the period of treatment (Table I).

During the past year one adsorbent ant-acid powder has been employed to the exclusion of all others because of its greater effectiveness without such untoward effects as a tendency to alkalosis or hypersensitiveness to bismuth salts. During the previous three years, when the dosage of other powders was increased to the required degree, there was a tendency in some patients to alkalosis. This was counteracted by the administration of aromatic spirits of ammonia in the ante meal medication (the ammonia was converted by the hydrochloric acid of the stomach to ammonium chloride). The preparation described contains the more stable type of amonium salt, di-ammo-

Submitted June 23, 1937.

nium-hydrogen phosphate, $((NH_4)_2HPO_4 \cdot 2H_2O)$, in sufficient quantity for the same purpose. None of the patients taking this powder have required additional ammonium salts for the prevention of alkalosis.

The various adsorbents available for internal administration have been employed in an attempt to reduce the alkali or potential alkali requirements. Among these were kaolin, bismuth salts, magnesium hydroxide and oxide, aluminum hydroxide, aluminum silicate and various pharmaceutical and other combinations of the usual ant-acid chemicals used for such purposes. It has been found that a synthetic hydrated magnesium trisilicate is the most effective adsorbent for the purpose of this treatment.

Synthetic hydrated magnesium trisilicate is a light, fine powder, insoluble in water. However, distilled

* In a variable proportion of ulcers [illegible] between meals it may be necessary for a time to give half the "meal time" dose of powder between meals and at bed time. The extra dosage can usually be terminated in 3 to 6 weeks even in severe ulcers, when the hypersecretion is controlled by before and after meal doses of powder.

water in contact with this compound acquires a slightly alkaline reaction, (pH 8.4), evidently due to the presence of traces of magnesium oxide and carbonate. It adsorbs large quantities of hydrochloric acid as shown by the following experiments:

To 1.000 gm. of the silicate was added 100 c.c. N/14 HCl. This was allowed to adsorb for 24 hours, after which the excess acid was neutralized with N/14 NaOH.

A series of tests on various batches of this chemical, based on the above procedure, gave an average adsorbent value of 81:2 c.c. N/14 HCl (or 116 c.c. N/20 HCl) for one gram of magnesium trisilicate.

The rate of adsorption of magnesium trisilicate by hydrochloric acid is shown in the following tables:

A. 0.250 gm. of silicate titrated with N/14 HCl using Brom Phenol Blue 0.04%.

Impurities in magnesium trisilicate such as soluble salts or free alkali must be guarded against, since this chemical has no standard of purity. In the author's use of this substance, it is analyzed for free sulphates, sodium oxide, sodium silicate, sodium hydroxide, soluble magnesium salts and heavy metals. The powder must also be fine enough to pass through a 200 mesh sieve for maximum efficiency.

The chemical formula of synthetic hydrated magnesium trisilicate may be expressed as the ratio of MgO to SiO_2. Analysis of various batches of this chemical, according to Scott (5), have given the following results:

Batch Sample	MgO (ignited)	SiO_2 (ignited)	Ratio	% Loss on Ignition
A.	17.6%	80.0%	1:3.00	21.0
B.	14.3	70.0	1:3.28	16.8
C.	15.3	78.4	1:3.40	28.2

Mutch (6) has referred to hydrated magnesium trisilicate *per se* as a very effective adsorbent for the treatment of peptic ulcer. Experiments with hydrated magnesium trisilicate, (which is not at the present time obtainable in this country in prepared form), demonstrate that the adsorption and neutralization of the pepsin-HCl is not very effective within the first ten minutes of contact. Since this fact would allow the digestion of food by the gastric enzymes, the substance administered alone is not suitable for the treatment of peptic ulcer. Furthermore, while the hydrated magnesium trisilicate is a very effective adsorbent, it is not perfect in this capacity, since its adsorption is available only up to approximately 50% of the salt. The remainder is converted to $MgCl_2$, and thus becomes a potential alkali. For this reason, a small amount of sodium bicarbonate and a larger quantity of a potential alkali, such as refined calcium carbonate, were incorporated in effective proportions to be at hand for immediate neutralization of peptic digestion, when the mixture was ingested before meals. The advantages of this powder containing diammonium hydrogen phosphate, sodium bicarbonate, calcium carbonate and hydrated magnesium trisilicate were readily apparent.

This powder has been employed in cases of recurrent peptic ulcer subsequent to operation, in cases with primary active hemorrhage, in recurrent cases, in previously untreated peptic ulcers, as well as in recurrent cases, treated by other physicians and myself. Only two of this series was treated with Larostidin (La Roche) without results. These responded well to the method described.

All diagnoses were definitely confirmed by operation or X-ray previous to installation of the treatment, and to the present time all have shown responses of a gratifying type. The results are given as a preliminary report so that others may avail themselves of the data.

CONCLUSION

An outline is given of a method for the treatment of peptic ulcer, based on findings concerning gastric digestion which have been previously reported. Only those cases treated during the past year with the alkali adsorbent powder*, of which a description is given, are included in this series.
tion is given, are included in this series.

The Cholesterol Problem*

By

HORACE W. SOPER, M.D., F.A.C.P.
ST. LOUIS, MISSOURI

WE are indebted to Bridges (1) for a more complete table containing the cholesterol content of various foods. It is now not difficult to prescribe a diet low in cholesterol. Those foods poor in cholesterol are breadstuffs, cereals, egg white, low fat fish, fruits, lean meats, skim milk, syrups and vegetables. Those excessively high are the solid internal organs, liver, kidney, sweetbreads, etc., egg yolk and caviar.

It is to be noted that fruits and vegetables contain some cholesterol and the only food in the list that is entirely free from it is egg white. Therefore, there is no danger in giving too little cholesterol in prescribing a diet for adults who clinically require such a regimen. Of course, the growing child requires a diet rich in cholesterol.

A review of the articles on this subject in the Transactions of the American Gastro-enterological Association for 1936 discloses that a great deal of confusion exists in evaluating the blood and bile cholesterol content. Wilkinson (2) observes that the level of blood cholesterol is affected by variations in the function of the pituitary, thyroid, gonads, pancreas and adrenals. Hyperthyroidism causes a decrease in blood cholesterol values while in hypothyroidism the values are increased. The discussion on the treatment of Chronic Hepatitis with jaundice reveals that no clear cut method has as yet been established.

The recent meeting of the American College of Physicians with a program largely devoted to cardiology contained no mention of this subject. The cardiologists appear to adhere to the theory of intravascular tension as the etiologic factor in the production of arteriosclerosis, and do not consider the lipoid deposit theory.

Elliott and Nuzum's study (3) on the "Cholesterol Content of Whole Blood in Patients with Arterial Hypertension" is of extreme interest. They state "Uncomplicated arterial hypertension is not accompanied by hypercholesteremia." "Higher values for cholesterol are found more frequently among underweight than among obese persons." Is it not possible that the cholesterol may be deposited in the tissues and not appear to excess in the blood plasma of the obese individuals? I suggested to Nuzum to subject a group to the administration of thyroid and iodide with periodic blood analyses to determine whether these lipoid solvents might release the bound cholesterol and cause larger blood plasma content.

The recent article by Jacobi (11) is a good illustration of the manner in which cholesterol deposited in the body tissues, may be released by a resolving agent. He found that cases of ulcerative lesions of the extremities due to peripheral arterial disease, were found to have a subnormal or low normal blood cholesterol. After a course of treatment with two per cent sodium iodide intravenously, the blood cholesterol showed a gradual and marked rise.

Wilder's masterly review (4) on "Diseases of Metabolism and Nutrition" shows considerable divergence of opinion among the investigators of the cholesterol factor, particularly in diabetes. Geyelin (5), Sansum (6), Adlersberg (7), Rabinowitch (8), and others are all convinced of the desirability of the high carbohydrate and low fat diet in diabetes. Wilder's final conclusion is in favor of the more liberal use of fat, and he believes his patients get along as well as those whose diets are restricted in fat content.

In the midst of all this confusion we are justified in employing our clinical judgment rather than to rely upon uncertain and misleading blood analyses. Clinically it is not a difficult problem to determine the group of patients we should subject to a dietary of low cholesterol content.

Individuals of this type, endowed with poor cholesterol metabolism have a tendency to develop *obesity, gall stones, athero-sclerosis, degenerative arthritis,* and *cataract.*

I have reviewed old case records in my files and find many such life histories. A few case reports are presented with full appreciation of the fact that one might become too enthusiastic in the evaluation of therapeutic procedures.

CASE REPORTS

Case 1. R. D. H., male, aged 39, business executive. Came under observation in June, 1913. He had digestive disturbances that appeared to be functional in character. Finally at the age of 57 in 1931 he experienced definite pain in the chest upon exertion, characteristic of angina pectoris. The pains were immediately relieved by the administration of nitroglycerin (spirits glonoin) on the tongue. He was seen in consultation with Dr. Oliver Abel, Jr., in November, 1931. His basal metabolic rate was well within the normal limits. Electro-cardiograph report was as follows: P. R. interval = 0.12 sec. 'T' waves upright in lead I. Diphasic in leads II and III. Diagnosis: Myocarditis; right axial deviation. His kidney function was good. He had a slow pulse and his skin was dry. He had a definite pruritus ani, brittle nails, and suffered a great deal from day drowsiness and fatigue. He was put on Sansum's alkaline-ash diet, being allowed four glasses of milk a day; the balance of the diet made up of cereals, bread, butter, fruits, and vegetables—in fact, quite a low cholesterol diet. He was given one grain dessicated thyroid daily. He reported from time to time and at the end of one year found that he could exercise without any further pain, had no weight loss and was in a good state of nutrition; suffered no longer from fatigue, continued his work and outdoor exercise. At the end of another year he was again checked up and we found that after discontinuing the thyroid medication he again suffered from fatigue. The dosage has been continued regularly since that time. He was last seen in January, 1937, in splendid physical condition and has never had any return of his anginal pains, six years after the initial attack of angina pectoris.

*From the Soper-Mills Clinic, St. Louis, Mo.
Submitted June 9, 1937.

Case 2. F. L. S., female, aged 65. Came under observation in 1926. Referred by Dr. W. A. Shoemaker for detached retina. Her gastro-intestinal symptoms were functional in character and responded very well to dietetic treatment. In June, 1931, at the age of 69, she developed anginal pains following exertion which were controlled by spirits glonoin in drop dosage on the tongue. In 1933 she had quite severe attacks of nocturnal pain so was put on one grain dessicated thyroid because of extreme fatigue and dry skin, although the basal rate was normal. She was seen in consultation with Dr. Oliver Abel, Jr. Electrocardiograph report was as follows: P. R. Interval = 0.16 sec. 'T' waves upright in leads I and II. Inverted lead III. Diagnosis: Left axis deviation. She was advised to limit her activities and given both thyroid and iodide of sodium, and a low cholesterol diet. The nocturnal attacks became less severe but she continued to have substernal pain upon exertion, always relieved by nitroglycerin. In January, 1934, she showed considerable degree of improvement but was not faithful to her diet and continued to be too active socially. She remained in this condition until April 9, 1936, when she experienced a severe attack of *Coronary Thrombosis*—she was sent to St. Lukes Hospital and was in a precarious condition for months. The attack was quite typical, accompanied by fever and pain, no decompensation. Since leaving the hospital she has adhered strictly to her diet and continued the use of thyroid and iodide and has resumed her usual social activities, and has not had to resort to the use of nitroglycerin which she had used for six years prior to the attack of coronary occlusion.

Case 3. C. M. S., male, aged 39. Was seen in consultation with Dr. C. E. Barnett at the Deaconess Hospital October 27, 1936. Jaundice was very definite and a tentative diagnosis of carcinoma of the pancreas was made at the hospital because of the intensive jaundice of painless onset. He was placed on small doses of magnesium sulphate every morning and a low cholesterol diet. His jaundice disappeared completely by the 4th of December. He continued to improve steadily. Cholecystogram disclosed the presence of gall stones, but his general condition is so good that he decided to postpone the operation which was advised. He continues to adhere to a strict low cholesterol diet.

Case 4. F. R. T., female, aged 58. Came under observation in November, 1921. Blood pressure 150/70. Referred by Drs. Meyer Wiener and B. Y. Alvis who found that the eyes showed some areas of retinal hemorrhage. Diagnosis of chronic interstitial nephritis was made. She was placed on a low protein diet and foci of infection corrected about the teeth and rectum. Her eye history presented by Dr. Alvis is as follows: "Her vision was normal in each eye until in 1921 when the vision of the right eye became impaired due to the presence of hemorrhage in the retina. This eye continued to a hemorrhagic glaucoma until it became so painful that it had to be enucleated in 1924. In 1926 a chronic glaucoma developed in the left eye which was controlled by miotics for some months. In November, 1926, a trephining was done on this eye followed by a good recovery; return of normal tension, vision being normal. In 1930 there was a recurrence of the glaucoma but this was controlled by the use of Pilocarpine and Eserine. In 1931 she suffered a mild deep infection which cleared up immediately on the administration of typhoid intravenously. In November, 1932, it was noted there was a clouding of the lens of the left eye with the vision reduced to 15/25 with best correction. This clouding of the lens has progressed very slowly. In February, 1935, it was noted that the lens was quite dense in the center and the vision was reduced to 15/200 and the sight remained at that level until June 20, 1935, when she suddenly noted an abrupt diminution of her vision. With dilated pupils, the lens was sufficiently clear so that the fundus could be seen, and it was observed the disc was blurred; veins were dilated and tortuous; there were numerous hemorrhages. The vision at that time was 7/300. Since that time there has been some improvement in the vision due to the absorption of the hemorrhages and retinal edema while the lens remains sufficiently clear to afford a fairly satisfactory view of the fundus. On February 3, 1937, the vision was 15/200 and the details of the fundus could be seen rather clearly."

She was placed on small doses of thyroid and kept under continuous observation since then. In 1932 her blood pressure was 180/100; N.P.N. -35 mg. per 100 c.c. of blood. Since the retinal hemorrhage in 1935 she has been on a diet very low in cholesterol, to which she has adhered conscientiously. Her daily dose of dessicated thyroid is two grains. Sodium Iodide is given intermittently. Her N.P.N. is now 26 mg. per 100 c.c. of blood; blood pressure 140/80. She maintains a good state of nutrition and is active for her age (74 years). Is able to read large print better than she could in 1934.

Case 5. B. H. B., male, aged 56, banker, 5 feet. 8 inches. Weight 210 lbs. Came under observation October 20, 1936. Had diabetes for 18 months. Was taking 20 units insulin daily and was on a diet of high fat content.

His blood sugar curve was as follows:

Fasting	½ hr.	1 hr.	2 hrs.	3 hrs.
126 mg.	194 mg.	201 mg.	207 mg.	189 mg.

He complained of great deal of nervousness, slept poorly and had digestive disturbances. The urine was found to contain hyalin and granular casts and approximately one per cent sugar. N.P.N. was 35 mg. per 100 c.c. of blood. Physical examination showed blood pressure 120/70; palpable arteries were definitely sclerotic; *liver was very hard a hand's breadth below the rib margins.* His basal rate was well within the normal limits. He was placed on a low cholesterol diet, gradually increasing the carbohydrates, given one grain dessicated thyroid once daily. He made steady improvement; his liver became smaller and within 60 days was barely palpable at the rib margins. He now discontinued his insulin and continued to lose weight. A check-up on March 1, 1937, revealed fasting blood sugar 115 mg. per 100 c.c. of blood; N.P.N. -24 mg. per 100 c.c. of blood. Weight 170 lbs. General condition excellent. 24 hour specimen of urine free from sugar.

Following the suggestive work of Lockie and Hubbard (9) I have achieved excellent clinical results in the treatment of a group of 6 patients suffering from *Gout.* In the acute stage, Colchicine was given followed by low cholesterol diet and the administration of thyroid and iodide. No patient has had a recurrence of the acute symptoms. This method is far better than the use of the dangerous drug Cincophen so much in vogue in the treatment of gout.

Dr. J. Albert Key, Professor of Orthopedic Surgery in the Washington University School of Medicine has had quite a large experience in the treatment of degenerative arthritis. Quoting from his paper on the subject (not yet published) "the treatment consisted of a low fat diet supplemented by thyroid medication." "We found that our patients with degenerative arthritis do better than have similar patients in the past under any other form of treatment which we have used." "We feel that we are able to prevent the progress of the disease in cases in which it is definitely present and to prevent its development in the type of individual in whom it is to be expected."

Of course, there exists spontaneous arrest of cataract as well as unexpected improvement in heart dis-

ease regardless of diet or other forms of therapy. Dr. Paul D. White (10) in his report "A New Record of Longevity After Coronary Thrombosis" advised and achieved weight reduction in this patient.

The cases that I report are representative of the various conditions in which low cholesterol diet and the administration of thyroid and iodide have been useful. A proper appraisal of the method comes from retrospect and consideration of the general results secured in patients treated prior to the employment of this method.

The larger number of patients who have been benefitted by this treatment include those who in middle life begin to develop symptoms of degenerative arthritis, gall bladder disease, and arteriosclerosis.

It looms large on the Horizon of Preventive Medicine.

Hypoglycemia

A Study of 404 Patients Who Had No Insulin and Had This Common Finding*

By

LAY MARTIN, M.D. *and* GEORGE HELLMUTH, M.D.

With the assistance of

M. L. MUTH, M.D.

BALTIMORE, MARYLAND

HISTORY

IN spite of the importance of hypoglycemia there has been but little about it in the medical literature until the past ten years. Since then, although the reports have been numerous, the main interest has been centered in one phase of the subject, hyperinsulinism. In most of the reports this condition has been taken for granted as an explanation of a symptom complex, the nature of which is yet to be proved and for which a state of hyperinsulinism could at most be postulated as its immediate cause.

The study to be reported was undertaken since there did not seem to be an adequate investigation of a large group of cases covering the broad field of hypoglycemia. It seemed unlikely to us that the label hyperinsulinism was sufficiently conclusive and that Camidge's conclusions were correct interpretations of the nature of the condition.

To this end we have reviewed the available histories of the patients in the Johns Hopkins Hospital in whom hypoglycemia was discovered. It has been our aim to determine the frequency with which hypoglycemia was found and to correlate this finding with diagnosis, symptoms, and as many abnormal characteristics as would seem feasible and logical.

We have found that a low blood sugar was associated with a number of organic pathologic conditions and furthermore that it is also at times low in association with a condition which we can now best classify as an abnormal functional state. Later in the article we attempt to describe the hypoglycemia found in psychoneurotic individuals and which we do not feel is responsible for their symptoms since these symptoms remain during shifts of the blood sugar concentration to normal levels and in contrast to them there is a small group whose low level of the blood sugar seems definitely connected with their symptoms. These patients are always temporarily relieved of their unpleasant symptoms by partaking of carbohydrate, preferably in the form of sugar.

Porges (1) in 1910 noted that individuals suffering from Addison's disease frequently had a low concentration of sugar in their blood. Carrying on the suggestion stimulated by this finding he was able to show that when dogs were adrenalectomized their blood sugar also diminished. In 1912 in his book "The Pituitary Body," Cushing (2) mentions the finding of a low blood sugar in one of his patients who had a pituitary tumor. Another observation on hypoglycemia was made by Joslin (3) in 1921; in three diabetics who had been undergoing the Allen Treatment he found an abnormally low concentration of blood sugar.

The first references to a state of hyperinsulinism were made by Seale Harris (4) and by Ross and Josephs (5) who in 1924 independently reported cases of spontaneous or idiopathic hypoglycemia. Since then Harris has followed up the subject and has reported a number of additional cases. He recently reviewed this phase of hypoglycemia (6).

Three years later, Wilder, Allen, Powers and Robertson (7) published a detailed report of a patient with carcinoma of the islets of Langerhans in whom the blood sugar was very low. They state that extracts from the tumor and from the metastases in the liver contained increased amounts of insulin.

Several additional cases have been reported since. Phillips (8) described the pancreas of a man who died

*From the Gastro-Intestinal Division of the Department of Medicine—The Johns Hopkins Hospital and University.

Submitted June 21, 1937.

of nephritis in whom there was a low concentration of blood sugar. At section he states that the islets of Langerhans were definitely increased in diameter throughout the gland.

The first report of a large number of cases was made by Cammidge (9) in 1930. His series includes two hundred patients of whom he said that 47 per cent had some infection in the upper intestinal tract. He did not give his criteria for diagnosis. He also stated that there was an hereditary hypoglycemic factor in 35 per cent and that acetonuria was found in 25 per cent. He asserts that most of the cases could not be cured until the upper intestinal infection had been successfully treated. He did not mention technic of therapeusis.

There are two splendid critical reviews on the subject of hypoglycemia, one by Sigwald (10) in 1932 who also reports some cases of his own and the other by Wauchape (11) in 1933. As they both have fully covered the available reports on the subject, a further discussion of it here would be superfluous.

TABLE D-I

Showing the total number of cases (404) arranged according to organic, nonorganic, and unknown basis for hypoglycemias. Also arranged to show the relationship of symptoms to diagnosis

INTRODUCTION

Before presenting our data and discussing their possible significance we wish to give our definition of hypoglycemia and, what is equally important, that of a normal glucose tolerance test.

From the numerous reports in the literature it may be accepted that the normal fasting blood sugar is generally about 100 mg. per cent, but it may vary from 80 to 110 mg. per cent. These limits are somewhat conservative in the opinion of certain investigators, but it is our belief that blood sugar estimations below 80 mg. per cent represent an unusual condition if not an actual abnormality.

Considerable investigative work has been devoted to the purpose of establishing the limits of a normal glucose tolerance test. Many of the earlier articles reported upon too small a number of cases to be convincing. Later reports have eminated from the Scandinavian countries which do carry conviction. From these reports it seems settled that after the ingestion of 75 to 125 grams of glucose the blood sugar rises rapidly from a control level of about 100 to 140 or 180 mg. per cent and during the period of the next two or three hours drops back to the fasting level. During the descent it frequently drops below the control level, but if it drops below 70 to 65 mg. per cent it again represents an unusual if not abnormal reaction.

METHODS

All of the laboratory findings to be presented on the test cases were made in the biochemical laboratories of the medical department of the Johns Hopkins Hospital. Recognized standard methods were used for the various determinations. Specimens of blood were in the great preponderance of cases obtained from the vein. But few of the blood sugars were estimated from the capillary blood; those that were done in that manner were usually made in conjunction with venous blood in especially selected cases such as Addison's disease, myxoedema and parenchymatous liver disease.

The urine determinations were made in the customary manner by medical house officers or fourth year students and in general were carefully and accurately performed and interpreted.

CONTROL

The control cases represent one hundred patients studied in the office laboratory of the senior author. The laboratory investigations were made in accordance with standard technic and performed by an experienced technician. Capillary blood was used for the glucose tolerance tests.

The patients represent a cross section of the usual private practice and as some investigative work was being done on cases of hypertrophic arthritis, a good proportion of these cases are among those reported. The control patients selected were those whom fasting blood sugar, a glucose tolerance test and a basal

metabolic rate had been determined on each. In none of these cases was the fasting blood sugar below 80 mg. per cent.

The glucose tolerance curves of 50 cases showed a slightly lowered tolerance and only one dropped below seventy. There was one case with suggestive symptoms of hypoglycemia in which the curve remained flat and dropped below 70. In three patients with otherwise normal glucose tolerance curves the blood sugar dropped below 70 mg. per cent during the test. We were unable to find any relationship between the type of curve and the basal metabolic rate.

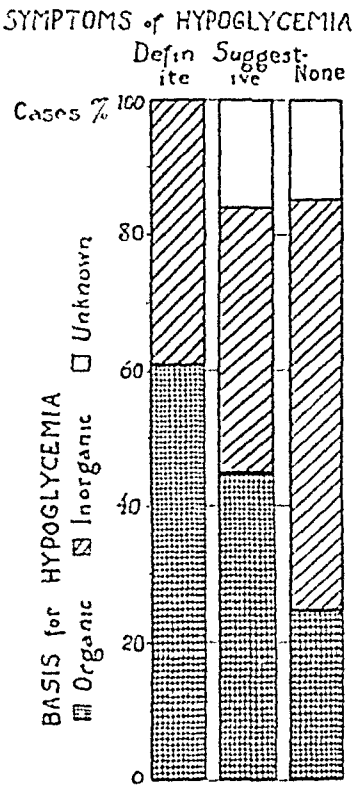

Fig. 1. Shows the percentage of the total number of cases with definite symptoms, suggestive symptoms and no symptoms whose hypoglycemia was the result of organic, inorganic or unknown etiology.

TEST CASES

There were 63 patients whose fasting blood sugar was above 80 mg. per cent but which dropped below 70 mg. per cent during the glucose tolerance test. There were 63 patients whose fasting blood sugar was between 71 and 79. The large group includes 278 patients who were found to have at least one fasting sugar below 70 mg. per cent. In 54 of them there were one or more tests made, when the fasting blood sugar was below 50 mg. per cent.

The lowest reported is 4 mg. per cent, the exactness of this reading is of course questionable, but was repeatedly obtained from the same blood specimen. This was determined on the fasting blood of a patient who was in a coma. He was given glucose intravenously, as a result of which his blood sugar level went above 200 mg. per cent and restored him to a temporary state of well being. It was proved at autopsy that he had an adenoma of the pancreas.

The next lowest determination 15 mg. per cent (repeated) was found in a blood specimen removed from a man who was in deep coma as a result of what was apparently an unwise, if not excessive use, of hard liquor.

Age and Sex: The roster of patients included persons of all ages, the youngest a few months, the oldest aged. The largest representation was between twenty years and fifty years and was more or less equally distributed among the decades.

SYMPTOMS

While the histories were abstracted notes were made for guidance in the determination of which symptom group the patient was to be classified. They are as follows:

1. Symptoms of hypoglycemia: The patients in this group were selected when there seemed to be a direct relationship between symptoms and hypoglycemia. Either as found in a fasting blood specimen or in specimens taken during the day or during the progress of a glucose tolerance test.

Weakness, nervousness, recurrent early morning headache, anxiety, trembling, lassitude, sweating, inability to concentrate before meals, marked hunger were considered significant symptoms. Some of the patients become semi-comatose and even developed convulsive attacks. It was generally noted that if hypoglycemia was the cause of these symptoms, they were quickly dissipated by food. This group contains 36 patients.

The number of patients actually observed having spontaneous hypoglycemia symptoms during the course of a day, normal for them, was small. A patient with adenoma of the pancreas, one with myxoedema, several with Addison's disease, three during severe acute alcoholism, and ten with symptomatic functional hypoglycemia of unknown etiology.

2. Symptoms suggestive of hypoglycemia: There were a number of patients whose symptoms were suggestive of hypoglycemia but which we were unable to recognize as directly related to their blood sugar concentration. It is probable that some of them were the result of hypoglycemia and others were merely expressions of psychoneurosis connected with a lowered blood sugar which was above the symptom producing level. There are 82 cases in this group.

3. No symptoms suggestive of hypoglycemia: In this group of 286 we have placed the great bulk of the patients. It may be that some of those diagnosed as psychoneurotics should have been placed in Group II but we feel that the potential errors in both groups will more or less balance.

PHYSICAL EXAMINATION

Obesity was noted in 22 of the patients, 17 of whom were found to have blood sugar levels which placed them in the second group. Malnutrition was evident in 29 patients and again was most in evidence in those patients with a low fasting blood sugar. The liver was definitely enlarged in 16 nonjaundiced patients and the spleen in 8. Jaundice was noted in 16 patients in some of whom the liver was thought to be decreased in size.

DIAGNOSIS

It is noteworthy that an hypoglycemia was found to

be associated with a large number of ailments. The complete data are given in the tables and only the more significant findings will be mentioned here.

The largest group of cases was placed under the diagnosis designated as General, which included 35 entities such as: dermatitis, flat feet, ureteral stricture, chronic bronchitis, furunculosis, benign prostatic hypertrophy, inguinal hernia, allergic conditions, etc., other more specific diagnosis were: psychoneurosis, renal glycosuria, hypertension, myocardial insufficiency, neurological disorders, Addison's disease, arthritis, hyperthyroidism, low basal metabolic rate, parenchymatitis, liver disorders, gastro-intestinal disease, blood diseases and others less frequently noted.

There were 33 patients with renal glycosuria, a striking proportion of whom had a psychoneurotic leaning.

We were interested in 43 cases of liver disorders, among which carcinoma, arsphenamine induced hepatitis, alcoholism (3 cases), cartarrhal jaundice and induced malarial infections in patients with central nervous system syphilis, all of which gave low fasting blood sugar readings. On a case of cirrhosis, which was verified at necropsy, and which was clinically thought to be due to chronic alcoholism, an epinephrine test was done, it failed to show the usual rise in blood sugar.

Among the patients, three suffering from the effects of sustained use of alcohol, were especially interesting. The first, a man, was brought into the accident ward in a coma. His extremities were rigid, his skin moist, his blood sugar 15 mg. per cent. Dr. Tom Brown, a house officer, saw him, and was so impressed with the clinical picture that he made the diagnosis on the other two cases. In these patients two features are of importance, one the abstinence from food, and second the possible glycogenolytic influence of alcohol on the liver.

For the sake of thoroughness we add the specific diagnosis of the cases grouped under the heading "neurological." It is not deemed of importance to go into a detailed description of each as they were not particularly interesting from the point of view of sugar metabolism. The neurological diagnoses include multiple sclerosis, 3 cases; trigeminal neuritis; Parkinsonism; brain tumor, 3 cases including hypophysial tumor; myasthenias gravis, 3 cases; progressive muscular dystrophy; familial periodic paralysis; brain abscess, 2 cases; and severe head injury.

There were 5 cases of myxoedema; from a physiological view point hypothyroidism would seem to be one of the factors causing hypoglycemia.

Arthritis has frequently been reported to be associated with a low sugar tolerance. We report 27 patients in whom the fasting blood sugar was low or in whom the glucose tolerance test shows a low blood sugar at some time.

COURSE

On a number of the patients blood sugar tests were repeated at long intervals of time. They frequently varied from low to normal and it has been impossible, except in rare instances, to correlate this with a change in the condition of the patient.

Addison's disease offers an interesting illustration of symptomatic improvement in association with rise in blood sugar. It was repeatedly noted that epinephine would temporarily raise the blood sugar and relieve symptoms. Successful treatment with cortin would also cause a rise in blood sugar. Patients recovering from severe parenchymal liver disease also showed an increase in blood sugar in association with improvement.

We could find no correlation between hypoglycemia and death rate.

GLUCOSE TOLERANCE

One of the tests which has held our sustained interest in this investigation is the glucose tolerance. On analysis one is enabled to divide the results into seven main groups.

1. The normal curve starting about 90 to 100 mg. per cent, not going higher than 170 and returning to the starting level by three hours. At some time a low fasting blood sugar was found in each of the patients.

2. The low curve starting below 70 rarely going higher than 110 to 115 and returning to, or somewhat

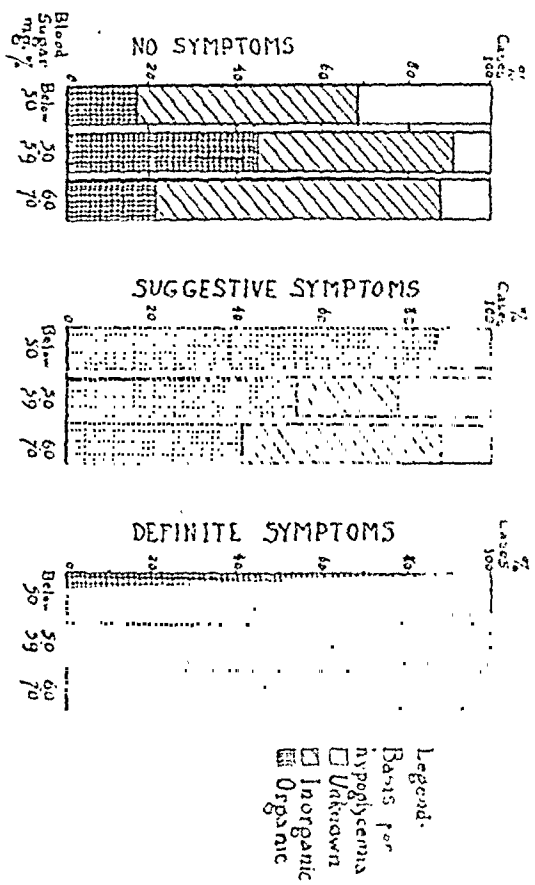

Fig. 2. Cases having no symptoms, suggestive symptoms and definite symptoms are arranged according to their respective fasting blood sugar levels and the percentage of cases having organic, inorganic and unknown etiology are shown in relation to symptoms and fasting blood sugar levels.

below, the starting level by three hours.

3. The normal rise with hypoglycemia drop. Starting about normal, reaching the usual elevation, and rapidly dropping below 65 mg. per cent.

4. The low starting diabetic curve which does not return to normal in three hours.

5. The normal starting, high rising curve going above 200 mg. per cent and rapidly descending below 65 mg. per cent.

6. The normal starting diabetic curve found in association with one or more low fasting blood sugar concentrations.

7. The flat curve sometimes remaining constantly at a low level, and at times just about 90 to 100 mg. per cent throughout.

For ease in tabulation curves four and six have been grouped together. Study of the cases to show

TABLE D-III

Showing the relation between symptoms and type of glucose tolerance curve

Type of Curve	1	2	3	4 & 6	5	7
Patients with Definite Symptoms	1	5	5	2	1	9
Patients with Suggestive Symptoms	4	8	15	1	2	2
Patients with No Symptoms	5	19	50	7	5	3

the relation of fasting blood sugar to glucose tolerance brings out the fact that normal curves are rare, twelve in number. It demonstrates that the low starting, but slightly rising curve (type 2) is the second most common, and that the one starting from a normal level, rising moderately, and dropping below 65 mg. per cent (type 3) occurred in about 50 per cent of the cases. It occurs most frequently in association with normal fasting blood sugar. The diabetic curves are not very common. Curve 5, i.e. that starting at a normal level, rising above 200 mg. per cent, and dropping below 60 was found to be associated with a constant normal fasting sugar.

The Relation of Glucose Tolerance Curve to Diagnosis: The distribution of the type of glucose tolerance curve among the various diagnoses had a general spread. There were one or more typical curves found in association with whatever diagnostic group the tests were performed. Furthermore where a sufficient number were done on the patients of any diagnostic group it was noted that three or more types of curve occurred. If the number of patients was sufficiently large, all types were to be expected.

BASAL METABOLIC RATE

The basal metabolic rate was determined on 141 patients, on 60 of them it was found to be between +10 and —10 per cent, on 48 of them below —10 per cent, on the remaining 33 it was above +10. It was very low, below —30 on 6 patients, and very high above +30 on 12. It is, therefore, evident that hypoglycemia is found associated with wide variations in basal metabolic rates.

There were 54 of the hypoglycemic patients on whom both basal metabolic rates and glucose tolerance tests were done. No correlation with symptoms was noted.

The relation of basal metabolic rates to blood cholesterol in the presence of hypoglycemia was studied in only 13 cases. In 2 cases of myxoedema and 1 of Addison's disease there was a low basal rate in conjunction with an elevated blood cholesterol. There was one undiagnosed endocrinopathy with a normal basal rate and a high cholesterol. In 3 cases of Addison's disease

there was a low basal and a low cholesterol. In 3 cases of Addison's disease there was a low cholesterol and a normal basal rate. The other 4 cases of Addison's disease had a low basal rate and a normal blood cholesterol. Consequently a relationship seems unlikely.

VARIOUS ANALYSES

There was no correlation between hypoglycemia and the blood pressure, Wassermann reaction, blood cell counts, non protein nitrogen, blood uric acid, gastric analysis, phenosulphonophthalein test, serum calcium, phosphorus, bicarbonates, cholesterol and proteins.

Epinephine Tests: Epinephine tests were carried out on 9 patients, on some of them repeatedly, in only one instance, a case of cirrhosis, did a normal response fail to occur.

PHYSIOLOGY

The fundamental approach to an understanding of the several bases of hypoglycemia is a physiological one. That our discussion may be presented in a setting that will give the widest scope to the significance of the data outlined we take the liberty of reviewing a few of the recent and simple facts and theories of carbohydrate metabolism.

It is substantially accepted that after glucose is absorbed into the blood stream of a normal individual, it is stored in the liver as glycogen, held in the muscles for energy requirements, excreted, at times, in the urine, or perhaps stored for a time in the intercellular fluid. It is also apparently true that any other hexose than glucose such as fructose, galactose and levulose, is changed into glucose by the liver before it becomes acceptable for use in furnishing local energy to muscles.

In the fasting stage we may consider the liver to be the storage organ for glucose. The factors which control the distribution of glucose to the body center in this gland. It is logical if glucose is not available for storage or if the liver does not store it, either as a result of external influences or from intrinsic parenchymatous pathological processes, that there should be changes in the blood sugar content. It is likewise logical that this should be the result of an exaggerated or uncompensated increase in the strength of those factors which promote glycogenolysis. If the organism is deprived of glucose and other glucose producing food, the glycogen storage in the liver is markedly diminished. It has been noted that protracted fastings in man will lower the blood sugar level.

All of the stages in the formation and breakdown of glycogen are not understood, but it is possible to postulate conditions which will interfere with the removal of glucose from the blood stream and its deposit as glycogen in the liver. That insulin plays an important part in this process is suspected; when it is present in sufficient amounts the normal storage of liver glycogen takes place, when it is diminished or lacking as in diabetes, a diminution of liver glycogen follows. Whether it aids in the formation of liver glycogen, is an unsettled point, but that it has an important action in inhibiting glycogenolysis, or the liberation of glucose from the liver to the blood stream is apparently proven. Consequently, when the liver is functioning within stabilizing limits, a normal secretion of insulin is associated with a normal blood sugar level, but a diminished secretion, as in diabetes, will either diminish the storage rate of glycogen and permit glucose to accumulate in the blood or fail to hold glycogenolysis in check. As the secretion of insulin is controlled by hormonal or neurogenic factors, functional states of hypersecretion are theoretically possible. That such a state occurs clinically has not been proven, although it has been postulated as an explanation for some of the reported cases of hyperinsulism with symptomatic hypoglycemia. Increased secretion is also asserted to be the result of adenoma and carcinoma of the island cells of Langerhans. The effect of an hypersecretion of insulin would be of such a nature as either to withdraw an excessive amount of glucose from the blood for glycogen storage in the liver or to further inhibit glycogenolysis. This would reduce the concentration of sugar in the blood.

Houssay's (12) observation, that the hyperglycemia in pancreatectomized animals was notably reduced after hypophisectomy opened the way for demonstrating the importance of another substance of unknown nature which assists in the maintenance of a normal blood sugar level. Apparently the pituitary gland secretes this substance and it acts directly on the liver or in combination with insulin to increase storage of glycogen or to decrease glycogenoloysis. In a pancreatectomized animal the liver, when protected from this influence is apparently able, in a degree, to compensate for the loss of insulin.

A third equally important chemical substance essential for maintaining a normal blood sugar level is epinephine, a secretion product of the adrenals. Its influence is opposed to that of insulin and acts as a brake against it. When the blood sugar drops below a certain level the adrenals are stimulated to secrete more epinephrine. This in turn acts upon the liver to cause increased production of glucose and a rise in blood sugar. When the adrenals are removed the blood sugar level drops. Addison's disease in man offers an excellent example of the effects of lowered adrenal efficiency. That the associated hypoglycemia is not due to an hypersecretion of insulin or to liver disfunction is shown by the prompt elevation of the blood sugar that follows an injection of epinephrine. It may be added that following cortin injections in these patients their blood sugar as well as cholesterol also increases.

Although there may be no discernable changes in the secretion of substances which govern carbohydrate metabolism and maintain a normal blood sugar level, there may be extreme changes noted in it as a result of parenchymatous liver change. The investigations of Mann (13) and Banting (14) and further corroborated by Soskin (15), prove the fundamental importance of the organ in supplying glucose to the body. As could be expected from the fact that removal of the liver causes a precipitous fall in blood sugar, severe parenchymatous liver disease will, as shown in our data, bring about the same result. At this point, it may be noted that in one case of severe cirrhosis (proven post mortem) an injection of epinephine failed to produce the customary rise in blood glucose; the obvious cause being a markedly diminished glycogen store in the liver. An interesting corrolary to this has been shown in the case of Von Gierke's disease in which the glycogen storage of the liver is excessive and there is an hypoglycemia. When epinephine is injected into these patients there is no increase in blood sugar. The suggestion naturally presents itself that some other external influence must be

acting not only to increase the action of insulin in inhibiting glycogenolysis but also sufficiently strong to prevent the added increment of epinephine from stimulating that process. This might well be the hormone liberated by the hypophysis and responsible for the phenomenon noted by Houssay.

The secretion of the thyroid gland has an effect in carbohydrate metabolism which may act in two ways. First physiological, and presumably in the adrenals, and second as a toxin reacts on the liver cells. Consequently although in states of hypothyroidism an hypoglycemia is to be expected it may also be a result of liver damage by thyroxin.

DISCUSSION

In the description of the data noted in the tables we have shown a number of normal or abnormal conditions in their relation to a state of hypoglycemia. We have shown that it was found irrespective of age, sex or color. It has been found within wide variations of basal metabolic rates. It is associated with extreme quantitative changes of the blood count, blood pressure, N.P.N., uric acid, phenolsulphonphthalein excretion, gastric acidity, phosphates, proteins and cholesterol. It has been noted in acidosis and it is associated with almost any type of glucose tolerance curve. We have not found a significant change in serum calcium to be concomitant with it.

It is associated with a large number of pathological conditions some of which are responsible for the lowered blood sugar by interfering with the organs, or nerves or hormones which control the normal carbohydrate metabolism. Cases falling in this group might be said to have an organic basis for their hypoglycemia. We have also found a number of pathological states in which we cannot recognize any conditions which cause a lowering of blood sugar. Exception might be made to the inclusion of cases of renal glycosuria in this group; nevertheless, we cannot recognize any basis for the glycosuria.

There is a number of patients with blood dyscrasia, neoplasm, neurological states (including three cases of myasthenia gravis), hypertension, and undiagnosed conditions the nature of whose etiological association with hypoglycemia we do not understand. These are listed as of unsettled etiology.

We have, in Table D-I, classified our patients in three groups representing the etiological basis for their hypoglycemia and find that the distribution is as follows: 1. Organic basis: 32.2 per cent; 2. No organic basis: 54.2 per cent; 3. Unsettled basis: 13.6 per cent; it is especially noted that only about a third of them had a recognizable organic basis for their abnormality.

This table also divides the cases according to their symptoms, i.e. whether they had definite or suggestive or no symptoms of hypoglycemia; from the Table D-I and Figure 1 the following summary may be deduced:

1. Definite symptoms were noted in only 8.9 per cent of all the patients whereas those with suggestive and definite symptoms were calculated as 28.8 per cent of the total number.

2. There were no symptoms of hypoglycemia in 71.2 per cent of the patients.

3. Among the patients with definite symptoms of hypoglycemia there was a recognizable organic basis in 60 per cent of the cases.

4. Among the patients with symptoms suggestive of hypoglycemia there was a recognizable organic basis in 43 per cent of the cases.

5. In the patients with no symptoms of hypoglycemia there was a recognizable organic basis for the condition in 24 per cent of the cases.

It is furthermore shown in Table I that in each of the diagnostic grouping with the exception of our diagnostic group called true functional hypoglycemia with symptoms, and Addison's disease, there are more patients having no symptoms than with positive or suggestive symptoms. This would naturally suggest to the reader the thought that those having positive or suggestive symptoms had a lower blood sugar than those who had no symptoms.

The data relative to this sensible query are shown in Table D-II which includes 278 cases whose fasting blood sugar was below 70 mg. per cent. They are classified, as in Table D-I, according to the organic or non organic or unknown basis for their hypoglycemia, and these cases are further yet subdivided in regard to the presence or absence of symptoms of hypoglycemia. The other 126 cases which are not included were either in the 70's or were low only during the course of a glucose tolerance test.

When classified according to their etiology as described above the distribution is as follows: 1. Organic basis 38.3 per cent; 2. Non organic basis 48.2 per cent; 3. Unsettled basis 13.5 per cent. These figures are close enough to those of the entire group (Table D-I) to be significant. This is especially so when we compare the percentage of the smaller groups having positive or suggestive symptoms, 28.8 per cent, to a similar percentage of 27.2 when the total number of cases was calculated.

The most important data in Table D-II was obtained by dividing the cases into three parts arranged according to their lowest fasting blood sugar; first those below 50 mg. per cent, 25 cases; second, between 50 and 59 mg. per cent, 54 cases; third, between 60 and 70 mg. per cent 197 cases.

The data has been summarized in Figure 2 to show the relation of symptoms and etiology to fasting blood sugar levels. Where definite symptoms were noted an organic basis was also present in the vast majority of cases whose blood sugar dropped below 50 mg. per cent. When the fasting blood sugar was in the fifties and the sixties there was a smaller number of cases with definite symptoms. To a striking degree this same relationship was noted in those cases who had symptoms suggestive of hypoglycemia. When the fasting blood sugar is in the sixties there is less than a 50 per cent chance that the patients having definite or suggestive symptoms will also have an organic basis for their hypoglycemia. A marked contrast is to be noted in that large group of patients with no symptoms. There a very much smaller number of cases having an organic basis was noted. It is equally important to realize that 70 per cent of all the patients with a fasting blood sugar in the sixties had no symptoms of hypoglycemia and that only 23 per cent of these had an organic basis.

Most of the cases of functional hypoglycemia with definite symptoms in this study were found to have fasting blood sugars in the higher ranges. Their fasting blood sugars were 60, 81, 65, 57, 45, 70, 60, 78, 90, 68 mg. per cent. On 6 of those cases symptoms of hypoglycemia were apparent during a glucose toler-

ance test. These cases seem to have symptoms at a higher level of blood sugar than those patients who have an organic basis for their hypoglycemia.

The facts stated in the last few paragraphs must give us pause when we consider the increasingly large number of reported cases of so-called "hyperinsulinism." What is it that produces symptoms in some patients when the blood sugar level is in the 70's and in others only when a lower concentration is attained? In the first place, there seems to be no definite point below which symptoms of hypoglycemia will become clinically discernable. In the second place, it would seem that the patients with symptomatic functional hypoglycemia are hypersensitized to a lowering of the blood sugar level. Further studies may reveal some fundamental basis for this reaction.

We have found 179 patients with fasting blood sugars below 70 mg. per cent who did not have symptoms of hypoglycemia. In contrast to this, we can point to 26 patients with fasting blood sugars at 70 or above who had definite or suggestive symptoms and includes 6 of the 10 cases of symptomatic functional hypoglycemia; these patients apparently have symptoms at a higher level of blood sugar than those patients who have an organic basis for hypoglycemia, and also at a higher level than the psychoneurotic individual, who by definition has no known organic basis for his symptom complex.

To evaluate the importance of hypoglycemia in the cases of psychoneurosis is very difficult. There is in the literature considerable reference to a number of patients with hyperinsulinism, who, until this diagnosis was pinned on them were considered psychoneurotics. Then after their diets were adjusted many were reported as being markedly benefitted, or symptom free. Many of our patients had symptoms that might have been considered as suggestive of hypoglycemia. It should be noted that these symptoms were constant and that they were also present when their blood sugar was normal. It is our opinion that, in the preponderant majority of instances, the symptoms were those so common in psychoneurosis and not a result of hypoglycemia. Furthermore, as we more carefully choose our cases we shall probably find other factors which help to differentiate the symptoms of true functional symptomatic hypoglycemia from psychoneurosis with hypoglycemia.

It has been mentioned just above that 6 of our cases of functional symptomatic hypoglycemia were positively classified on the basis of a glucose tolerance test. This brings up an important question. Do the results of this test have a real significance, and are we able by them better to classify our cases of hypoglycemia?

It has been noted that this test was performed on 144 patients and their various types of response to the ingestion of large amounts of glucose are shown. In Table D-III we have arranged these types of response in relation to the patient's symptoms. It demonstrates that there is no relation between symptoms and type of response. It may be recalled that there were 286 patients with hypoglycemia in whom no symptoms were noted and from Table D-III one can deduce that 19 per cent of them were found to have an hypoglycemia only by means of the glucose tolerance test. By individually picking out the cases, we found that 21 per cent of those with definite or suggestive symptoms were recognized or proved by means of the glucose tolerance test. Of this number, 8 were recognized as having definite symptoms and constitute 22 per cent of all the cases with definite symptoms, obviously a sufficient number to give significance and importance to the test.

In the discussion of glucose tolerance tests one might ask if the extent of the fall of the blood sugar might not be an important factor and again as in the discussion of fasting blood sugar whether the presence of an organic condition responsible for the disturbed carbohydrate condition might not also be an important factor?

In 11 patients, the glucose tolerance curve at some point dropped below 49. mg. per cent and in 74 per cent of these cases there were suggestive or positive hyperglycemic symptoms. It might furthermore be stated that only 2 of these patients had discernible pathologic bases for this abnormal reaction. In 17 instances the glucose tolerance curve was noted to fall to between 50 and 59 mg. per cent. Fifty-nine per cent of these patients had suggestive or positive symptoms of hypoglycemia, but only 29 per cent of them had an organic basis for the alteration in glucose metabolism. In 25 patients the low point in the glucose tolerance curve was between 60 and 70 mg. per cent. On analysis it was shown that 48 per cent of them had definite or suggestive symptoms, but only 28 per cent were suffering with organic conditions which might be the cause of the abnormal response.

These results offer us an interesting comparison between the cause and effect of low blood sugar concentrations during glucose tolerance tests and low unprovoked, fasting blood sugar levels. In the latter condition, the lowest sugar determinations were generally found associated with and dependent on definite pathologic processes. In the former the large majority of the lowest blood sugar levels were found associated with functional states.

It is unfortunate that so few glucose tolerance tests were made on the cases of parenchymatous liver disease that no conclusions can be drawn. In Addison's disease the glucose tolerance test varied with the condition of the patient. Before the institution of treatment or during the crises, a low blood sugar was found in the fasting stage and during the performance of the glucose tolerance test. After the institution of successful therapeusis there was an approach to or an attainment of a normal range. The patients with renal glycosuria showed all types of curve but rarely exhibited symptoms. The flat type of curve was found with greatest frequency in patients whose basal metabolic rate was well below normal.

There is a number of circumstances in which two or more glucose tolerance tests have been done on the same patient within a short period of time and the results of which have been divergent; so much so that typical diabetic responses have been found only a few days or a week from the time of subnormal elevations due to the ingestion of glucose. We cannot explain this finding.

SUMMARY AND CONCLUSION

1. We have given certain findings on 341 patients whose blood sugar, uninfluenced by insulin injection, was found at some time to be below 70 mg. per cent. Also on 63 patients whose blood sugar was in the 70's.

2. Hypoglycemia has been found associated with a large number of pathologic conditions. In these con-

ditions symptoms pathognomonic of hypoglycemia were found in 8.9 per cent of the cases. Suggestive symptoms were present in 20 per cent.

3. In patients with symptomatic functional hypoglycemia, symptoms may appear at a higher level of blood sugar than in patients with a recognizable basis for their hypoglycemia.

4. Except for the cases of symptomatic functional hyperglycemia and of epilepsy there are relatively few other instances where patients with definite symptoms of hypoglycemia had no recognizable basis for their hypoglycemia.

5. In the body of the article we have shown that a number of laboratory and clinical data could not be correlated with hypoglycemia. These are too numerous to renumerate.

6. We believe that there is a number of individuals with symptoms of hypoglycemia of unexplained etiology which we classify as "symptomatic functional hypoglycemia." We do not believe that at this time one is justified in diagnosing them as cases of hyperinsulinism.

7. It is our belief that many individuals become accustomed to or do not react to a lowered blood sugar, that would produce symptoms in others. This is true particularly of the cases of hypoglycemia arising from an organic basis.

8. We wish to express our belief that one should be very cautious in accepting a lowered blood sugar concentration as a cause of that vague symptom-complex which is especially typified by the psychoneurotic individual.

The Relation of the Hydrogen Ion Concentration of Bile to the Formation of Gall Stones*

By

RALPH E. DOLKART, M.S.,† K. K. JONES, Ph.D.

and

C. F. G. BROWN, M.D.

CHICAGO, ILLINOIS

IN spite of the numerous hypotheses concerning the formation of gall stones, no explanation has yet been advanced that adequately accounts for all of the phenomena involved. The evidence offered by Walsh and Ivy (1) in our opinion, more completely explains the immediate chemical factors concerned in maintaining the stone forming elements of bile in solution, than any theory suggested thus far.

Aschoff (2), Torinoumi (3), and others have noted the fact that cholesterol is the essential building material from which the framework of a gall stone is constructed. In the absence of cholesterol the other ingredients usually found in gall stones do not form more than a compact precipitate. Hence, the mechanisms by which cholesterol is held in solution are the *same mechanisms* which prevent gall stone formation.

Walsh and Ivy's evidence is based upon the previously established observation (4, 5, 6, 7), that human gall stones are readily dissolved in dog gall bladder bile both in the living animal and in vitro. An analysis of this phenomena in an effort to find the fraction of bile responsible, revealed that the greatest difference between human and dog bile was in the ratio of the non-saponifiable (cholesterol) to the saponifiable (fats and fatty acids) substances in the bile. On the basis of their experiments, the significant difference between human and dog bile did not revolve around the cholesterol content but around the relatively tremendous difference in content of fats and fatty acids. They concluded that the solubility of cholesterol in bile depends upon an interrelationship between: (1) fats and fatty acids; (2) bile salts or bile acids which act either by holding the fats and fatty acids in aqueous solution or by combining with fatty acids to form soaps.

More recently Feldman, Morrison and Krantz (8) have reported that the acidity of bile is a significant factor in explaining the reasons for the dissolution of human gall stones in the bile of certain animals. Their arguments are based upon their observations that human gall stones dissolve in the gall bladder of the dog which has an acid bile but do not dissolve in the gall bladder of the guinea pig which has an alkaline bile.

Submitted July 6, 1935.

In the course of our experiments on the factors concerned in gall stone formation we have obtained considerable data on the relationship between the hydrogen ion concentration of bile and the dissolution of gall stones. The object of this report is to present our findings concerning this phase of the studies.

METHODS

The relationship of the hydrogen ion concentration of the bile and the solution of gall stones was studied in two ways:

Method 1: Following in general the procedure used by Walsh and Ivy, human gall stones were weighed and placed in the gall bladders of dogs. After an interval of 65 days, the dogs were either re-operated or sacrificed and before the stones were removed, the bile was aspirated from the gall bladder for analysis. As a routine procedure, hydrogen ion concentration determinations were made on the bile so obtained. In some animals bile was aspirated at the time of operation so analyses on two samples from the same dog could be carried out.

Method 2: Another group of human gall stones, similar in character and obtained from the same human gall bladder, were weighed, wrapped in gauze to prevent mechanical injury and suspended in flasks to which was added either acid or alkaline bile. These flasks were then placed in a mechanical shaking device operating at a speed of 25-30 half revolutions per minute. The stones were shaken continuously for 7 days in a constant temperature chamber at 39° C.

TABLE I-A

Rate of dissolution of human gall stones in the gall bladder of the dog in 65 days. All stones from the same human gall bladder

The bile used in these experiments was pooled gall bladder bile from a number of cattle as received from a local packing firm. Part of this bile was buffered to a pH of 4.5-5.0 and part to a pH of 8.4-9.0. The bile in the flasks was replaced by fresh bile every 2 days. Similar experiments were carried out using bile obtained from dogs with chronic biliary fistulas and from human drainage operations.

In a third group of studies quantitative chemical analyses of the human, beef, and dog bile were performed using a specially modified analytical technique devised by one of us (K.K.J.). Mucin, non-saponifiable (cholesterol) and saponifiable (fats and fatty acids) fractions were determined. In addition to these analyses, pooled bile obtained from 18 normal guinea pigs was analyzed by similar methods for the purpose of comparison.

TABLE I-B

Determinations of pH of dog gall bladder bile at the time of operation for insertion of a stone and 65 days later at time of removal of stone. All stones from same human gall bladder as in Table I-A

Dog	Per Cent Dissolution	pH First Determination	pH After 65 Days
1	72.7	6.8	6.8
2	98.5	6.3	6.0
3	69.6	6.8	6.8
4	100.0	7.5	7.5
5	88.2	6.5	7.0
6	68.4	6.8	6.8
7	100.0	7.3	7.5
8	73.6	6.9	7.0
MEAN	85.2	6.85	6.92

RESULTS

Normally there is a wide variation in the rate with which dogs dissolve human gall stones when experimentally placed in their gall bladders. Unless stones obtained from the same human gall bladder are used in a large series of animals it is difficult to evaluate results upon a comparable basis due to the variability in the character of the stones. Table I-A shows the results of our findings in 22 normal dogs in which stones from the same human gall bladder were allowed to remain for 65 days. Table I-B shows the results of a similar group of dogs, eight in number, using stones from the same gall bladder as above, but in which determinations of pH of the bile were made both at the beginning and at the end of the 65 day period. It will be observed that there is no correlation of the variation in the rate of dissolution with the values obtained for the hydrogen ion concentration of the bile. The pH determinations, of course, reflect only one or two determinations and do not indicate the possible daily variations that may occur.

TABLES I-A AND I-B

Forty experiments were performed using acid and alkaline bile in vitro. Tables II and III respectively show the results of these studies. Comparing the mean values for the rates of dissolution in the acid and alkaline bile, it will be observed that the rate of dissolution in acid beef bile was 4.6 per cent greater than

in the alkaline. Statistical analysis of the results, however, shows there to be a combined probable error of ± 3.59 per cent in the two series. Therefore, there is no significant difference between the rates of dissolution in acid and alkaline beef bile.

TABLES II AND III

Twenty experiments were performed with acid and alkaline bile obtained from dogs with biliary fistulas. These results were tabulated in Tables IV and V and

show there to be a difference of 1.0 per cent in the rates of dissolution in the acid and alkaline bile. Statistical analysis of the results, however, demonstrate that the difference is definitely not significant when the probable error is computed.

TABLES IV AND V

Tables VI and VII show the rates of dissolution in the acid and alkaline human fistula bile. As with the series of experiments using the beef and dog bile, no statistically significant difference was obtained. In these experiments a difference of 2.88 per cent was found in the means of the rates of dissolution of the two series. This difference, however, is subject to a probable error of ± 1.44 per cent.

TABLES VI AND VII

Quantitative analyses of the bile obtained from humans, dogs, guinea pigs, and the ox offer a much more comprehensive explanation of the differences in the rates of dissolution of human gall stones when experimentally placed in various animals. Table VIII shows the results of these analyses.

TABLE VIII

It will be seen that the human bile closely approximates that of the ox and guinea pig as far as the fatty acid—cholesterol fraction is concerned. Both man and ox are spontaneous formers of gall stones and the

guinea pig does not dissolve human stones if placed in their gall bladders. Dogs on the other hand have a comparatively high concentration of fatty acids both in proportion to the other animals and in proportion to the amount of non-saponifiable material present in the bile. The ratios for the fatty acid fraction to the non-saponifiable material are as follows: Human drainage bile 1.4:1, Ox bile 6.75:1, Guinea pig bile 15:1, Dog gall bladder bile 20.3:1, and Dog fistula bile 18.1:1.

In comparing the fatty acid — non-saponifiable ratios, it will be observed that guinea pig gall bladder, bile almost approaches that of the dog as far as the relative concentration of these two components are concerned. It would appear, therefore, that human gall stones should dissolve in guinea pig gall bladder bile. Sufficient guinea pig bile, however, cannot be economically obtained in the quantities required for testing. A careful study of the data presented by Feldman, Morrison, and Krantz, in which they report no dissolution of human gall stones in the gall bladder

of the guinea pig, shows that small weight losses actually did occur. When their data is re-computed upon a percentage basis, weight losses of 2.2, 2.2, 15.8, 17.6 per cent respectively occurred in four of their seven experiments, running the animals from 110 to

small in size, into a viscus the size of the guinea pig's, of necessity brings about a marked impairment of filling and activity. Some idea of the size of the guinea pig gall bladder may be obtained when only 5.0 c.c. of bile were obtained from 18 normal guinea pig gall bladders for our analyses.

DISCUSSION

It is becoming more and more apparent that gall stones occur as the result of a disturbed chemistry of the bile. Whether this disturbance is the direct result of pathologic changes in the liver, aberrations in metabolism, or stasis and infection involving the gall bladder is still uncertain. Certainly the immediate

factor in stone formation is a change in the relative concentration of the various biliary constituents.

Andrews, Schoenheimer, and Hrdina (9) have suggested that gall stones form as the result of an abnormal diffusion of bile salts out of the gall bladder, allowing the cholesterol, which is held in solution by the bile salts to precipitate out and form stones. It was shown that while the normal dog's gall bladder absorbed neither cholesterol nor bile salts in appreciable amounts, the abnormal gall bladder absorbed bile salts and thus lowered the ability of the bile to hold cholesterol in solution. Subsequent observations by these workers on patients with cholelethiasis subjected to surgery confirmed this hypothesis. On the basis of Walsh and Ivy's observations, however, we believe this mechanism to be secondary to changes

occurring in the fatty acid component since, in the absence of bile salts, fatty acids are precipitated as soon as the bile becomes acid in reaction. Their studies demonstrate that bile salts are secondary in the process of keeping cholesterol in solution and act by virtue of their combination with the fatty acids of the bile. Using various fatty acids as solvents, they reported that stones increased in weight in butyric acid

but lost markedly in oleic, lauric, or myristic acid solutions of a 1 per cent concentration in a pH 8 buffer solution. Greatest dissolution was obtained in lauric acid. It was found that better solvent action could be obtained at a more alkaline reaction. Walsh and Ivy explained this upon the basis that there was more soap available to hold the fatty acid in solution. It was further demonstrated that fatty acid was apparently the most active principle since in vitro, pure fatty acids dissolve gall stones readily whereas neutral fats or bile salts do not have such marked solvent action. The addition of bile salts, however, to a lauric acid solution increases the solvent capacity of the solution.

TABLE VIII

Results of quantitative analyses of human, dog, ox, and Guinea Pig bile

Animal	Bile Fractions—Figures in Grams /100 c.c. Bile			Remarks	Ratio—Fa: Non-S
	Alcoholic Precipitate (Mucin)	Non-Saponifiable	Fatty Acids		
MAN (Drainage Bile)	0.207	0.149	0.211	Results of analysis — 27 samples on 3 patients	1.4:1
OX (Gall Bladder Bile)	0.350	0.810	0.540	4 analyses from 2 pooled stockyard samples	6.75:1
GUINEA PIG Gall Bladder Bile)	0.500	0.020	0.303	Pooled samples from 18 guinea pigs	15:1
DOG (Gall Bladder Bile)	1.521	0.142	2.850	Mean value from 8 normal dogs	20.3:1
DOG (Hepatic Bile)	0.316	0.018	0.328	Mean value from 3 dogs with chronic biliary fistulas	18.1:1

On the basis of our studies it does not appear that the hydrogen ion concentration of the bile has any prime significance in the mechanism whereby cholesterol is held in solution. In the in vitro experiments, the trend, if any, was for somewhat greater solution at an acid pH but the difference between the rates of solution in the acid and alkaline bile cannot be considered significant in view of the statistical analyses.

The quantitative analyses of human, dog, guinea pig, and ox bile demonstrate quite definitely that there are variations in the relative proportions of fatty acids to the non-saponifiable material of the bile which must be considered significant. A comparison of these figures offers a much more plausible explanation for the differences in stone solvent properties of the bile of various animals than that revealed by a study of hydrogen ion concentration.

CONCLUSIONS

1. No statistically significant difference was obtained in the relative solvent action of acid and alkaline bile from the ox, dog, and man on human gall stones of the mixed cholesterol variety.

2. Comparison of quantitative chemical analyses of human, dog, ox, and guinea pig bile shows that there are distinct differences in the relative concentration of the fatty acid to the non-saponifiable (cholesterol) fraction of the bile. We believe these variations to account for the difference in the solvent action of the bile of various animals rather than being due to variations in hydrogen ion concentration.

Is Uremia an Allergic Manifestation?

By

S. KENNETH ROBINSON, M.D.*

CHICAGO, ILLINOIS

MEDICAL science, the same as the physical sciences, has arrived at a stage when much of its hitherto accepted knowledge must be reevaluated and rewritten. Due to the large number of investigators in medicine and the ancillary sciences, medical knowledge has increased very rapidly in recent years. This has created an unusual problem, in that the lag in its application bids well to defeat the benefits from these new discoveries. Attention must be given to methods that will disseminate our new knowledge. Since the work of the Argentinian physiologist Houssay, the older conception that the pancreas regulates the glucose content of the blood must be modified to a great extent. In the same way the older belief that an elevation in the urea nitrogen of the blood depends on a structural lesion in the kidney is no longer tenable. There are many conditions that may produce uremia

*From the Department of Medicine, Michael Reese Hospital and Rush Medical College.

Submitted June 25, 1937.

in the presence of normal kidneys. It is the purpose of this paper to review some recent developments on the subject of uremia and to show that in many cases the uremia is best explained on a sensitivity or allergic basis.

The usual teaching associates uremia with a kidney lesion of sufficient magnitude to cause renal impairment. Such conditions as diffuse glomerulonephritis and vascular nephritis can produce sufficient renal impairment to cause uremia. Such are the "true uremias." Another important syndrome is "pseudouremia." Olivet (1) claims that in pseudouremia the kidney function is good and the urea N. is not much elevated. In his 6 cases the urea in the blood did not exceed 50 mg. per cent. He quotes Volhard who states that the important symptoms in pseudouremia are headache, disturbances of the senses chiefly the eye and ear, aphasia, acute psychic disturbances with mental aberrations that pass over quickly. This is very much similar to what is seen in hypertensive encephalopathy.

The uremia chosen for discussion in this paper centers around the gastro-intestinal tract and is termed by various writers, enterorenal syndrome (2), uremia syndrome (3), manque de sel, hepatorenal disease (4), gastric uremia (5), and extrarenal uremia (5, 6). The clinical picture is as follows: It is usually an acute process appearing rather abruptly and running a rapid downhill course. The syndrome begins with malaise, headache, muscular weakness, sleepiness and vomiting. This is followed by hiccup, restlessness, dry tongue, intestinal paresis, stupor and coma. In some, renal function is good; in others there is anuria. Cerebral symptoms and icterus may be present. A shock syndrome is usually associated as evidenced by tachycardia, dyspnea, cyanosis, fall in blood pressure, and subnormal temperature. Azotemia is usually present, being due, in most instances, to an increase in urea; but an increase in creatinine has been observed (7, 8). There is usually no early history of nephritis and the kidneys are normal on autopsy. However, a few investigators have reported kidney lesions in such cases but the reports are not uniform and on the whole poorly described and unconvincing. Cooper (7) and also McCance (8) who have devoted much time to this subject are both of the opinion that the uremia is functional and that renal excretion remains normal or is only slightly impaired.

Uremia or high blood urea has been reported in the following conditions: Gastro-intestinal intoxication (5), acidosis (9, 10, 11), alkalosis (12, 13), salt deficiency (14, 12), pancreatic insufficiency (15), hypohydration (6, 9), post-operatively (16), diabetic coma (17), hypertension (3), prostatic disease (18), after blood transfusion (19), with adrenal insufficiency (20, 21), with sterile abscess (22, 23), pleuritis (22, 23), anaphylaxis (24), pneumonia (22), coronary thrombosis (23), and with liver injury (23). Uremia has also been reported when magnesium or calcium is taken into the body over long periods (26, 27), and with disturbances of calcium metabolism as in hyperparathyroidism (28) and in myeloma. In such cases, as well as in prostatic disease, obstruction by mechanical means, by calculi, and nephrocalcinosis, may play a factor in the uremia but further work along this line is required. In most of the other conditions the uremia is probably extrarenal. Some of these will now be considered in greater detail.

GASTRO-INTESTINAL INTOXICATION

Under this grouping could be included the uremia with high intestinal obstruction, also uremia after intestinal allergy, food poisoning, ulcer, colitis, gastro-intestinal bleeding and the uremia with paralytic ileus.

High Intestinal Obstruction: That high intestinal obstruction is associated with an elevation of the N. P. N. which is made up for the most part of urea has been known for a long time. There are several other equally important principles that could also be mentioned:

1. If the intestinal contents above an obstruction is injected intravenously into another animal, "toxin injection," that animal will show almost the same clinical picture as the animal with the obstruction.
2. The symptoms in high intestinal obstruction are usually explained by two factors:
   A. Salt deficiency and hypohydration.
   B. Toxemia or shock.

If the symptoms come on quickly and death occurs in a few days, the latter factor is the more important. In recent years the toxic idea has been losing ground and the idea that death is due to shock and fluid loss has been gaining adherents. The idea, however, is not new and was expressed by Braun and Boruttau (29) as early as 1908.

3. If the bowel of an animal is obstructed by the use of clamps so there is no strangulation and the circulation is not cut off, the animal will survive a long time if water is supplied, dying finally from starvation. In this way the element of shock is eliminated.

The above ideas were taken from Cooper's review of the subject in 1928, he gives the symptoms in obstruction as follows:

1. Vomiting
2. Dehydration
3. Tremors and weakness of the hind legs
4. Weak and rapid pulse
5. Drop in the blood pressure
6. Coma and death.

The clinical pathology is as follows:

Blood:
1. Leucopenia
2. High non-protein nitrogen
3. High Co_2 combining power
4. Low chloride content.

Urine:
1. Scanty
2. Slight trace of albumin
3. The N. P. N. excretion is much increased
4. Low chloride excretion.

The clinical picture in obstruction is stressed because it resembles very closely the picture of extrarenal uremia and is also seen in several other conditions that appear to be related. More will be said about this later.

Foster and Hausler (30) tied off loops of bowel in animals and found an increase in the urea of the blood. They believed this was due to retention since all the animals dying from strangulation had anuria. Most investigators, however, believe that the uremia is due to excessive protein destruction and in spite of

good kidney function, the urea cannot be excreted quickly enough. What the true modus operandi is we cannot say at the present time. It appears that both factors, retention and urea overproduction may be operative.

Uremia with Gastro-Intestinal Lesions: The following case shows the development of extrarenal uremia in a patient with ulcer; the picture of shock is evident.

Case 1. A male 49 years of age was admitted to the Cook County Hospital with convulsions and coma. Two days ago he felt poorly and he had several attacks of convulsions. For 15 years he had had frequent attacks of stomach trouble with vomiting. The pulse was 96, respirations 34, temperature 100 and blood pressure 126 mm. of hg. systolic and 78 diastolic. The pupils were equal and reacted. The spinal fluid was clear and not under pressure. The urine showed 4 plus albumin, the phenol test was faintly positive and the urea N. 100 mg. per cent. There were convulsive movements of the extremities. The blood pressure fell to 70 over 60 and he died the next day in what was considered a uremic state. Autopsy was performed by Dr. R. H. Jaffe. The stomach was tremendously dilated and in the duodenum there was a constricting scar also an ulcer. The kidney changes were minimal.

Mallory (31) reported a case in a young girl of 22 with a history of hypertension. Her symptoms came on 10 minutes after eating a meal. She was operated and a gangrenous appendix removed; thirteen days later she died in uremia. Kiefer (32) reported a case where a high N. P. N. was observed in a patient with diarrhea. One month later an X-ray showed the characteristic picture of ulcerative colitis.

Gastro-Intestinal Bleeding: Sucic (33) cited several cases with an elevated urea N. following gastro-intestinal bleeding. He also showed that bleeding from other parts of the body such as hemoptysis and venesection are not followed by uremia. He also showed that this was not due to blood digestion and since none of his cases showed nephritis, renal insufficiency could not be accepted as a cause for the elevated urea. Two of his cases follow:

Case 2. The patient had a duodenal ulcer, the urea N. was 64 mg. per cent. Ten days later there was melena and the urea rose to 92 mg. per cent and the blood chloride was 426.

Case 3. This patient had ulcers in the stomach and duodenum. There was hematemesis and the urea was found to be 120 mg. per cent. After transfusion it dropped to 84, the patient recovered.

Christiansen (34) does not believe that patients with bleeding peptic ulcer actually die from loss of blood; he suggests uremia as the cause of death in such patients.

Meyler (6) has reported similar cases. He advances the idea that all extrarenal uremias are in reality "production uremias" due to the great destruction of protein and the kidneys cannot excrete the excess nitrogen. It is well to mention at this time, that gastro-intestinal bleeding occurs for the most part with ulcer and colitis. We do not know the cause for these conditions at the present time but it is of interest that the literature contains many references to their allergic nature. Kern (35), Gay (36), Clarke (37) and Ryss, et al (38) claim that peptic ulcer is allergic in nature; whereas Rowe (39), Duke (40), Vaughn (41), Bisset (42), Hollander (43), Beecher (44) and Strumpel (45) claim the same for colitis. Later, evidence will be presented to show that "extrarenal uremia" occurring in such patients is probably best explained as a "hypersensitivity" or "allergy." It might be further added that the intestinal bleeding and uremia seen by Sucic and Meyler are also seen in anaphylactic shock.

ACIDOSIS, ALKALOSIS AND HYPOHYDRATION

The association of uremia and acidosis is discussed by Andrews (10, 11), also Fantus (9). Andrews explains the anuria in such cases by the tendency on the part of the tissues to fix water in acid medium resulting in hypohydration. He produced a uremia in animals in the presence of normal kidneys. Salt infusions aggravated the condition. It is possible that acidosis is the dominant factor in the uremia seen with diabetic coma, it may also be a factor in pancreatitis or pancreatic insufficiency.

Uremia can also occur with alkalosis. Hurst (13) states: "I have seen some patients who were thought to be dying from uremia, but who were really suffering from alkalosis and who were saved by discontinuing alkalies." The following cases taken from Cooke (12) are instructive:

Case 4. A male 46 years of age was put on a diet and alkalies for 12 days. He developed malaise and pains all over his body. The urine showed albumin and casts. The urea N. was 173 mg. per cent. The alkalies were stopped and after eight days, the urea N. had dropped to 28 mg.

Case 5. Another patient had taken sodium bicarbonate for 8 years. One day he developed intense vomiting, irritability, headache, and tetany. The plasma carbonate was 97, the N. P. N. 90 and urea N. 71 mg. per cent. On ammonium chloride therapy, these same values dropped to 67, 43, and 17 respectively.

Comment: In the first case, it appears as though there was a hypersensitivity to the alkali powder. In the second case, the evidence is not nearly so clear, and we could ask why a man should suddenly become sick from a powder that he had been taking with comfort for 8 years? In reading over the cases cited in the literature as due to alkalosis many are found to be similar to the last case and some authors admit that some factor exclusive of alkalosis must play a part. Cooke states: "A patient who has once had an attack of uncompensated alkalosis always shows himself intolerant to alkalies in the future." He also stresses the resemblance between the blood picture in alkalosis and excessive vomiting. The latter symptom is an early one in anaphylactic shock and it seems that much of the evidence points to the uremia in alkalosis as a manifestation of sensitivity to alkalies.

Hypohydration as a cause of uremia is widely accepted. A uremia has even been produced in animals by rapid diuresis. In hypohydration the uremia is explained by some writers (6) as resulting from excessive protein destruction, being further aggravated by anuria which is frequently seen in such cases. The fact that certain forms of uremia may be corrected by the administration of water only, speaks for the importance of water in nitrogen metabolism or in its elimination.

SALT DEFICIENCY OR "MANQUE DE SEL"

The uremia due to salt deficiency and the growing importance of sodium in disease generally, has been extensively discussed by Blum (46), Koranyi, Graber, Haden and Orr (14), Mellinghoff (47), Keller (48),

McCance (8), Harrop (20), Siedeck and ZukerKandl (49) and others. A review of this important subject cannot be undertaken at the present time but reference may be made to some of the above publications. The importance of sodium chloride in uremia and in nitrogen metabolism is very incompletely understood at the present time. In the first place, it is very difficult to obtain a pure sodium chloride deficiency because in most instances it is complicated by water loss, alkalosis, and usually some other illness. To produce a hypochloremia in normal persons is a difficult thing as was shown by the work of McCance. Every one interested in this subject should read his Goulstonian lectures (6). McCance made human subjects salt deficient by the use of a salt free diet and the use of a daily sweating chamber. This produced anorexia, thirst, cramps, and anginal like pains on exertion, but all subjects were able to continue their occupations. They also showed hemoconcentration, a rise in the urea N., a drop in the plasma chloride and plasma sodium and a negative nitrogen balance. One subject failed to show a rise in the urea N., it was also very difficult to make her salt deficient. We must accept from this work that salt deficiency uncomplicated by water loss is associated with a rise in the urea N. However, under clinical conditions an uncomplicated hypochloremia is probably a rarity. Certainly a parallel between the hypochloremia and the elevation in the urea N. cannot be established in such cases. Kerpel-Fronius and Butler (50) could find very little parallism between these. They also observed that the nitrogen retention could be removed by water without salt. Kline (51) reports a case of Addison's disease where salt deprivation caused the plasma sodium to drop to 223 mg. per cent but the rise in N. P. N. was only 12.8 mg. per cent. In another case evidently not Addison's disease after 7 days of strict salt deprivation there was very little if any change in either the plasma sodium or N. P. N. Contrast with Blum's case (v.i.). However many investigators hold that the uremia is due to salt deficiency. Cooper quotes Haden and Orr who using dogs with simple high obstruction prolonged life with salt solution and as long as they kept the blood chlorides at normal level the other blood changes did not occur. It is well to remember, however, that dogs with an obstruction which is produced by clamps so that no injury to the circulation occurs, may not develop the syndrome at all but will live for weeks, dying in the end from starvation, as long as the water balance is maintained. It might also be said that the drop in the azotemia seen in some cases after salt infusions may be due to the correction of the anuria by overcoming renal spasm as was shown by Takeda (53).

One reason why confusion exists regarding the importance of reduced chlorides in uremia, is that uremia may exist with different conditions that vary as to their pathogenesis. This is well borne out in the case of high intestinal obstruction where there are at least 2 factors involved, and either one may of itself be a cause of uremia, these are:

1. Toxemia or shock.
2. Dehydration and salt deficiency.

If death occurs early it is usually due to shock, if the patient survives for a longer time the factor of dehydration and salt loss may enter because of persistent vomiting. Foster and Hausler (54), also Gatch, Trusler and Ayers (55) showed that water and salt were of no benefit in the treatment of strangulation where toxemia (shock) has the upper hand. However, in dehydration it may be of distinct value.

PANCREATIC INSUFFICIENCY

The loss of pancreatic juices may produce uremia as was shown by Walters and Bollman (56) and confirmed by Bolton (57). By experiments on dogs, they showed that continued loss of pancreatic juice through a duodenal fistula resulted in uremia and death in 7 days. There was no change in the blood chlorides or the Co_2 combining power. Life was not saved by salt.

How pancreatic insufficiency is related to uremia is not known. However, Oelgoetz et al (58) claim that pancreatic insufficiency may cause allergy to foods. They state that normally sufficient pancreatic juice is secreted to combine with all the food eaten and so acts as a buffer. Food hypersensitivity is caused by "free food" free of pancreatic enzymes. Another explanation for this type of uremia is the one suggested by McCance. He points out that pancreatic juice is very rich in bicarbonate and its continued loss may result in acidosis.

BLOOD TRANSFUSION

The uremia following blood transfusion has been observed by several investigators. Bordley (19) reported 3 cases and collected 14 from the literature. De Gowin and Baldridge (59) reported 2 cases and point out the dangers of hemolysis even though the blood be compatible from the standpoint of agglutination. Both patients developed anuria followed by an elevated blood urea and death. The blood chlorides were normal in both instances 555 and 600 mg. and the authors also ruled out acidosis as the cause. They quote Mason and Mann who have shown that the intravenous injection of hemoglobin has a specific vasoconstriction effect on the kidney which can be relieved by the transfusion of compatible blood. The latter point was also shown by Hesse and Filatov (60) and is very important in therapy. However, Sellards and Minot have shown that hemoglobin itself may not produce anatomic or functional changes in the kidneys. In Bordley's cases the transfusion was followed by a febrile reaction with hemoglobinuria and oliguria. This was followed by an interval of symptomatic improvement, after which there was agitation, drowsiness and uremia. The appearance of the symptoms in 2 phases an early and a late, should be noted. This will be referred to later.

Several writers claim that the anuria in hemolytic shock is due to the blocking of the renal tubules with hemoglobin crystals. Such a belief is unlikely since it has been shown that hemoglobin itself may be harmless to the kidneys (v. s.). The clinical picture is also against such an interpretation because oliguria comes on suddenly, and with recovery there is a sudden diuresis. Wesselkin also Iljin claim that hemolytic shock resembles histamine shock and have demonstrated by kidney measurements that renal spasm is part of the acute phase of such shock (v.i.). Hypochloremia can be ruled out as the cause because in several cases the chloride values were normal (v.s.) and in uremia with hypochloremia there is usually diuresis. De Gowin and Baldridge claim to have ruled out acidosis also. There remains nothing but sensitivity to explain this uremia and the whole clinical

picture fits it quite well. The weakness, choking, dyspnea, continuous vomiting and coma is the picture of anaphylactic shock.

POST OPERATIVE UREMIA

The uremia that occurs post operatively has been investigated by the French physicians. Some of their ideas may be summed up as follows: Patients lose weight and feel weak after an operation, this should leave after 24 hours, if it persists there is danger of paralytic ileus. They think that this is in some way associated with nitrogen and salt metabolism and their reasoning is as follows:

1. After every operation there is an increase of urea in the blood and an increase of nitrogen in the urine which is due to the destruction of protein. At the same time there is a reduction in chlorides and in the red cell count.
2. There is a decrease of salt elimination in the urine.
3. Not only does the urea in the plasma increase but also the "azote residual" (the total non urea fraction of the N. P. N.?).
4. Sodium chloride has a neutralizing action for the toxic protein products of the wound. In the treatment of several post operative cases the N. P. N. was reduced by the use of 500 c.c. of 4 per cent sodium chloride.

The following case is one of post operative uremia reported by Gabriel and Lloyd Davies (61):

Case 6. A 55 year old male was diagnosed cancer of the rectum. The heart showed no abnormality, the blood pressure was 175 mm. of Hg. systolic and 125 diastolic. The blood urea was 67 mg. per cent. Colostomy was done under spinal anesthesia. 80 hours post operatively he began to vomit, there was dull abdominal pain, pulse 106, this was followed by hiccup. The abdomen was silent and there was distension. Continuous I. V. normal saline in 5 per cent glucose was given 10 ounces per hour, for 7 hours. Twenty-two hours after onset the pulse was 130 and the blood pressure 160 mm. Hg. systolic and 120 diastolic. The pulse gradually increased and the patient died in 48 hours. The urinary chlorides were absent despite the infusions of chlorides. The blood urea rose steadily suggesting a uremia, however, the Van Slyke clearance tests showed that the kidney function was unimpaired and urine with a very high urea concentration continued to be excreted.

Autopsy findings: The stomach and small bowel were distended to within 2 feet of the ileocecal valve. At this point the distention gradually faded and the small gut distal to this point and the colon were collapsed. No peritonitis and no adhesions were present in any part of the abdomen. There was no abnormality in any of the other organs.

Comment: In this case the uremia supervened with the kidneys functioning well. Salt infusions were without effect. The vomiting, hiccup and paralytic ileus are suggestive of the extrarenal uremia syndrome. Distension of the small bowel leaving the colon unaffected is characteristic of paralytic ileus. The rapid pulse is suggestive of shock. Large amounts of urea were being produced or urea was being reabsorbed. In this case, we are probably dealing with a true "production uremia."

UREMIA WITH DIABETIC COMA

Lyall and Anderson (62) cite 19 cases of diabetic coma with elevated urea N. They estimate that as high as 50 per cent of patients with diabetic coma also have an elevated urea N. Acidosis as a contributing factor must be considered. They cite this instance:

Case 7. In this patient with diabetic coma, there was a period of anuria lasting 4 days, during which time the urea rose to 230 mg. per cent. The plasma chloride was 580 mg. per cent.

McCance believes that this uremia does not depend on an organic change in the kidney. He states: "One must conclude that the abnormality is a temporary one of function only and not a permanent one of structure." Again in discussing salt deficiency, he says: "If the patient recovers from the intestinal obstruction or diabetic coma renal sequelae are never observed."

McCance believes that the blood picture in diabetes and in diabetic coma is in keeping with a salt deficiency. He quotes Haldane and Denny et al, who demonstrated that in severe experimental acidosis there is at first a large loss of fixed base, mostly sodium. There is also an increase in plasma proteins and hemoconcentration in comatose patients. He admits, however, that the latter can be caused by hypohydration, and it is well known that this also occurs in shock.

Lyall and Anderson quote Blum in the following case which shows a relation to salt deprivation:

Case 8. The blood sugar was 355, the alkali reserve 16 and the urea 55 mg. per cent. The patient improved and the urea fell to 45 mg. while the urine contained albumin and casts. Upon a chlorine free diet the urea rose to 480 mg. in six days while diuresis was good and the urine contained only a trace of albumin and casts. Upon giving salt by mouth the blood urea returned to normal.

Comment: Again we have a case of uremia with good diuresis which appears to be another instance of "production uremia." The relation of the azotemia to salt deprivation is most striking. This case should be compared with the work of McCance (v.s.) it is obvious that some persons are much more sensitive to salt deprivation than others.

The symptoms produced on the withdrawal of certain substances that the body has become accustomed to resemble very closely an anaphylactoid reaction. Ormislensky (63) claims that the withdrawal symptoms in opium addicts are similar to anaphylaxis and considers the reaction an allergic one. This raises a very interesting point but at the present time we can do little more than speculate about it.

Steinberg reported 2 cases of azotemia following coronary occlusion with a rise in the N. P. N. and death. At autopsy the kidneys were found to be normal in both cases. Mazer reported 3 cases of azotemia with tuberculosis of the adrenals; at autopsy, the kidneys were normal.

The uremia seen with adrenalectomy is probably a functional one, since renal function may often be restored by the use of cortin. There is evidence that the renal insufficiency is secondary to hypochloremia. The adrenal cortex contains a hormone which controls the kidney threshold for sodium and in its absence a sodium deficiency is manifest (64, 65). The use of sodium chloride in the treatment of experimental and clinical adrenal disease has been reported as successful in some cases (66) and unsuccessful in others. It is also worthy of note regarding the adrenals, that Dale was able to show that adrenalectomy enhanced

the toxic action of histamine and that the use of eucortone was found of therapeutic value in the "shock syndrome" following burns (68) (v.i.). Sweet (69) also Ellis found that dogs after suprarenalectomy died with symptoms very much similar to "toxin injection" and were able to recover a similar toxin from the intestinal tracts of such animals. Stewart and Rogoff described the following syndrome in adrenalectomized dogs:

1. Vomiting
2. Staggering
3. Tremor
4. Collapse
5. Weak pulse
6. Low blood pressure.

The blood showed:

1. Leucopenia
2. High N. P. N.
3. Rise in creatinine
4. Fall in chlorides.

The organs showed at autopsy:

1. Congestion of the Lungs
2. Congestion and hemorrhage in the G. I. tract.

Later it will be shown that the symptoms of food poisoning also resemble this syndrome very closely. Wilmer and Miller (70) were impressed by the similarity between adrenal insufficiency and allergic manifestations and injected adrenal cortical hormone in certain select cases of allergy. Some of these patients jority, there was a definite improvement in general health. Wyman (71) compared adrenal insufficiency to anaphylactic shock and histamine poisoning. Swingle (72) compared it to traumatic shock. Harrop (20) injected intraperitoneal glucose into intact dogs thereby causing a reduced plasma sodium and was able to produce the clinical picture of adrenalectomy.

THE RELATION OF EXTRARENAL UREMIA TO HISTAMINE SHOCK AND SEVERE BURNS

It must by now be apparent to the reader that a shock syndrome is a frequent accompaniment of extrarenal uremia and it is the shock and not the elevated urea that accounts for the severe collapse and the fatal outcome. An increased amount of urea in the blood is not incompatible with life. In the elasmobranch fishes it may reach one per cent. On the other hand the uremia syndrome may exist with a normal blood urea; Beaumont and Dodds, quoted by Andrews, have reported 4 such cases. The shock is probably the result of histamine release. Death in such cases may be due to fluid loss as the result of capillary atony as was shown by Braun and Boruttau (29) also Blalock (23). The collapse, fall in blood pressure and hemoconcentration speak for loss of extracellular fluids.

Clinically the picture of extrarenal uremia shows a close resemblance to, and may occur with the following conditions. In all of these conditions the shock syndrome is present and many workers have stressed the similarity to histamine poisoning (v.i.).

1. Severe burns
2. Food poisoning
3. Allergic manifestations
4. Anaphylaxis
5. Acute pancreatitis
6. Bilateral suprarenalectomy
7. Obstruction with strangulation of the bowel or mesentery
8. Hemolytic shock, etc.

Eppinger et al (74) described a syndrome after the ingestion of spoiled meat with the following symptoms:

1. Vomiting
2. Collapse
3. Cold sweats
4. Signs of peritonitis
5. Hemoconcentration
6. Leucopenia
7. Albuminuria and cylinduria.

The pathologic picture of the internal organs was as follows:

1. The stomach mucosa was dark and covered with erosions and ulcerations
2. The duodenum was similar and the picture was intense in the colon
3. The liver showed the picture of "tissue albuminuria."

They noted a relation between food poisoning and histamine poisoning. They isolated an "allylamine" product from spoiled meat and were able to produce a similar picture in dogs by injecting this substance. Moon (75) claims that the pathologic picture in severe burns is almost identical to those found in shock. He claims that histamine is released by the burning of the skin and may be responsible for the shock.

The similarity between anaphylactic shock and histamine shock has been stressed by Dale and Laidlow (76), Abel and Kubata (77) and Dragstedt and Mead (78). Loeper et al (79) and also Unger et al (80) were able to produce gastro-intestinal hemorrhage with histamine. Similarly Gregoire (81) observed hemorrhagic pancreatitis and intestinal infarcts when anaphylactic shock was produced in animals. Watanabe (82) also Watanabe and Hosoya (83) demonstrated a marked reduction in the histimine content of the various tissues after anaphylactic shock. Tinel et al (84) demonstrated a well marked increase in the gastric juice in dogs with anaphylactic shock and attributed the shock to histamine release. Bartosch, Feldberg and Nagel (85) have shown that a histamine-like substance is liberated in the perfusate when isolated lungs are rendered anaphylactic by adding the antigen to the perfusion fluid. Several workers including Dzinich (86, 87) going on the theory that allergy is a sensitivity to histamine, desensitized allergic patients to histamine with very encouraging results. The Russian scientists have busied themselves with this phase of the subject in recent years. Wesselkin et al (88) claim that hemolytic shock resembles very closely histamine shock. They also claim to have substantiated the work of Hesse and Filatov in that renal spasm is part of the acute stage of shock from blood transfusion. Iljin (89) was able to demonstrate not only renal spasm as the result of hemolytic shock but azotemia as well.

It is probable that histamine release is the common denominator for a large number of apparently dissimilar conditions in which the shock syndrome is outstanding. A few more instances will be given. Stone (90) also Gerard (91) showed that the action of toxin taken from the gut above an obstruction and injected intravenously into another animal was almost identical

with histamine shock. Ellis (92) showed that the injection of a toxin similarly obtained into dogs with duodenal fistulae, renders the duodenal contents toxic to another animal almost immediately. This probably speaks for the release of a histamine like substance by the duodenal mucosa. Schloss (93) was able to isolate a histamine like substance from the intestinal contents of infants dying from obstruction. At this point it is well to again recall to the reader that all of these conditions in which histamine release appears to be the modus operandi also show an elevated blood urea; the one exception being food poisoning. This condition is however similar in all other respects, and an elevated blood urea will undoubtedly be revealed when more cases have been studied. The symptoms of food poisoning are similar to intestinal allergy and in several such cases there is an elevated urea N. (v. i.). One hears it frequently stated that the intestinal ulcerations seen in uremia are produced by the urea which is being excreted through the intestine, but from what has gone before it is apparent that these two conditions are both secondary to another underlying condition probably histamine release.

ALLERGY, UREMIA, AND GLOMERULONEPHRITIS

In the following instances gastro-intestinal symptoms and uremia occurred under circumstances that suggest an allergic basis. The first two cases suggest some form of intestinal or food allergy.

Case 9. A male 66 years of age developed acute abdominal pain after eating canned apples that he found on the city dump. This was followed by vomiting the next day, which continued for 4 or 5 days during which time there were no bowel movements. The pulse was 112 and the white count 6,400. The abdomen was quiet with rigidity, pain and tenderness. The blood pressure was 190 mm. of Hg. systolic and 118 diastolic, the Widal test as well as the urine were negative. After a few days, he had several normal bowel movements and he improved. Ten days after admission he developed pain in the abdomen again and some distension with rigidity. The urine now showed a specific gravity of 1008, contained a large amount of albumin with numerous red and white blood cells and granular casts. A few days later he became dyspneic, irrational and weak; his pulse became feeble, his temperature subnormal and the blood N. P. N. was 120 mg. per cent. He died in uremia.

Comment: The symptoms in this case were closely related to food taking and started with vomiting followed by ileus. The white count was rather low. This picture fits in quite well with a sensitivity or allergy. A cyclic response with an immediate and late reaction is typical in allergic conditions (v.i.). It is possible that the terminal state was an acute glomerulonephritis, the findings in the urine and the uremia would speak for it. The late time interval would put it in the period of antibody building—a close parallel to post scarlatinal nephritis. Also in hemolytic shock an early and late reaction is quite typical (v.s.). Barnes has shown that the same holds true for the shock syndrome following burns.

The next case also demonstrates an acute uremia under circumstances suggestive of food allergy:

Case 10. A middle aged man was brought to the hospital because of vomiting. His symptoms started after a party when he ate heavily of foods that he ordinarily was not accustomed to. The vomiting was followed by anuria with severe azotemia with very high values both for urea and creatinine. He died shortly afterward.

Comment: In this case the first phase of the reaction was so severe that the patient died in it. The patient related his illness to the meal that he had eaten and food allergy is suggested. The clinical picture resembles anaphylactic or hemolytic shock very closely.

The next case was reported by Motley (94) as periarteritis nodosa:

Case 11. A male 31 years of age who had suffered with asthma for 5 months began to notice fever, abdominal pain and bloody diarrhea. A biopsy of a piece of skin showed the typical picture of periarteritis nodosa. There was an eosinophilia of 87 per cent and the blood nitrogen reached 100 mg. per cent.

Comment: The allergic nature of the azotemia in this case is strongly suggested by the history of asthma and the eosinophilia. That periarteritis nodosa is an allergic reaction is believed by Rössle, Jaffe, and many others.

In another case where the patient was sensitive to wheat, a coincident rise of the blood nitrogen and a marked rise in the eosinophile count was observed. Hisanobu (95) has demonstrated experimentally that a rise in the urea nitrogen is associated with anaphylactic shock.

The allergic nature of acute glomerulonephritis was suggested by Schick as early as 1907. He observed that scarlatinal nephritis appeared during the period of antibody building and considered it an allergic reaction. Recently, experimental nephritis was produced by Masugi (96, 97, 98) with the use of allergins and confirmed by Arnott et al (99). The work of King and Finner (100) is also along the same line.

THE ROLE OF THE LIVER IN UREMIA

The frequent association of liver injury and uremia has been referred to in the literature from time to time. Faltitscheck and Hess (101) state that liver injury causes a disturbance of water exchange and that in acute atrophy of the liver a typical symptom is oliguria and anuria. They assume that the liver influences the water economy by a hormone action on the kidney. Boyce and McFetridge (102) in discussing a post operative liver-kidney syndrome believe that in liver injury the toxins cannot be detoxified and an extra load is thrown on the kidneys which soon break down and a lethal toxemia results. Hammerschlag claims very good results with liver injections in cases of uremia. He has divided the cases that benefit from such therapy into 5 groups, which makes apparent the association of liver injury and azotemia. They are as follows:

Group 1. Liver disease, jaundice, diabetes, increased N. P. N. and coma.

Group 2. Gastric tetany with duodenal ulcer, hypochloremia and uremia.

Group 3. Acute gastro enteritis, coma with no uremia or hypochloremia.

Group 4. Gastro enteritis, jaundice, stupor, uremia with normal chloremia.

Group 5. Empyema of the gall bladder with coma.

Eppinger et al claim that gall bladder edema is seen in uremia, eclampsia, severe burns and in hypersensitivity.

Nonnenbruch (103) claims that liver disease is re-

sponsible for a certain type of nitrogen retention which may be recognized by a partition of the nitrogen bodies in the blood. He claims there are 3 groups of nitrogen retention:

1. Increased urea and a normal non urea "rest nitrogen." This is seen in decreased concentrating ability of the kidney for urea, also in renal insufficiency, in extrarenal oliguria and in circulatory illnesses with water retention.

2. This group is characterized by a decrease in the urea and a rise in the non urea "rest nitrogen." It is not an expression of an excretory disturbance but a disturbance of the intermediate protein metabolism and is found in liver disease.

3. The second group may go over into severe renal insufficiency in which case the urea as well as the non urea "rest nitrogen" are elevated.

In the last year I have seen a case of liver necrosis, sepsis, with high values for both urea and creatinine, but with normal kidneys except for a few abscesses. Lichtman and Shoval (4) state that there is no evidence for the existence of a specific relation between the disturbance in the liver and renal manifestations and advise the term "hepatorenal" be dropped. They also state: "Similar renal changes and renal functional disorders have been noted in ileus, intestinal intoxication of infants, and diabetic acidosis. The primary factor is accepted to be extra-renal." Sutton (104) in discussing the "post operative high temperature liver death syndrome," states that the clinical picture resembles that seen in burns and in intestinal obstruction and that liver necrosis is observed in all of these conditions.

DISCUSSION

A critical review of the uremia cases cited in this paper reveals beyond very much doubt, that uremia cannot always be explained by a structural lesion in the kidneys. In addition, such factors as hypochloremia, acidosis, alkalosis, etc., can frequently be excluded as the cause. It is therefore proposed that there is a form of uremia which is of the nature of a "hypersensitivity" or "allergy," and that histamine release is in some peculiar way associated as the modus operandi. That such cases of uremia may rest on an antigen-antibody reaction is also a possibility. It has been shown quite definitely that histamine release depends on an antigen-antibody reaction by the work of Tinel et al (84) and Bartosch et al (85). In anaphylaxis, the resulting shock is also most probably due to histamine release; and according to Dale, anaphylactic shock is an antigen-antibody reaction. However, many allergists especially in this country do not believe that the antigen-antibody reaction is the "sine qua non" for allergy. For want of space this subject will not be pursued any further.

Exclusive of allergic reactions, there are several other possibilities for histamine release:

1. Trauma to the tissues might release the histamine contained in them as:

A. In burns it may be released from the skin.

B. Traumatic shock may be on the same basis.

2. Loeper et al (79) think that histamine may be released in protein metabolism.

3. Saylor and Wright (105) have demonstrated in a patient with urticaria that cold applications to the skin would produce the urticaria and an increased gastric acidity which they attributed to histamine release.

The cyclic type of reaction is not new in allergic thought, indeed it adds some weight to the belief that in uremia we are dealing with a type of allergy. In serum shock and serum sickness, we have examples of the early and late reactions to injections of horse serum. The cyclic reaction after blood transfusion has been well described by Bordley. The first phase is featured by hemoglobinuria and oliguria, the final phase by anuria, uremia and death. Recently Waldbott (106) has drawn another parallel in early and late asthma. He found that in infants who had died in very early asthma, the pathologic findings resembled more closely "shock" than they did chronic asthma. Tezner (107) claims that after intracutaneous skin injections, there are two skin reactions that differ as to time. There is an early one with wheal formation which goes away in an hour and a late one with tissue infiltration lasting several days.

SUMMARY

There are certain forms of uremia which depend on temporary functional changes of the kidneys, or to some cause entirely independent of the kidneys. For this type of uremia the term "extrarenal uremia" has been applied by some writers.

This uremia occurs under a wide variety of conditions. There is reason to believe that the uremia seen with hypochloremia, intestinal obstruction, acidosis, alkalosis, hypohydration, adrenal insufficiency, anaphylaxis, hemolytic shock, acute pancreatitis, etc., are all "extrarenal."

Shock is such a frequent accompaniment of the extrarenal uremia syndrome, that it is offered as the explanation for the sudden quick death observed in some of these patients.

Because of the close similarity between extrarenal uremia and anaphylactic shock and also because it occurs in situations suggestive of allergy, the idea is suggested that extrarenal uremia is a form of "hypersensitivity" or "allergy."

Histamine release or some related substance, should be considered as a possible modus operandi in many of the apparently dissimilar conditions exhibiting extrarenal uremia.

The evidence that extrarenal uremia rests on a hypersensitivity is not equally clear in all instances. In ileus, anaphylaxis, hemolytic shock, the hepatorenal syndrome and intestinal allergy we are probably dealing with a sensitivity; but in hypochloremia and adrenal insufficiency the evidence is not so clear because we cannot evaluate the factor of salt depletion at the present time. That salt poverty resulting from salt withdrawal can cause uremia in the presence of normal kidneys has been demonstrated experimentally; however, there is some evidence that the "withdrawal symptoms" in themselves are the manifestation of a sensitivity. In alkalosis, pancreatitis and intestinal intoxication, sensitivity or histamine release is suggested.

CONCLUSION

After reading this paper there are many questions that arise in one's mind which must remain unanswered. It is also apparent that the nature of uremia is exceedingly complex. Despite the fact that much space has been allotted to this subject, much

material had to be omitted and several important subjects had to be withheld or passed over with a sentence or two. Some of this material will be published in another article on treatment, but it is hoped that others will take up this important subject and discuss the many angles that remain. The importance of a review such as this lies in focusing attention on an important disease entity which at present is either overlooked or misunderstood. Undoubtedly, some of the theories developed herein will later be modified or found unsound but if discussion is stimulated, much will have been achieved. Despite the great contribution of Richard Bright to medical learning, nevertheless, it is true of him as of most outstanding personalities of the past in the field of science, their ideas and influence extend to a time when those ideas have become outworn. We have lived too long in the era of Bright; the light is seen in a different direction; and it is there that we must turn for the newer knowledge.

Observations on the Nature of Heartburn*

By

ANDREW M. BABEY, M.D.†

BROOKLYN, N. Y.

INTRODUCTORY REVIEW

OF the many symptoms of disorder along the gastro-enteric tract of which a great deal has been written and only little definitely known, heartburn certainly ranks high. It is commonly met with in disorders of the esophagus, stomach, duodenum, biliary tract and even of the large bowel. Frequently the only explanation to be found for its presence is a neurotic temperament.

Because its cause is still not clearly understood, a review of the more important literature may be helpful. One group of writers lay especial stress on presumed changes in the esophagus. In 1926, Jones and Richardson (12) distended the esophagus in 29 normal subjects with a balloon while watching with the fluoroscope. Nineteen of these people noticed a hot, burning sensation during distension of the lower third of the tube while the rest had only a sense of fullness or pressure. Distension of the middle or upper third of the esophagus caused a pressure sensation in twenty-five and burning in only four. Introduction into the lower third of the esophagus, through a tube, of small quantities of acid, alkali, cold water, gastric contents or barium suspension caused heartburn in two-thirds of those experimented upon. These workers also fluoroscoped their subjects as barium was given and found spasm at the level where the fluid had been introduced, with reverse peristalsis above. The spasm and reverse peristalsis persisted as long as did the heartburn. The conclusions were that heartburn is probably analogous to referred pain due to hunger contractions and is associated with a reflex disturbance of lower esophageal tone; or with abnormal peristalsis occasioned either by local disease or by functional or organic disease elsewhere in the body.

In 1931, Bloomfield and Polland (5) repeated this work with different results. They found that no matter at what point along the esophagus a balloon was placed, the majority of persons felt pain over the suprasternal notch or the lower sternum; that the sensations experienced were usually vague and widespread around a center, and that the site of pain bore no definite relation to the site of the stimulus. Only a few of the subjects complained of heartburn during the experiment. Bloomfield and Polland felt that this burning sensation might be due to spasm of the esophagus, and not necessarily to back flow of acid into the esophagus which occurs in many instances.

Bartlakowsky (4), who suffered with severe heartburn, was of the opinion that the presence of ectopic gastric tissue in the esophagus gave rise to heartburn. Basing his opinion on certain autopsy findings in children, he concluded that 70% of people have ectopic gastric glands chiefly in that part of the esophagus about the level of the thyroid gland. Kaufman, cited by Lewin (15), believed that the burning occurs because of an insufficient "slime" production by the esophagus which thus becomes more susceptible to irritation by gastric contents.

Barsony and Szemzo (2), studied thirteen patients after injections of barium suspension either with dilute hydrochloric acid or N/20 sodium hydroxide solution. They found that the hydrochloric acid would not cause burning in every case; that in two patients it actually caused the heartburn to disappear, and that sometimes the rapid injection of the dilute solution of sodium hydroxide gave rise to a burning more severe than that produced by the acid. They felt that esophageal tension with compression of the nerve endings in the wall played the chief part in the etiology of heartburn. From their experience and that of Schur, whom they cite as having allowed patients to *drink dilute hydrochloric acid without producing* heartburn, they doubted the importance of the acid factor in the production of this symptom.

Payne and Poulton (19), concluded that heartburn is associated with peristaltic movements of the esophagus and often with a rise in the mean pressure. In their opinion, heartburn is associated either with tonic contractions, or with alternating contractions and relaxations of the esophageal muscle. In their second paper (18) these investigators stated that esophageal pain or heartburn results from the stretching and deformity of sensory nerve endings in the wall of the tube. Hurst's (10) experiments in 1911 indicated earlier that distension was the important stimulus in the esophagus.

Bartels (3), in eighty-two post mortem studies of acute ulcerative esophagitis found varying degrees of inflammation which he felt probably explained the heartburn complained of by some of the patients before death. The lesions were probably terminal and due to the erosive action of gastric juice that was being vomited. That this is probably the explanation was shown by the work of Weiss and Mallory (23).

Hartmann's (9) solitary but very important case discounts the importance of the stomach and its acid juice in the production of heartburn. In 1921 he reported a case in which the stomach had been completely excised for a carcinomatous ulcer at the cardia. The jejunum was joined to the esophagus, yet the patient complained of heartburn. X-ray studies of the jejuno-esophageal juncture were negative on two occasions. Einhorn (8) doubted the influence of acid gastric juice in the causation of heartburn.

Most of the writers on the subject have been inclined to lay stress on a *combination of gastric and esophageal factors* (6). In 1884 Reichman (21) performed some important experiments which are now often forgotten. He tied small gelatin-coated sponges

*Work done at Guy's Hospital, London, under the direction of Sir Arthur Hurst.

†Bowen Scholar, New York Academy of Medicine, 1935-1936.

Submitted July 10, 1937.

on a string and allowed them to pass down into the lower esophagus where they were left until the patients experienced heartburn and on pulling them out he found that only those from persons who had complained of heartburn contained fluid that gave an acid reaction. Another factor, he thought, was the opening of the cardia. This was caused apparently by contraction of the stomach, and his belief was that the degree of this contraction determined whether or not a patient had simple heartburn or heartburn with acid regurgitation. The cardia opened, he believed, because of the contraction of the stomach and because of reflex action started by alcohol, fatty foods or sauces in the gastric contents.

Hurst in his early work discovered that burning similar to that in heartburn could be caused by ordinary alcohol. In 1929 he suspected that there were two different types of heartburn. One came with acute indigestion and probably arose from fermentation, with possibly the production of alcohol or organic acid. Patients with this type were relieved by vomiting but not so well by the taking of alkalis. The second type was found in chronic dyspepsia with hyperchlorhydria and he thought it was due to tension on the muscle coats of the stomach.

Lewin (15), Lukacs (16) and Hugo Schmidt (22), all looked on the gastric and esophageal factors as intimately related. Briefly, their idea was that irritating gastric juice is thrown up into the lower part of the esophagus by a contraction of the stomach associated with an opening of the cardia; that the esophageal mucosa is thereby irritated and that this irritation expresses itself in heartburn of varying degrees of intensity. Schmidt suggested, on the basis of this theory, a form of treatment in which the fluid intake is lowered so as to keep the gastric contents thick and heavy so that they cannot easily run upward.

Lukacs (16) and Kauders and Porges (13) were quite sure that heartburn never occurred where real anacidity was present. They explained away exceptions by assuming that in such cases the anacidity after a test breakfast was not genuine and that more acid would be formed in response to a mixed meal.

Lukacs (16) expected to find two factors in the etiology, one an irritant and the other a hypersensitiveness. Porges and Sternberg (20), concluded that heartburn is brought on by an abnormal gastric motility, or contraction, associated with pyloric spasm, the gastric contents thus being pushed up into and irritating the esophagus. Crohn (7) was of the same opinion.

Winkelstein (24) in 1935 described a hitherto unknown abnormality which he felt explained heartburn in his cases. Five patients were examined by esophagoscopy because of recent complaints localizing trouble in the esophagus. Three had duodenal ulcers and another had a gastric ulcer. In addition, there was evidence, confirmed by biopsy, of acute or chronic inflammation in the lower third of the esophagus. Winkelstein explained this by assuming regurgitation of acid and pepsin into the lower esophagus, and retention of these substances because of spasm of the cardia. He thought the patient might be predisposed to this reaction by an "ulcer constitution." He found no evidence of ectopic gastric glands.

In addition to the two theories noted above, namely the esophageal and the gastro-esophageal, there remains a consideration of the *neurotic* factor in heartburn. Many writers describe it as a very important feature and Lukacs (16) especially pointed out how frequently a sudden change in milieu or a happier domestic or business situation cleared up the trouble. Finally, Kofler (14), in 1928 cured several cases of heartburn by removing their *infected tonsils* and felt that their trouble was due either to absorption of toxic material with a resultant vagus neuritis or to direct injury by swallowed septic matter.

RESULTS OF EXPERIMENTS CARRIED OUT BY THE AUTHOR

In five persons complaining of heartburn and six with achalasia of the cardia (cardiospasm), the following procedures were carried out:

1. A history was taken.
2. Gastric analysis was made before and after the giving of a test meal.
3. The effect of fasting gastric juice was noted on the lower third of the esophagus.
4. The patient was given a meal which usually provoked heartburn.
5. This meal was aspirated as completely as possible and divided into three parts.

(a) One portion was injected into the patient's esophagus at various levels.

(b) A second portion was injected into the esophagus of a person without a tendency to heartburn.

(c) The remainder was submitted to fractional distillation to detect the presence of alcohol or organic acids.

6. There was injected into the lower esophagus small amounts of from 0.3 to 1% hydrochloric acid, acetic acid, lactic acid; sodium bicarbonate, also water and brandy.
7. Whenever possible the injections were made while the patient was being observed with the fluoroscope.
8. In cases of achalasia of the cardia, the esophagus was first washed and then injection was made of various acids, an alkali, and some brandy.

SUMMARY OF RESULTS

1. Two of the first five patients studied suffered from severe heartburn despite the presence of an achlorhydria.
2. Fasting gastric juice injected into the lower third of the esophagus caused burning in two cases.
3. Injection into the lower esophagus of a portion of the "provocative meal" produced no heartburn. Injection of this same material into the esophagus of normal persons caused slight burning in the throat of one.
4. Fractional distillation of the "provocative meal" showed no alcohol or organic acids were present.
5. Injection of acid and later alkali produced no burning in three cases. In one case the rapid injection under pressure of anything, even water or a saturated solution of sodium bicarbonate, produced intense burning. One patient complained of burning only when 6 c.c. of 1% hydrochloric acid, or 1% acetic acid was injected.
6. During fluoroscopic observation no evidence was obtained of any motor abnormality such as regurgitation of a thin barium mixture from the stomach into the esophagus. However, heartburn could not always be induced while the patients were thus being observed.

7. The injection of acid or alkali into the lower esophagus of six patients with achalasia of the cardia did not produce heartburn.

8. Brandy almost always produced burning when allowed to trickle over the lower esophagus.

CONCLUSIONS

1. Hydrochloric acid injected into the lower esophagus in strengths up to 1% did not regularly cause heartburn in patients with this complaint.

2. In one case in which it did, the *rapid* injection of water or a solution of sodium bicarbonate (under slight pressure) had the same effect. This suggested the possibility of a reverse motor disturbance set up by an irritating forceful injection, and was in harmony with Alvarez's (1) theory.

3. Neither alcohol nor fatty acid was found in the stomach contents of patients who suffered from heartburn even though the meal had just recently provoked heartburn.

4. Injection of this same "provocative meal" into the esophagus of a normal patient seldom produced any burning.

5. The type of esophagitis present in cases of achalasia of the cardia seldom favors the production of heartburn from injections of 0.3% hydrochloric, or acetic acid or dilute solutions of sodium bicarbonate.

6. Brandy almost always caused burning when it was allowed to trickle over the esophagus.

7. On the basis of this preliminary study, and the work of Alvarez, Jones and Richardson, and Payne and Poulton, it appears that in some cases a reversed or a spastic motor activity in the esophagus is associated with heartburn.

ACKNOWLEDGEMENT

I wish to express my gratitude to Sir Arthur Hurst for his valuable advice and helpful suggestions.

Editorials

EDITORIAL NOTE

The two papers in this issue by Drs. Verzár and Wilhelmj, Finegan and Hill, are the first to be published of a series solicited by the editors from directors of laboratories where work is being done of great interest to gastro-enterologists. It is to be hoped that each year these directors will send a brief resume of work done by them and their associates so that the readers of this Journal can keep closely in touch with what is being done on the firing line of research.

TEST MEALS AND METHODS OF GASTRIC ANALYSIS

THE study of the gastric secretory curve following administration of a test meal, once heralded as an important diagnostic procedure, is gradually falling into disrepute. Many clinicians believe that its only function is to show whether or not the stomach is capable of secreting acid and for this purpose histamine is gradually replacing the test meal. This change in attitude is in reality an expression of dissatisfaction with the methods and test meals commonly employed. A critical study of the usual methods reveals certain grave errors and points the way for improvements which may greatly increase the value of gastric analysis.

The commonly used clinical test meals (dry toast, bread, shredded wheat biscuit or arrow root cookies with water or weak tea) are unsatisfactory because of their low secretogogue content. This generally admitted deficiency has lead to the widespread use of *histamine*, the *alcohol test meal* and, especially in experimental work, the *ground meat and water test meal*. None of these test substances are entirely satisfactory as the following analysis will show.

Histamine is probably the most powerful stimulus for acid secretion known but this fact limits its field of usefulness, in that it commonly overpowers those regulatory mechanisms which normally lower gastric acidity. It is also said to stimulate only the acid and not the non-acid secretions of the stomach. For these reasons histamine should be used only to make sure that the stomach is quite unable to secrete acid; no other conclusions should be drawn from the test, and it should not be used when the investigator wishes to learn something of the *normal regulatory mechanisms*.

The *alcohol test meal* has no physiological justification and should be discontinued, since the response to it is probably a response to irritation of the mucosa. The *meat and water test meal* is theoretically ideal since it supplies commonly used secretaogogues in a normal manner, but due to the digestion of the meat and the use of phenolphthalein as an indicator in titration, the results are not only of doubtful value but probably are often grossly misleading. This can be shown in a striking manner by mixing finely ground meat with pepsin and hydrochloric acid until "free" acid is present and then titrating with N/10 sodium hydroxide, using phenolphthalein as an indicator. When this mixture is incubated at 37° C. it will be found that the titration values for "acid" increase rapidly and markedly and the so-called "free" acid disappears.

These changes are due to the liberation of protein digestion products which are amphoteric in nature and combine with NaOH as well as with acid. Hence, when this test meal is used, one is likely to titrate changes in the test meal, due to digestion, changes which may be large enough to overshadow those due to acid secretion by the stomach. This error has probably lead to much confusion in experimental work on animals.

Liebig's meat extract (Lemco brand) is a concentrated preparation of the secretogogues normally present in meat but it contains no protein. When a specially prepared 2 per cent solution is mixed with pepsin and hydrochloric acid and incubated at 37° C. the titration values (using brom-cresol purple as an indicator) remain unchanged. Liebig's extract thus possesses the advantages but not the disadvantages of meat. For this and other reasons it constitutes an ideal test meal.

A second grave error in the usual methods of gastric analysis arises through the failure of the laboratory worker to correct for the factor of dilution of the gastric secretions by the fluid of the test meal, originally pointed out by many continental workers, and later in this country by Gorham, (Jour. Am. Med. Assn. 1923, 81, 1738) and also through the failure to distinguish clearly between the acidity of the *gastric contents* and the acidity of the *gastric secretions* (Editorial, this Journal, Aug. 1937). These errors can be avoided by placing phenol red in the Liebig's extract test meal and determining the percentage of phenol red in each of the gastric samples withdrawn. The reduction in the percentage of phenol red enables one to calculate the volume of the secretions which have been mixed with each 100 cc. of the gastric contents.

Hollander has recently shown that the concentration of the acid secreted by the stomach remains constant (0.170 normal) regardless of the rate of secretion, and we have also shown that the concentration is unaltered by the degree of acidity of the gastric contents. Because of the constancy of the acid secretion one is able to separate the *total secretion* entering the stomach into two fractions, consisting of *the acid secretion* and the *non-acid secretions* and to study the changes in the amounts of each during the course of a fractional gastric analysis. In addition it is also possible to study the changes in the acidity of the total secretions entering the stomach.

A *third* error in the usual gastric analysis is the use of phenolphthalein as an indicator in the titration of total acid. In the presence of the organic material in the test meal phenolphthalein gives values which are very irregular and much too high when compared with the acid chloride in the gastric samples. This is apparently due to the fact that phenolphthalein combines with protein material. Hori (*Jap. Jour. Gastro-enterology*, 5, 13, 8, 1933), pointed out these errors and suggested the use of brom-thymol blue in place of phenolphthalein. We have found that titration with brom-cresol purple also gives figures in good agreement with the acid chloride values.

A *fourth* defect in the usual method of gastric analysis is the determination of the so-called "free" and "combined" acid. Both Martin (1934, 1, 330) and Hollander (1935, 2, 127) in this Journal, have criticized these nebulous concepts and suggested that the determinations be modified or discontinued. My associates and I have shown that sufficient information can be obtained from the measurement of the total acid alone and we have discontinued the determination of these doubtful entities.

In view of the above facts it appears that the value of gastric analysis could be greatly increased by introducing the following changes in technique: (1) The use of a suitable test meal such as that consisting of a specially prepared Liebig's extract solution. (2) Determination of the total secretions entering the stomach by adding phenol red to the test meal and determining the percentage of the original meal left in each gastric sample. (3) Titration of the total acid in the sample, using an indicator which is free from the errors inherent in the use of phenolphthalein. (4) The separation of the total secretions entering the stomach into the fluid of the acid secretion and the fluid of the non-acid secretions. (5) Determination of the acidity of the total fluid secretions entering the stomach. (6) Discarding the determination of what are known as "free" and "combined" acid fractions.

THE BACTERIAL FLORA OF THE GASTRO-INTESTINAL TRACT

ANY consideration of the bacterial population residing within the lumen of the alimentary tract should begin with the flora living on the lips. The junction zones where dry, stratified, squamous, epithelium joins with moistened mucous membranes are unusual bacteriological areas. The microbic inhabitants of such an area are different from those endogenous to the adjacent dry and moist surfaces. This is true for the lips, nares, anus, and external genitalia. This region of the lips has a very densely populated staphylococcus epidermic albus flora. These grow as very small, minute colonies, assume streptococci-like appearance on culture media. When the tip of the tongue moistens the lips there are many thousands of these cocci transferred to the oral cavity. The oral flora is seeded from the lips and the density of the oral flora is to a great extent dependent upon this habit of moistening the lips with the tongue. (Stuart, Knudson and Arnold, *Jour. of Dent. Research*, 15, No. 1:41, 1935).

The dorsum of the tongue supports a rich bacterial flora. Subcultures show active dissociation of this flora. Many types can be observed in smears that cannot be cultivated on any known media. Many pleomorphic forms can be grown for one generation only on artificial media. The dorsum of the tongue ranks next to mucosa of the colon in supporting a densely populated bacterial community.

The gingival margins of the gums allow a large number of bacteria to live on their surfaces. These are predominantly staphylococci in the healthy oral cavity.

The remaining surfaces within the oral cavity support a very scant bacterial flora, such as the cheeks, frenulum of tongue, etc., which are usually free of viable bacteria if the tongue is held stationary for ten minutes. These areas are seeded by the saliva due to lingual movement from the reservoirs of the lip and dorsum of the tongue. (Arnold and Stuart, *Amer. Jour. Digest. Dis. and Nutrit.*, II, No. 5:275, 1935).

Those areas supporting a densely populated endogenous flora also allow exogenous bacteria to survive longer than on other surfaces. Gulbrandsen and Keller (*Illinois Med. Jour.*, October, 1935), showed that tubercle bacilli remained viable on the lips for one hour and forty minutes. The epidemiology of enteric diseases can also be influenced by this long survival of exogenous bacteria on the lips and dorsum of the tongue.

Hood and Arnold (*Amer. Jour. Digest. Dis. and Nutrit.*, IV, No. 1:40, 1937), showed that exogenous bacteria in the oral cavity remained viable for two and a half hours, hence there was constant seeding of the stomach during this time by the swallowed saliva. The fate of the swallowed oral flora is dependent upon the acid-base equilibrium within the gastric lumen. So long as free hydrogen-ions are present within this cavity, few viable bacteria can be demonstrated. When the hydrogen-ion concentration is more alkaline than pH 3.0, the stomach becomes a reservoir for oral bacterial flora. The oral bacterial flora extends from the lips to the pylorus in subjects with an acid-deficient stomach. (Hood and Arnold, *Amer. Jour. Digest. Dis. and Nutrit.*, IV, No. 2:95, 1937).

The bacterial flora residing within the lumen of the duodenum and jejunum is dependent upon the physiological status of the stomach. This in turn is dependent upon the age of the individual and the diet. Arnold (*Jour. of Hygiene*, 29:82, 1929) concluded from animal experimental evidence that the flora of the upper half of the small intestine was dependent upon the acid-base equilibrium of the populum within this part of the alimentary tract. When there were a predominance of acid over alkaline reacting substances, then the flora was very scanty and consisted of only a few undifferentiated cocci, the so-called enterococci. When the contents were neutral or slightly alkaline, the bacterial flora was more complex and increased in density. Van der Ries (*Ergebn. d. inn. Med. u. Kinder.*, 27:77, 1925) observed a similar type of flora in the human under similar intro-intestinal acid-base balance conditions.

The reaction of the contents within the lumen of the duodenum is not the determining factor in the type or density of the bacterial flora residing within its lumen in so far as this may explain the bactericidal or growth inhibiting factors involved in this sparsely populated bacterial community. The mucosal functional activity seems to be the most important factor. If the gastric mucosal glandular action is normal, then the food ingested is saturated with acid radicals and becomes an acid buffered pabulum. When this passes into the duodenum the free acid is quickly neutralized, the combined acid is replaced by alkaline radicals more slowly. If, however, the material passed beyond the pylorus has not been fully saturated with hydrochloric acid, both physically and chemically, then the mucosal function of the upper intestinal tract does not react in the same manner as when the contents are fully and completely saturated with acid radicals. The control of the intra-intestinal bacterial flora of the duodenum and jejunum is dependent upon the mucosal activity of the lining of the alimentary tract from the gastric region downwards. When the contents of the duodenum and jejunum are found to range in the neighborhood of pH 5.0 to pH 6.5, then the bacterial flora only consist of a few (10 to 25) enterococci per cubic centimeter of contents. This indicates an excellent acidifying gastric mechanism. The gastric mucosal activity is inseparable from the duodenal mucosal function in respect to the control of the bacterial flora. The acid-base equilibrium of the contents of this part of the alimentary tract only indicates a balanced and a physiological function of the lining mucosa. The contents or extractable substances have little, if any, influence upon bacterial flora. Almost all common gastro-intestinal bacteria can grow *in vitro* in the environment of the normal intestinal contents. The determining factor is the physiological state of the mucous membrane lining the small intestine from the gastric region downwards.

The lower segments of the small intestine are usually considered along with this anatomical unit and have been thought to have, in general, the same physiological functions. The ileum is entirely different from the jejunum in respect to the bacterial flora residing within its lumen. There is a predominance of coliform types of flora. Many of these are slow lactose fermenters. There is some evidence of dissociation of bacteria within the lumen of the ileum. One should not forget the increase in lymphoid tissue beneath the mucosa and the accumulating evidence indicating an excretory function of this lower level of the small intestine.

Most of the information obtained upon the mechanism of the control of the bacterial flora within the lumen of the duodenum and jejunum has been based upon animal experiments. Anyone with experience realizes that these conclusions must be taken with some caution and reservation when applied directly to man.

The mechanism of control of the bacterial life residing in contact with the mucosa of the gastro-intestinal tract from the oral cavity to the lower level of the small intestine has been briefly reviewed. This summary was intended to stimuate gastro-enterologists to study these factors. The bacteriologist finds the alimentary tract a very complex and complicated environment for microbic life. The controlling mechanism of the gastric and small intestinal bacterial flora seems to be predominately of a biological nature. The intra-intestinal content has never been proven to contain the inhibiting or differentiating factors which act on the viable flora, endogenous and exogenous, to produce the microbic population usualy found within the lumen of this part of the alimentary tract. Extracts of the mucosa by various chemical processes have also failed to demonstrate a controlling factor, as a matter of fact such extracts stimulate growth of bacteria. Until we know more about these various factors controlling the composition and density of the bacterial population residing within the lumen of the stomach and small intestine, we might for purposes of convenience consider this a biological mechanism. The physiological process of hydrolysis of foods and absorption of the split products takes place in those parts of the small intestine which have about the same density of bacterial flora as the Sahara Desert has botanical flora.

Lloyd Arnold, Chicago, Ill.

Book Reviews

Les Abscès Du Foie. By P. Huard and J. Meyer-May. Paris, Masson et Cie., 1936. 390 pp., 98 figs., 65 French Francs.

THIS excellent exhaustive monograph on the liver abscesses is due to the observation of 174 cases at the school of medicine, Hanoi, French Indochine. 43 autopsies are reported. The content of the book is based not only upon the personal experience of the authors, but also upon an extensive knowledge of the international literature. The bibliography is excellent. The authors state that the multiplicity of the abscesses dominates the entire question, especially the therapy. It always should be tried to demonstrate everyone of the multiple abscesses. Therefore the importance of the radiologic diagnosis after injection of lipiodol is emphasized; because of the preponderance of multiple abscesses therapeutic puncture usually is not sufficient, and operation is to be preferred. The clinical part begins with extensive statistics. The chapter on etiology, and this perhaps is the most important contribution of the monograph, demonstrates that amebiasis, at least at Tonkin, plays but a small role as etiologic factor. In only seven cases amebiasis was found! In 27 cases another microorganism rather than ameba histolytica was found. The symptomatology is discussed thoroughly. The importance of systematic radiologic examination is emphasized; the use of artificial pneumoperitoneum is rejected, that of hepatography with thorium salts was not tried. X-ray examination using injection of lipiodol preceding operation or during operation is considered indispensable. The chapter on treatment is of special value because of the comparison of therapeutic procedures in various countries; one paragraph renders very well the situation in the United States following the epidemic of amebic dysentery; the experiences of the Mayo Clinic are quoted in detail. The medical treatment is discussed as far as amebic forms are concerned, especially the use of emetine although it is not considered as a specific drug; the effect of acetarsone, carbasone, etc., is mentioned, while yatren, vioform and the bismuth compounds are considered as valueless in amebic abscesses of the liver. The last chapter contains a detailed description of the operative procedures. The monograph can be highly recommended. It is astonishing that it was possible to write it under the special circumstances of a tropical colony.

Rudolf Schindler, Chicago, Ill.

The Avitaminoses. By Walter H. Eddy, Ph.D. and Gilbert Dalldorf, M.D.

THIS book is a sequel of the "Vitamin Manual" which the senior author published in 1923. Although the scope of this book includes both pathological and clinical discussions of the vitamin deficiency diseases, the authors state that they have planned to present a helpful manual rather than a complete treatise of the subject. In the opinion of the reviewer they have accomplished their purpose.

In Part I they discuss the nature and functions of vitamins, A, B, C, D, and E and devote chapters to the clinical, sub-clinical and anatomical manifestations of the several vitamin deficiencies. In addition there are well presented chapters discussing Beriberi and vitamin B; pellegra and vitamin G; scurvy and vitamin C; and rickets and vitamin D. Also there are chapters devoted to a discussion of vitamins in relation to resistance to infection, to morbid effects of complicated dietary experiments and to the relation between vitamins and blood regeneration.

In Part II there are three chapters devoted to discussion of the standard methods for bio-assay of the vitamins; various clinical tests for the estimation of vitamin C in the blood and other body fluids and a chapter devoted to the vitamin content of various foods.

The authors' index and subject index are satisfactorily complete and brought up to recent date.

Although there is much within the covers of this book that may be rather stiff reading and somewhat over the heads of casual readers, to those genuinely interested in this subject there will be found much of practical interest and importance.

Abstracts

DONOVAN, EDWARD J.

Congenital Hypertrophic Pyloric Stenosis in Infancy. J. A. M. A., Vol. 109, pp. 555-561, Aug. 21, 1937.

Congenital hypertrophic pyloric stenosis is a condition which comes on early in infancy, usually between the second and fifth week after birth. The first symptom is vomiting which may, but usually does not, start abruptly. The vomitus is at first small in amount, but increases gradually and does not contain bile. This is persistent and results in rapid dehydration and loss of weight.

When the stomach is partially full, peristaltic waves may be visible. In addition to this, a pyloric tumor usually is palpable. The author believes this tumor to be pathognomonic of the condition.

Preoperative preparation is the all-important factor in surgical treatment of these conditions. There is no need to hurry operation. If the baby is in bad condition, he should be given one or two transfusions by the Lindenmann method. In addition, he should be given from 100 to 400 c.c. of normal saline by hypodermoclysis. The operation of choice is the Fredet-Rammstedt. It can be done easily, rapidly, and will give a permanent result.

In a series of 243 cases, the author has had only one death, with none in the last 143 cases.

Francis D. Murphy, Milwaukee.

HORSLEY, J. SHELTON.

"Emergency Surgery of the Stomach and Duodenum." South. Med. Jour., 30:549-553, May, 1937.

In a consideration of emergency surgery of the stomach and duodenum one must bear in mind the mimicry of symptoms offered by non-surgical conditions such as coronary thrombosis and pulmonary lesions as well as extragastric surgical diseases as cholecystitis, appendicitis, and acute pancreatitis. On the other hand while an external penetrating wound is obvious the possibility of serious damage to the stomach or duodenum by a blunt blow should be borne in mind.

Perforated peptic ulcers may not necessarily be preceded by gastric symptoms. Much confirmation of the diagnosis in suspected cases can be obtained by a flat X-ray plate showing gas under diaphragm. The operation should be as prompt and as simple as possible. The fluid in the peritoneal cavity should be aspirated, the perforation should be closed transversely by a few mattress sutures of fine chromic catgut, the adjacent peritoneal covered fat brought down against this suture line by another row of the same kind of sutures and no drain inserted except in cases of more than eight or ten hours duration. Decompression of the stomach by a Levine tube and intravenous dextros in Ringer's solution may be indicated.

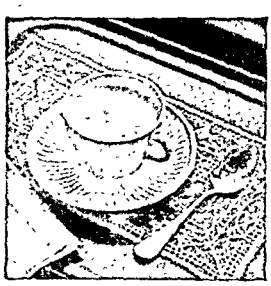
Perforation of a malignant growth demands a partial gastrectomy even though accompaning mortality is high. Drainage both locally and in the pelvis should be employed in such cases.

Patients with perforations caused by shot, particularly bird shot, usually do better when treated expectantly with morphine and rest of the gastro-intestinal tract. This is true since the tiny wounds are usually effectively plugged by the mucosa.

Stab or bullet wounds as well as indirect trauma with symptoms of a rupture of the stomach or duodenum require immediate exploration, control of the bleeding and closure of the perforation.

In any operation on the stomach or duodenum low blood pressure readings indicative of shock call for intravenous dextros in Ringer's solution or blood transfusions.

Grossly infected abdominal wounds are best closed by the "open method" of H. C. Gamble, suturing the peritoneun securely but leaving the remainder of the wound as open as possible.



Gastric hemorrhage preceding operation can usually be controlled by medical measures but if too extensive or persistent resection of the involved area may be required.

Post-operative hemorrhage after gastric surgery is rather rare now. Careful technique and decompression afterwards through a Levine or Jutt tube are usually all that is necessary. If these measures and free irrigation of warm tap water or saline at about 120 degrees are not effective the bleeding point should be exposed and sutured through an exposure in the anterior gastric wall, care being taken not to disturb the sutures of the previous gastro-enterostomy or partial gastrectomy.

Failure of the stomach to empty after a gastro-enterostomy in rare and gastric lavage, for a few days will often give relief. If the obstructing exudate does not absorb laparotony with jejunostomy or more complicated procedures may be required.

The after-treatment of emergency gastric or duodenal operations consists of free use of intravenous dextrose and transfusions, physiological rest of the stomach, permission for water by mouth if a Levine tube is in the stomach, and a very gradual resumption of a smooth diet.

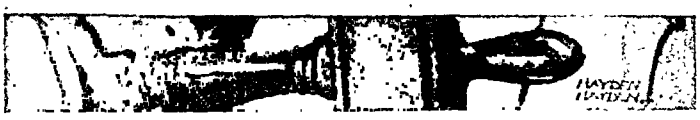
J. Duffy Hancock, Louisville.

In Digestive Disturbances Notably Ulcers

Horlick's Malted Milk is useful in the frequent feeding of ulcer patients because:

1. It is basically a milk food without a tough curd formation after ingestion. Therefore it is of value in a bland, smooth diet.
2. The malt flavor of Horlick's helps overcome the monotony often experienced in any straight milk diet.

Horlick's Malted Milk Tablets are most convenient to carry by the ambulatory patient, for frequent feeding, whether at work in office or factory.



HORLICK'S MALTED MILK CORPORATION

At the Helm – in time of need

RED CROSS HEALTH WORK

WORKING in cooperation with local public health authorities the Red Cross carries on each year hundreds of immunization programs in communities threatened with serious epidemics of typhoid and other communicable diseases.

In addition to its medical and health work on disaster scenes the Red Cross maintains a year-round Public Health Nursing service, which brings the visiting nurse to hundreds of small towns and rural communities where medical and hospital facilities are at a minimum. Not only through her nursing care of, but also by her instruction to mothers and girls in Home Hygiene and Care of the Sick does the public health nurse assist the country doctor to safeguard health in these sparsely populated districts.

All Red Cross services are supported by the annual membership dues of millions of Americans who join each year during the Roll Call, held from Armistice Day to Thanksgiving. Everyone is invited to have a part in the work of their Red Cross by enrolling in their local Chapter.

HELD, I. W. AND GOLDBLOOM, A. ALLEN.
Carcinoma of Stomach in a Cured Case of Addison's-Biermers (Pernicious) Anemia. J. A. M. A., Vol. 108, pp. 1398-1400, April 24, 1937.

The authors report a case of Addison-Biermer's anemia which was diagnosed and treated in 1927-1928. The patient was placed upon liver extract and diluted hydrochloric acid. The blood apparently returned to normal and the patient was considered one of those rare cases which was completely cured. In January, 1936, he returned with the complaint of loss of weight and appetite, weakness and occasional attacks of vomiting for the past six months. Physical examination and roentgen examination revealed a stomach mass which at operation proved to be a carcinoma of the pylorus. A gastric resection was done from which the patient apparently recovered.

Very few cases of this kind have been reported, and the author believes that when a recurrence of symptoms follows a cure of pernicious anemia gastric carcinoma must be thought of.

Francis D. Murphy, Milwaukee.

PAYNE, ROBERT L.
"Bile Tree Visualization — Its Surgical Importance." South. Med. Jour., 30:512-519, May, 1937.

Cholecystectomy alone in the presence of jaundice is an incomplete operation (except where acute cholecystitis is the cause of a hepatitis associated with a cholangetis) and the degree and type of common duct obstruction is often very difficult to determine clinically at operation even when a sound is passed into the duct and the ampulla is dilated. Furthermore, the status of the biliary tree post-operatively with a T-tube in the common duct can often be determined only inconclusively by the change in the degree of jaundice, stool examinations for bile, chemical and miscroscopical study of the external biliary drainage, and by irrigation through and by frequent clamping off the T-tube. For these reasons any procedure giving rather positive information regarding these conditions is of great value.

Such a method is used by Payne who follows the Mixter-Robins-Hermanson technic in his bile tract surgery. The procedure described in detail consists in the use of an opaque medium, hippuran, which may be injected into the common duct by a short shouldered angled No. 18 gauge needle during the operation, after aspirating the ductal system through the same needle, or may be injected through the T-tube post-operatively. One or more X-rays are taken after the injection to visualize the biliary tree. The use of hippuran appears to be harmless and properly interpreted plates reveal much positive information—not only regarding the degree or type of obstruction but also among other things even the reflux of bile into the pancreative duct.

Eight cases are described and illustrated with unusually good photographs. The method seems relatively simple and the results most convincing.

KING, E. L., FAUST, ERNEST C. AND SANDERS, JOHN T.
"Intestinal Parasitic Infections Complicating Pregnancy." South. Med. Jour., 30:545-549, May, 1937.

Most readers, especially those not from the South, will be surprised at the incidence of intestinal parasites found in white pregnant women admitted to the New Orleans Charity Hospital. In a period of six and one-half years there were 3,290 cases admitted and 10 per cent were found to have *Endamoeba histolytica*, 5.6 per cent hookworm, 3.5 per cent ascaris, and varying percentages of the re-

For Increased Palatability In the Special Adult Diet

It is possible to introduce considerable variety and palatability into a number of diets that require salt-poor, low-fibre and sugar-free foods, thereby assuring regular conformity to your instructions. This may be accomplished, for example, by utilizing certain of the eleven Gerber Strained Foods.

Because of the scientific methods used in their preparation, these foods are more uniform than those cooked at home. The vegetables retain vitamins and minerals to a high degree because (1) they are grown within an hour's trucking distance of the kitchens to which they are rushed immediately after packing; (2) they are strained and canned under carefully controlled temperatures with excess moisture evaporated.

Gerber Foods are also far more convenient for the patient.

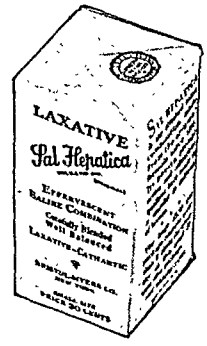
Salines

in Familial Constipation



Weak, feeble-acting colons are frequently encountered among members of the same family. Salines are decidedly helpful in familial constipation, and safe to administer even over a long period.

Sal Hepatica

simulates the properties of famous mineral spring waters. The intestines are gently, yet thoroughly, cleared of harmful waste by heightened osmosis and increased peristalsis. Natural mineral salts aid in conservation of body alkalines, thus helping to build resistance and to combat the acidity that so often accompanies constipation.

Sal Hepatica also stimulates an increased rate of bile flow from the liver into the gall bladder and thence, into the duodenum...Send for samples of palatable, effervescent Sal Hepatica; also literature.

Sal Hepatica Flushes the Intestinal Tract and Aids Nature to Combat Acidity

BRISTOL-MYERS CO.
19-NNWEST 50th STREET
NEW YORK, N. Y.

latively harmless parasites — many of the patients having multiple infections. Had the number of stool examinations per patient been more adequate the incidence would probably have been even greater.

None of the patients with emabic infections presented any serious symptoms although approximately 50 per cent had diarrhea of variable intensity. Because of the short period of hospitalization only a few were treated, and the drugs most favored were chiniform, carbarsone, and vioform.

Hookworm infection is serious because of the frequency associated anemia, the latter condition resulting in a lowered resistance. Toxemia, abortion, fetal death and premature labor have been reported by other observers as showing an increased incidence in badly infected patients. The treatment used in the hookworm cases consisted of tetrachlorethylene in 3 c.c. doses given in hard gelatine capsules on an empty stomach, a saline purge being given the night before and two hours after administration of the drug. This course of treatment was repeated in some cases and in others additional medication for ascaris was given when indicated.

Ascariasis is ordinarily not serious but nausea and vomiting, intestinal discomfort, obstruction, perforation or peritonitis may develop. Treatment consisted in the administration of one gram of hexylresoricinol crystals in hard gelatin capsules on an empty stomach, followed by a saline purge and no food for five hours.

In none of the infected cases given treatment did abortion or premature labor occur — in fact it was believed that those complications were actually avoided by the eradication of the infection.

J. Duffy Hancock, Louisville.

BORAS, EDWIN.

Hay Fever and Asthma During and After Jaundice. J. A. M. A., Vol. 109, pp. 113-115, July 10, 1937.

Cincophen has been reported many times as the etiologic agent in disease of the liver. The author reports the case of a man, 36 years of age, who came to him complaining of jaundice of three weeks' duration. For the past eight years he had been suffering with hay fever, which affected him during the month of August. The entrance complaint was due to the taking of one hundred cincophen tablets over the course of ten months, for some rheumatic pains he had. It was noticed that with the appearance of the jaundice, both the hay fever and the rheumatic symptoms disappeared. After a stormy convalescence the jaundice disappeared and the patient made a complete recovery. The next summer he was observed for the development of asthma which did not occur despite deliberately living in a ragweed infested area. An intracutaneous test was done at this time, followed by a conjunctival test, both of which were positive although no constitutional symptoms developed.

HIGH-CALORIC DIET

Indispensable to Convalescents

INFECTIOUS FEVERS deplete vitality. It is an exhaustion comparable to fasting. Convalescents show a low metabolism for several weeks following the disappearance of the fever. The low metabolism is the consequence of generalized cellular damages.

When the infection clears, activity is curbed and rest periods instituted. The patient is ready to gain. The problem is to bring about sufficient intake of food. The initial diet consists of small portions of each food prescribed and the amounts are gradually increased.

The high caloric diet is indispensable. It is made possible by reinforcing foods and fluids with Karo. Every article of the diet can be enriched with calories. A tablespoon of Karo provides 60 calories.

Karo is relished added to milk, fruit and fruit juices, vegetables and vegetable waters, cereals, breads and desserts. Karo consists of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor), not readily fermentable, rapidly absorbed and effectively utilized.

For further information, write CORN PRODUCTS SALES COMPANY, 17 Battery Place, New York, N. Y.

★ Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

mented chronic atrophic gastritis. These occur in three stages: (1) thinning out of mucosa; (2) effacement of gastric rugae; (3) arborization of the underlying and submucosal vessels.

The authors concisely discuss the opinions of various authorities on the etiology of the condition and believe, themselves, that it is the partial expression of a syndrome and not a disease entity. They conclude by saying that these cases will be studied during ensuing years, especially as regards the genesis of carcinoma of the stomach and esophagus, combined sclerosis of the cord and pernicious anemia.

LINDSAY, R. B., NEWMAN, J. R. AND HALL, I. C.

An Outbreak of Botulism in Wyoming. J. A. M. A., Vol. 108, pp. 1961-1964, June 5, 1937.

Cases of mushroom poisoning have frequently been reported, but only once has there been a report of botulism due to mushrooms.

The author reports an outbreak of botulism, type A, in a family eating home-canned mushrooms. Two children, aged two and one-half and five and one-half years, died because of respiratory paralysis before antitoxin could be administered. The mother and another child never showed any signs or symptoms of poisoning, but the father developed slight difficulty in swallowing during the second week, but recovered. These people received the antitoxin.

It was believed that the toxin of this strain was comparatively weak, but the culture showed a fairly patent strain of B. botulisms, type A.

APPENDICITIS

DAVIS, JAMES E., MUSKE, PAUL H., MULLIGAN, PHILLIP L. AND GUTOV, JULIUS.

A Statistical Survey of 10,000 Consecutive Cases at Providence Hospital. J. A. M. A., Vol. 108, pp. 1498-1500, May 1, 1937.

This is a survey of all the appendicitis cases occurring at Providence Hospital during the period from January, 1935, to May, 1935. More than 98 per cent of the cases were examined histopathologically. In 85.6 per cent of the cases clinically diagnosed as acute appendicitis, the diagnosis was confirmed pathologically.

There were 379 deaths in this series, of which 93 or 24.5 per cent were chronic; 257 or 67.8 per cent were acute; and 11.51 per cent were not classified. There were 6,076 females and 3,306 males in the group. There were more females because appendectomy was done in them in conjunction with other surgery. However, the mortality rate was higher in males because there were more acute, suppurative, gangrenous and ruptured appendices in this group.

The age of patients varied from ten months to 80 years. It was observed that the extremes of life produced 79.5 per cent of the total mortality, although 82.5 per cent of the cases were between the ages of 10 and 40 years.

The temperature on admission varied. Those with acute appendicitis had higher temperatures than the chronic cases had. Those which terminated fatally had temperatures ranging between 102 and 104 F.

EYERLY, JAMES B. AND BREUHAUS, HERBERT C.

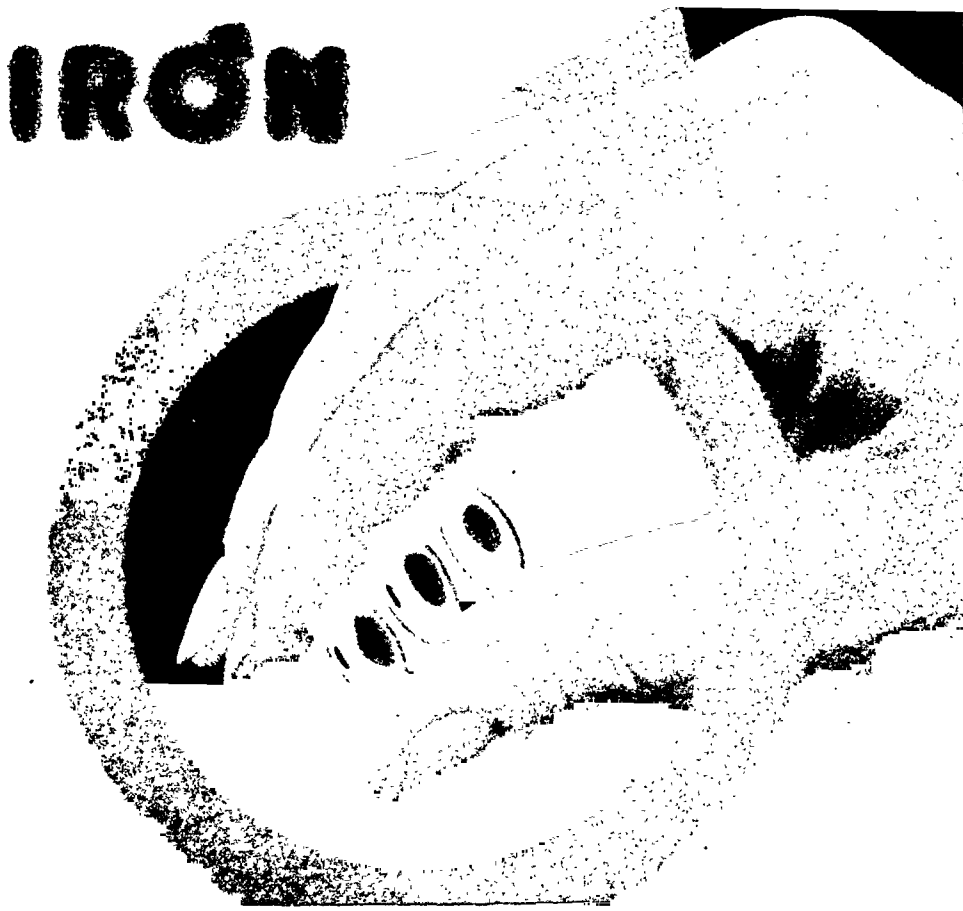
Treatment of Ulcerative Colitis with Aluminum Hydroxide and Kaolin. J. A. M. A., Vol. 109, pp. 191-195, July 17, 1937.

Kaolin is one of the oldest remedies for the treatment of colitis known to

Why
EFFERVESCENCE ?

YOUR PATIENTS will appreciate the increased palatability, convenience, tolerance of these standard medicaments as presented in the modern form of effervescent tablets.

Aspir-Vess
(ASPIRIN, BUFFERED ALKALI)
Effervescence safeguards against digestive upset, encourages rapid absorption, quick effect.
Buffered alkali helps to safely alkalize in respiratory infections, rheumatism, neuralgia.



Bromo-Vess
(BROMIDES, BUFFERED ALKALI)
The well known "Three Bromides"; palatable, no salty taste, no gastric upset even when large dosages are used.

Cinsa-Vess
(CINCHOPHEN, SODIUM SALICYLATE, COLCHICINE, BUFFERED ALKALI)
Anti-rheumatic medication in an easy to take form, better tolerated, assures necessary intake of water and free alkali.

HEMATINIC PLASTULES FOR ANEMIA

Small dosage, easy assimilation, and excellent results are all characteristics of Hematinic Plastules. The suggested daily dose of only three Hematinic Plastules Plain is usually sufficient to induce an early response in cases of secondary anemia. Hematinic Plastules obviate the necessity of massive iron feedings, encourage patient cooperation and provide an economical form of iron medication . . . . Doctors are invited to write for samples and literature on Hematinic Plastules Plain and Hematinic Plastules with Liver Extract.

THE BOVININE COMPANY • CHICAGO, ILLINOIS

man. It has been used successfully in the treatment of Asiatic Cholera. Its action is considered to be twofold: First, a mechanical action by which large numbers of bacilli are enclosed and carried off, but are not killed; second, the kaolin takes up toxins by adsorption.

Aluminum hydroxide is similar to kaolin, but has a greater colloidal activity, and also some astringent action. It also may act as a weak base or weak acid and has been used in the treatment of peptic ulcer. It has no demonstrable toxic effects when given orally, but has been known to cause a rapid drop in the red cells of two or three million when injected in large doses.

In the treatment of ulcerative colitis the author has used a mixture of three to five ounces of kaolin and aluminum hydroxide in three to five ounces of water given rectally once daily and retained as long as there is no discomfort. He has had excellent success in six cases and believes that it bears clinical trial.

Francis D. Murphy, Milwaukee.

KUNATH, CARL A.

The Stoneless Gall Bladder. J. A. M. A., Vol. 109, pp. 183-187, July 17, 1937.

The author has analyzed one hundred cases of noncalculous cholecystitis in which the gall bladder was removed. After comparing them with a similar series in which stones were present, he concludes that the stoneless cases show a greater morbidity, a higher postoperative mortality and only about half as many cures. He analyzed the stoneless cases from both the pathologic and the physiologic standpoint, but could find nothing indicative of the prognosis from either viewpoint. Generally, the more marked pathologic change present, the better the results. Colic was cured in eighty-six per cent of the cases, and dyspepsia in thirty-three per cent. Thirty-eight per cent of cases with no dyspepsia preoperatively complained of it postoperatively. He found some cases of poor results to be due to errors in diagnosis. These included cases of duodenal ulcer, duodenal diverticulum, a tuberculous spondylitis, chronic gonococcic peritonitis, and, in the majority of cases, gastro-intestinal nervous disturbances.

Francis D. Murphy, Milwaukee.

STEIN, J. J. AND HONTSCH, F. K.

Adenocarcinoma of the Rectum with Unusual Sites of Metastases. J. A. M. A., Vol. 108, pp. 1776, May 22, 1937.

There have been sixteen cases of adenocarcinoma of the rectum with metastasis to the liver reported. Many of these cases are characterized by priopism and the author believes that such a condition always should suggest the presence of some pelvic tumor. It is also believed that anatomically or physiologically such metastasis cannot be explained on a vascular or lymphatic basis. The author explains the metastasis by extension into the corpus cavernosum by way of the ischiorecta fossa and then through the junction of the deep and superficial triangular ligaments, with the fascia of Colles into the superficial perineal space. The author also reports a case with metastasis to the right leg and right foot.

Francis D. Murphy, Milwaukee.

CASE, JAMES L.

Comparison of Methods of Roentgen Examination of the Colon. J. A. M. A., Vol. 108, pp. 2028-2034, June 12, 1937.

The usual procedure in intestinal X-ray examination includes the opaque

Soricin in Tuberculous Enteritis

Soricin is a detoxifying agent. Clinical results have been gratifying in the treatment of many conditions originating from the bowel. It is indicated in mucous colitis, spastic and nonulcerative colitis, intestinal toxemia, "irritable colon," allergic diarrhea, and toxic absorption from the bowel.

Kline suggests the use of sodium ricinoleate (Soricin) in tuberculous enteritis because:

1. It has advantages over castor oil, being free from disagreeable and nauseating effect.
2. It may be administered steadily and over periods as long as may be desired.
3. It appears to maintain the normal intestinal gradient and to reduce toxicity.
4. It shows evidence of relieving the symptoms attendant upon intestinal tuberculosis without the necessity of producing purgation.

For oral administration Soricin is available in two forms:

Soricin Capsules (Enteric Coated):

10 grain size:
boxes of 20 and 100 capsules each

5 grain size:
boxes of 40 and 100 capsules each

Soricin Tablets (Enteric Coated):

5 grain size: bottles of 100 tablets

For the Aristocracy of Thought*

> Your highly valued Journal is made to order for the aristocracy of thought of the Medical Profession of America . . . it has become a habit with me, and I would not care to miss a single issue.

The American Journal of Digestive Diseases and Nutrition

Was NOT established as a *vade mecum*, a news magazine, a humorous monthly nor a fictional alleviation for the jaded nerves of busy doctors . . Most readers by this time have divined this point of policy, and have come to know that, month by month, this periodical gives a cross section of current and modern gastro-enterological thought. It sees most of the manuscripts in this specialty: it prints all of them that are suitable . . . BETTER articles will be printed only when BETTER articles are written. The reader may confidently believe that at present the best work in gastro-enterology finds its way into these pages . . . Another way of saying that the management of this JOURNAL is seeking to perfect a really worth-while Archive in a most important field.

> *I am an admirer and reader of your excellent magazine.*

> *You cannot improve on the editorial content — it is and should be, an outlet for scientific thought.*

It is the firm intention of the Editorial Council that the pages of this Journal shall be kept FULL of important matter, and entirely EMPTY of all matter that is irrelevant . . .

> *Material and format are excellent. I enjoy it very much because the articles are scientific.*

> *It is certainly a well edited Journal and anyone who subscribes to it certainly gets his money's worth.*

Readers feel today that an important contribution to American Medicine is being, and will be, made through the agency of the American Journal of Digestive Diseases and Nutrition . . .

Quality brevity, educational value, scientific dignity, good typography and singleness of purpose are making friends in increasingly large numbers.

*These are excerpts from voluntary letters received from readers and the names of the writers are on file at the Office and may be had upon application.

No Other Special Medical Journal Ever Made the Subscription Showing in 3 Years That Has Been Accorded to the American Journal of Digestive Diseases and Nutrition

With only the numerically small American Gastro-enterological Association as a formal backer, this Journal has independently attracted a record group of constant readers.

WHY? . . . .

The reasons are obvious—

- One of the strongest Editorial groups in American Medical Journalism, realizing the void that existed in gastro-enterological literature, determined to make a special Journal that would meet very specific needs.
- The needs were for a journal that would collect and attract under one head the important contributions in this field, thus enabling the reader to learn what he wished without the inconvenience of looking through an extensive literature.
- This has been done . . . today our Editor receives countless manuscripts from the investigators of the U.S.A. . . . today numerous readers volunteer the fact that they have never made better investments than in the Volumes of the American Journal of Digestive Diseases and Nutrition.

Spend $6.00 per year or $10.00 for two years NOW.

CANNED FOODS IN THE CONTROL OF LATENT AVITAMINOSIS C

• The identification of cevitamic acid (l-ascorbic acid) as vitamin C served as a direct stimulus for the intensive study of the multiple problems involved in determining the human requirement for this factor. As a result of much extensive work, there have been developed three methods for estimating the intake or store of vitamin C in the body.

The "retention or saturation" test is carried out by administering a massive dose of vitamin C and determining the amount excreted in the urine in a given time (1).

As a second method, the daily excretion of vitamin C in the urine is considered indicative of adequacy of the intake (2).

A third method is the determination of the amount of vitamin C in the blood plasma or serum (3).

These tests have been combined in balance studies and may serve as valuable checks in the diagnosis of latent scurvy, when used separately or in conjunction with the less specific capillary resistance test (4).

Evidence is accumulating from the application of these tests which confirms the older view that acute cases of scurvy are rare in this country. However, this evidence does indicate rather wide occurrence of the subclinical forms of scurvy (5).

Correction of this condition is largely a matter of modification of the diet to include more liberal quantities of the fruits and vegetables which are known to be good sources of vitamin C. Recent reports indicate that vitamin C in such fruits and vegetables is afforded a good degree of protection during modern canning operations (6).

Since they are available at all seasons on practically every American market, these canned foods afford a valuable and economical means of controlling latent avitaminosis C.

This is the thirtieth in a series of monthly articles, which will summarize, for your convenience, the conclusions about canned foods which authorities in nutritional research have reached. We want to make this series valuable to you, and so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

meal with observation of the opaque residues as they move along the large bowel, followed by contrast enema administered under screen control by the radiologist himself with appropriate film records during the course of the fluoroscopy and subsequent observations after the patient has attempted to expel the contrast fluid. In anal insufficiency, the use of barium may be necessary even though the contrast clysma would be the method of preference. In cases in which there is a serious obstruction the use of umbrather in the oral contrast method may be desirable. The author believes that preliminary cleansing of fecal residues is ideal. He uses liquid petrolatum orally for one or two days or even 30 c.c. of castor oil the day before, followed by enemas the morning of examination. If an obstructive lesion, such as a carcinoma of the colon is suspected, the contrast enema is given first, followed later by air injection and stereoscopic films if necessary. In differentiating various types of colitis, the diagnosis of early carcinoma or the discovery of polyps and mucosal ulcerations, the double contrast method is of value.

Francis D. Murphy, Milwaukee.

LONG, CHARLES FRANCIS.

Leukocyte Behavior During Gastric Analysis. J. A. M. A., Vol. 109, pp. 23-25, July 3, 1937.

Kern was the first to suggest the fact that there might be some relationship between peptic ulcer and allergy; Vaughan's work indicated that there might be a relationship between leukopenia and food allergy. Gay believes that some cases of peptic ulcer may be associated with food sensitivity.

If some peptic ulcers were allergic manifestations, then, according to the author, some cases would certainly be found in a gastro-intestinal clinic such as his, using the Ewald test meal containing the most powerful allergens, milk and wheat.

In a series of 100 patients on whom 113 fractional gastric analyses were done and 678 leukocyte counts and differential counts, the following results were obtained. Thirteen showed achlorhydria, twelve showed hypochlorhydria, thirty-five showed euchlorhydria and forty showed hyperchlorhydria. The differential counts were of no significance. The leukocyte behavior showed that sixty-nine per cent fell into the indeterminate group. The author concludes that there is no actual relationship between the acid values and the leukocyte behavior.

FREIBERG, HENRY B.

Esophageal Stricture Dilated with Urologic Instruments. J. A. M. A., Vol. 108, pp. 1781-1783, May 22, 1937.

The treatment of esophageal strictures is primarily the domain of the otolaryngolotist. They usually occur following the swallowing of lye, corrosive materials and some poisons. As the stricture develops, the patient notices increasing difficulty in swallowing first of solid foods, and later even of liquid foods or fluids. This stricture can at first be dilated from above, but as the stricture advances, this becomes more difficult and finally impossible. Then a gastrostomy is done and the patient fed in this way. The author presents two cases of esophageal stricture in which retrograde bouginage through a gastrostomy wound was performed with satisfactory results.

Francis D. Murphy, Milwaukee.

TRI-CALSATE

BUFFERED NEUTRAL ANTACID

A powerful neutralizer of gastric HCl, yet causes NO rebound in acidity, no alkalization of stomach contents. Tri-Calsate gives rapid relief without harmful systemic effects.

Non-toxic, non-irritating; palatable and economical. Available on prescription at your pharmacy or direct in 4-oz. and 18-oz. bottles.

Avoid the Vicious Circle of Alkali Neutralization

Write for trial package and literature.

Ephedrine Inhalants, Lilly

● Winter days bring inclement weather. Diminished physical vigor and lowered resistance furnish additional predisposing causes for upper respiratory infection.

The various prescription forms of ephedrine do much to bring symptomatic relief in such conditions, inasmuch as the discomfort from head colds is alleviated by relief of the nasal congestion.

Inhalant Ephedrine (Plain), Lilly, contains ephedrine (in the form of ephedrine cinnamic aldehyde and ephedrine benzaldehyde), 1 percent, in an aromatized hydrocarbon oil.

Inhalant Ephedrine Compound, Lilly, contains ephedrine, 1 percent, with menthol, camphor, and oil of thyme in a neutral hydrocarbon oil.

Elixir Ephedrine Sulfate, Solution Ephedrine Sulfate, 3 percent, and three syrups of ephedrine, as well as pulvules (filled capsules) in four different grainages, are also available.

GROSS, H.

Sclerosis of the Hepatic Veins in Chronic Congestive Heart Failure. Arch. of Pathology, 23:4-457, April, 1937.

In a study of the inferior vena cava and the hepatic veins to their terminal branches in cases of chronic congestive heart failure due to various causes, the author found histologic changes comparable to those seen in arteries subjected to increased intra-vascular pressure. Macroscopically thickening of the intima with raised yellowish plaques were seen together with dilatation of the vessel and longitudinal fibrous streaks. The smaller the caliber of the vein the less marked was the fibrosis, but fibrous streaks were observed into the smaller branches. Microscopically the intima was found well preserved and usually markedly hypertrophied. This hypertrophy appeared roughly proportional to the degree of muscular hypertrophy of the media. The elastic tissue was also hypertrophied and especially was it marked in those veins in which the muscle elements of the media had suffered fragmentation and subsequent hyalinization and invasion of replacement connective tissue. This type of change was especially seen in cases of very long standing passive congestion. In cases of less duration the degree of muscular hypertrophy was very marked and oftentimes the outstanding feature of the picture. In places a localized accumulation of muscle cells on opposite sides of the vein greatly narrowed its lumen. Although yellowish plaques were found in some places these lesions were not marked by fatty changes and calcium deposition; this in contradistinction to the changes found in arteriosclerosis. The author believes these changes in the wall are essentially the result of increased intravascular pressure, that they are local in significance, largely compensatory in nature, and are not a part of a widespread vascular disease.

N. W. Jones, Portland.

CONNOTATIONS. By H. J. Sims, Denver, Colo.

Nephropexy was first performed by Hahn on April 10, 1881. Kuester, Esmarch and Delhaes each report having performed nephropexy in 1882. Kuester performed bilateral nephropexy in 1883. Weir was the first in America to successfully perform a nephropexy. Dowell of Galveston, was long credited with priority. Whether Dowell should receive this recognition may be judged by his case report. He passed a large needle threaded with a tape through the abdominal wall and the tumor. The ligature remained three months. Six months later an attempt was made to reintroduce the seton. The needle was broken and the broken end remained in the abdomen. At the end of two months the ligature was again successfully introduced. The patient was admitted to the State Lunatic Asylum in Austin, Texas, for two years. During this confinement the seton passed. Her condition improved and she was discharged from the institution. Two years later the kidney was removed.

Sonnenberg, in 1881, aware of unsuccessful autoplastic methods of repair of exstrophy of the bladder advocated extirpation of the bladder and union of the ureters to the urethal mucosa. Maydl suggested and Mikulicz attempted on two cases to transplant the ureters into the rectum. One patient died from chloroform poisoning and the other passed urine and feces involuntarily.

Causalgia, as a clinical entity, has been known since the days of 1864 when Weir Mitchell, Moorhouse and Keen first described the syndrome. It follows an injury and is characterized by severe constant and burning pain in the region supplied by one or more of the major nerves to an extremity.

Oppenheim, in 1899, was the first to recognize a hyphphyseal tumor with Roentgen evidence.

When GALLBLADDER STIMULATION is needed

Low grade chronic cholecystitis, in the absence of calculi and when surgery is not indicated, usually responds to gallbladder stimulation. Improved gallbladder emptying facilitates drainage of stagnant bile, and corrects biliary stasis. In consequence, epigastric and right upper quadrant discomfort is overcome, and intolerance to fatty foods is corrected.

TAUROCOL (Plessner)

The formula of Taurocol (bile salts, phenolphthalein, cascara, oleoresin capsicum, oil of peppermint) provides indicated therapeutic influence in many forms of chronic gallbladder disease. Bile salts are effective cholagogues, enhancing biliary drainage; phenolphthalein and cascara stimulate intestinal peristalsis, correcting the frequently associated constipation; stomachics effectively hasten gastric emptying * * * Taurocol (Plessner) provides prompt subjective relief in mild gallbladder involvement, especially when accompanied by chronic constipation. Epigastric discomfort is relieved, and liberalization of the diet becomes possible.

TAUROCOL COMPOUND (Plessner)

Taurocol Compound is indicated in the management of faulty gastric and intestinal digestion, especially when associated with chronic cholecystitis. It contains, in addition to the ingredients of Taurocol, pepsin and pancreatin. Thus the digestion of proteins, fats, and carbohydrates in both stomach and intestines is augmented, with definite subjective relief; the feeling of postprandial fullness disappears, and the patient is again enabled to enjoy his food and partake of a more liberal diet.

Samples of Taurocol and Taurocol Compound sent upon request.

The

CONSTIPATED CHILD

Constipation in children often requires no more than softening of the intestinal contents and lubrication of the tract. LORAGA is a plain mineral oil emulsion well adapted to this purpose.

Children like Loraga because of its pleasant taste which is attained by skillful blending of highly purified ingredients, without artificial flavoring. There is no objectionable oily taste. And Loraga is free from sugar, alkali or alcohol—it contains nothing that may interfere with its use under any condition, at any age period.

We shall gladly acquaint you with the efficiency and palatability of Loraga by sending you a trial supply. Please ask for it on your letterhead.

Loraga is available in 16-ounce bottles.

LORAGA

WILLIAM R. WARNER & CO., INC., 113 West 18th Street, New York City

Wutz, writing in 1883, denied that any large cyst of the urachus had been reported. He rejected all previous case records believing all reported cases represented either notable diagnostic errors or the description was so elusive to prevent classification.

Werth, in 1899, recommended enterostomy for relief of intestinal obstruction.

In 1890, Vanderveer was able to collect from the literature twenty-two cases of sarcoma of the bladder occurring in childhood.

The McBurney incision for appendectomy was described in 1894.

Gross, one of the ablest surgeons in the eighties, said, "The treatment of renal abscess must at first be strictly antiphlogistic and afterwards supporting."

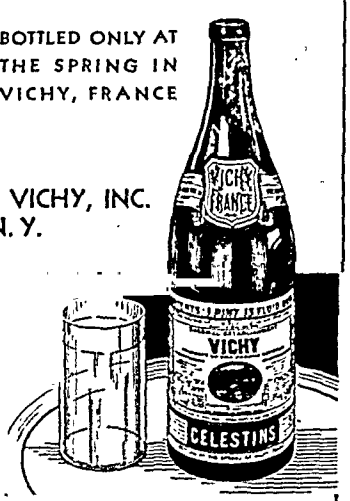
Emil Bock, in 1880, described adenoma of the sebaceous glands.

In 1894, Gallup was able to collect sixty cases of fracture of the astragulces.

Twenty-seven years prior to 1877 only 150 excisions of the thyroid gland had been recorded.

A. C. Butler-Smythe, in 1897, was the author of a text book containing 119 pages. This book recorded all the ovariotomies done by the author—a series of 54 cases. He attributed his unusual success to abundant flushings of the peritoneal cavity with warm boiled water.

The treatment of exstrophy of the bladder previous to 1850 was mechanical. The object was to protect the bleeding mucous membrane and retain the urine. The first defined operative procedure was outlined by Roux, in 1852.



In Cholelithiasis and Chronic Cholecystitis

AS an adjuvant in all forms of cholelithiasis and in chronic cholecystitis, whether surgical intervention is employed or not, physicians have long prescribed Vichy Celestins. When there have been attacks of gallstone colic, its cholagogic action is of especial advantage. Vichy Celestins is palatable, easily assimilated and therefore gratefully received by the patient.

A valuable FREE booklet on the Therapeutic Value of Vichy, with medical bibliography, will be sent to any physician on request.

Meckel's Diverticulum Associated with Intussusception and Adenocarcinoma of Ectopic Gastric Mucosa. J. A. M. A., Vol. 108, pp. 1480-1483, May 1, 1937.

Meckel's diverticulum occurs in about 3 per cent of all individuals and benign ulcerating processes in ectopic gastric mucosa have also been described frequently, but the development of a malignancy in the ectopic gastric mucosa of a Meckel's diverticulum is extremely rare. The authors report the case of a woman who complained of vague abdominal pains of six years' duration. This was in the epigastrium in the lower abdomen, particularly on the right and in the lower back. Physical examination revealed a diastasis recti, slight tenderness over the right costal margin, and tenderness and a mass in the right lower quadrant. There was also an egg shaped mass in the ileocecal region. X-ray of the colon revealed a filling defect involving the ileocecal region. At operation an intussusception of the terminal portion of the ileum was found which, when reduced revealed another intussusception which appeared to be a large Meckel's diverticulum. A segmental resection of the ileum was performed by making an end to end anastomasis with an enteroanastomosis. The patient made a successful recovery and reported one year later that she was feeling fine, except for some slight discomfort in the right side at times. Microscopic examination of the diverticulum revealed that the mass within it was an adenocarcinoma.

TRIMAX

HYDRATED MAGNESIUM TRI-SILICATE, STEARNS

A New Antacid, Antipeptic and Antitoxic

Comprehensive investigation has clearly demonstrated its unique therapeutic advantages:

1 Its antacid power is sustained for hours.

2 Its adsorbent capacity at body temperature is more than seventeen times that of colloidal kaolin.

3 The range of adsorptive affinities includes alkaloids, bacterial toxins, putrefactive amines and food poisons.

4 Its "strong antipeptic powers" protect the base of a peptic ulcer against destructive digestion.

5 It causes neither constipation nor diarrhea.

6 It cannot produce direct alkali poisoning (alkalosis).

7 Trimax combines in a single substance three therapeutic effects: antacid, antipeptic and antitoxic.

FURTHERMORE—

8 Trimax is a single chemical substance and not a "shotgun" type of preparation.

9 Trimax is efficient, ethical and economical.

Available through wholesale and retail druggists as a white powder.

Average dose—one slightly rounded teaspoonful (21 grains) midway between meals. Booklet furnished physicians on request.

WINDSOR, CANADA SYDNEY, AUSTRALIA

rhal jaundice. Pain is usually absent until late in the condition. The liver is diffusely enlarged and there is a polymorphonuclear leukocytosis. The diagnosis of the primary form is usually very difficult, but when it can be established as being secondary to something like gall stones, the diagnosis is fairly simple.

The author presents the case of a physician who presented himself with the complaint of jaundice of three weeks' duration. The illness began after an emotional shock and was characterized by jaundice, clay colored stools, bile stained urine, pruritus, anorexia, loss of weight and weakness. The temperature varied between 100 and 105, and there was a leukocytosis of 10,000 to 22,000. The comparison of the blood phosphatase and urobilinogus tests suggested involvement of some liver tissue.

Operation was performed, the gall bladder and bile ducts were examined and no stones were found. Choledochostomy was accomplished with a T tube, and cholecystogastrostomy was performed. A densely adherent appendix was removed. Microscopically, small sections of liver showed small foci of necrosis with polymorphonuclear infiltration. The wall of the gall bladder showed an active inflammatory process. After a very stormy convalescence, he recovered and is now back at work.

Francis D. Murphy, Milwaukee.

DAVID, VERNON C.

Chronic Intestinal Obstruction Due to Lesions of the Large Bowel. S. G. O., Vol. 64, No. 2A, pp. 281-285, Feb. 15, 1937.

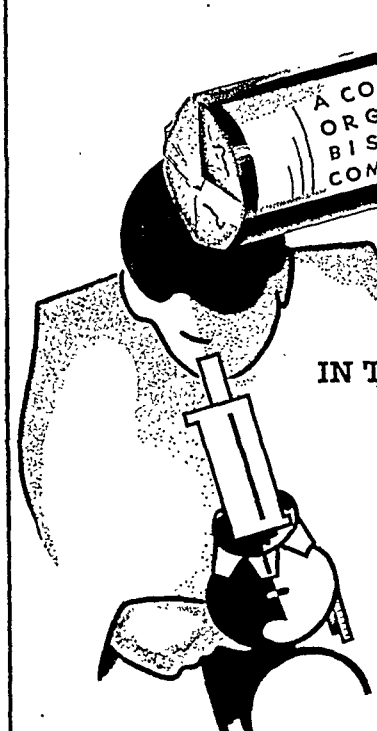
Sub-acute and chronic obstruction of the large bowel is caused by cancer far more often than by any other disease. Diverticulitis and ulcerative colitis are next, while strictures, granulomatous lesions, and endometriosis and polypoid tumors are rare causes. Acute obstruction develops when any of those processes completely occludes the bowel or in other uncommon conditions, such as congenital atresia of the bowel, volvulus, intussusception or strangulation, as occurs in a sliding or diaphragmatic hernia.

The symptoms of chronic obstruction due to cancer may be so slight as to escape the notice of any but an alert patient.

After the point of obstruction has been determined a colostomy or cecostomy, proximal to that point, should be made as a preliminary operation. At that time the abdomen should be explored and the operability of the tumor determined. If it is found to be inoperable a short circuiting operation around the tumor may be made. The author warns against radical operations or even short-circuiting anastomoses in the presence of even a slight degree of obstruction.

When diet, belladonna, heat and rest do not relieve the obstruction due to the diverticulitis, colostomy may be necessary. After six to twelve months the colostomy may be closed if the diseased portion has returned to a fairly normal state.

Acquired strictures of the rectum caused by advanced lymphogranulomatosis inguinale is best treated by permanent left-sided colostomy.



Rarely congenital strictures are not recognized in childhood and persist, causing megacolon in adults.

Six figures accompany the article.

HORSLEY, J. SHELTON.

Resection of the Rectosigmoid and Upper Rectum for Cancer with End-to-End Union. S. G. O., Vol. 64, No. 2A, pp. 313-321, Feb. 15, 1937.

The desirability of preserving the function of the rectum and anus in the treatment of cancer of the recto-sigmoid and upper rectum prompts the author to report a method of resection

Bisiodide
IN THE ORAL TREATMENT OF SYPHILIS

PHYSICIANS, hospitals and clinics, in increasing numbers from coast to coast are finding Bisiodide to be a more effective treatment for Syphilis.

A complex organic compound of 25% Bismuth and 58% Iodine, Bisiodide produces an exceptionally high and constant tissue concentration of Bismuth and Iodine. Used concurrently with arsenicals in primary and secondary stages; independently in tertiary stages.

A comprehensive brochure on the origin, nature and qualifications of Bisiodide will be mailed upon request.

Bisiodide is available through the ethical drug trade

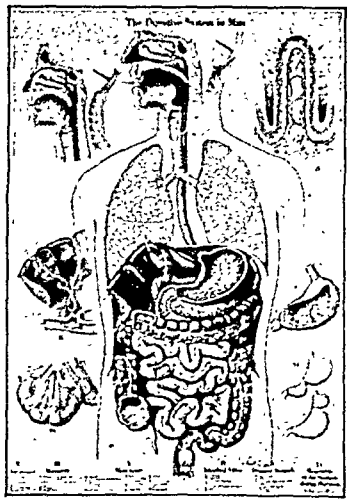
[CEVITAMIC ACID MERCK]

ACCEPTED AMERICAL MEDICAL ASSN

Crystalline Vitamin C

The use of Cebione (Cevitamic Acid Merck) is indicated in the treatment of scurvy and may be of value in the treatment of anemia, undernutrition, and in hemorrhagic diseases when they are due to a demonstrable deficiency of vitamin C.



Such conditions may arise not only from an inadequate diet, but also from an inability to assimilate sufficient vitamin C from the diet. Vitamin C deficiency not infrequently results from the use of special diets, either self-imposed or prescribed.

Cebione is supplied in tablets, 10, 25, and 50 mg. size; in solution for injection (100 mg. in 2.1 cc. ampuls); and as crystals (0.1 gram and 1.0 gram ampuls).

All forms may be obtained readily from your pharmacist.

of that part of the bowel with end-to-end union.

Since the spread of cancer of the recto-sigmoid and rectum is by way of the lymphatics and therefore mainly upward, it is not necessary to remove a large part of the bowel below the growth.

A preliminary cecostomy by means of which all fecal material is diverted from the distal colon is absolutely essential to the success of any end-to-end anastomosis in the colon. In order to secure this the author inserts a plug of vaseline gauze into the distal opening of the bowel through the opening in the cecum if it is necessary. The bowel is cleansed by irrigations from above and enemata from below. If, after the establishment of the cecostomy, there is a tendency to looseness of the bowels that must be controlled for several days before the resection is undertaken.

For the operation spinal anesthesia is preferable. The patient is grouped and a blood transfusion is given at the close of the operation, or later if it is deemed necessary. If the liver contains metastases which are not extensive and the lesion is obstructive in type, the resection is carried out as planned. If the tumor is found to extend too low to allow end-to-end union, the abdomino-perineal resection after the method of Miles, is carried out. The author has used Steinberg's colibactragen in all cases and believes it to be a distinct advantage.

After the operation enemata or irrigations of the large bowel should not be given. After two weeks the plug in the distal stoma of the cecostomy and what passes through is allowed to pass. Mineral oil is given in adequate amounts and a low residue diet is advised for at least a month after operation.

When it is evident that the colon has resumed its function, the cecostomy may be closed. The author inverts the mucosa of the cecum and finally frees the cecum from the parietal peritoneum and fixes it against the peritoneum above the incision, which is closed with catgut sutures. The remainder of the wound is packed open with vaseline gauze.

Three cases are reported in detail. Eleven figures accompany the article.

NOTICE

The 1938 meeting of the American Proctologic Society will be held at the St. Francis Hotel in San Francisco on Saturday, Sunday and Monday, June 11th, 12th and 13th, under the Presidency of Dr. H. Z. Hibshman of Philadelphia. Dr. Granville S. Hanes of Louisville, will deliver the first annual Joseph M. Matthews address.

Guests sponsored by members of the Society will be admitted to the sessions.

Curtice Rosser, Dallas.

Immediate Relief and Rapid Healing in

PEPTIC ULCER

Because of its profound and sustained acid-fixing qualities, Creamalin produces prompt subjective and objective improvement in peptic ulcer. All pain is relieved immediately, and is held in complete abeyance throughout the period of therapy. Healing, as demonstrated by x-ray, occurs in 7 to 10 days under continuous drip administration with the Creamalin Automatic Drip Control, and in 3 to 6 weeks under oral administration.

Creamalin is a distinctive colloidal cream of aluminum hydroxide. It fixes 12 times its volume of HCl in less than 30 minutes (Toepfer's reagent). Since it neutralizes by physico-molecular adsorption, it cannot lead to alteration in blood pH or acid base balance, hence cannot produce alkalosis. Creamalin provokes no secondary HCl rise, produces no bloating or eructations; its action is sustained, in contradistinction to the alkalis.

Reprints of published reports dealing with Creamalin and clinical test sample sent on request.

THE SUCCESSFUL ULCER TREATMENT

IF there were no germ of disease in the world . . .

there would be no need to employ the sterility of milk to safeguard against infection of healing ulcer tissue.

Purely hypothetical, of course;—presented, however, to emphasize the fact that modern gastro-intestinal therapy requires the use of a milk free from pathogenic organisms, and that Irradiated Pet Milk is the only form of milk surely and completely free from bacterial life.

Even though it were impossible for milk of any kind to cause infection there still would be good reasons to prescribe Pet Milk in the dietary for digestive disorders:

Being whole milk evaporated to double strength, it is high in calories, and a better balanced food than a milk and cream mixture.

Flocculent in coagulation, it is not likely to have traumatic effect on tissue in the region of healing.

Containing coagulated whey proteins, there is less likelihood of allergens entering the blood stream of individuals sensitized to milk.

Furnishing complemental vitamin D created by irradiation, it facilitates utilization of calcium and phosphorus.

Costing less than either high or low grade bottled milk, it is the least expensive of all milks.

These qualities, added to sterility, strongly indicate the usefulness of Pet Milk in the dietary for digestive diseases.

WANGENSTEEN, OWEN H.

Rationalizing Treatment in Acute Intestinal Obstruction. S. G. O., Vol. 64, No. 2A, pp. 273-280, Feb. 15, 1937.

In a review of some the pathologist physiology of intesintal obstruction the author points out that the increased intraluminal pressure by compromising the blood supply of the bowel wall leads to tissue necrosis and perforation leading to transperitoneal absorption. The concept that a toxic substance is absorbed from the wall of the obstructed bowel has been discarded. Intraluminal pressure is reduced in high obstructions by reverse peristalsis which, with vomiting, reduces the mineral and fluid content of the patient so rapidly that death ensues from their insufficiency. Replacement of fluid and minerals prolongs life in cases of high intestinal obstruction. The important factor in the treatment of low intestinal obstruction is the reduction of intraluminal pressure before the bowel wall has been damaged.

The concurrent occurrence of intermittent cramp-like pain and borborygmus establishes the presence of intestinal colic. This, in the absence of enterocolitis and in combination with some degree of distension of the abdomen, establishes the presence of an intestinal obstruction.

Where this obstruction is due to volvulus, intussusception, or a strangulated hernia, the treatment is apparent. In certain other instances in which the required treatment is not so plainly indicated the author observes three essentials for the proper procedure. (1) The sterility of the peritoneal cavity must be preserved inviolate. (2) The operation of least magnitude which will undo the injurious effect of the obstruction be performed. (3) That immediate restoration of the continuity of the intestinal tract be a matter of secondary importance unless the resulting fistula would prove serious.

In certain simple obstructions in which the location of the block has been determined by X-ray, suction may be applied and its results followed carefully by frequent films of the abdomen. If the bowel is returning to normal state the treatment may be continued. This form of treatment should not be undertaken alone for low intestinal obstruction or for any occlusion of the large bowel. It is valuable only as a pre-operative procedure in those cases.

Four figures and a bibliography accompany the article.

NICKERSON, D. A. AND WILLIAMS, R. H.

Malignant Tumors of the Small Intestine. Amer. Jour. Path., XIII:1, 53, Jan., 1937.

The authors report 10 cases of primary neoplasm of the small intestine occurring in 11,206 autopsies performed in the Mallory Institute of Pathology during the past 40 years, and review briefly the literature on the subject. The 10 cases consisted of 2 leiomyosarcomas arising in the duodenum and 8 carcinomas, 6 of which occurred in the duodenum and 2 in the jejunum. The incidence of the latter to carcinoma of the intestinal canal in the series was 2.33 per cent.

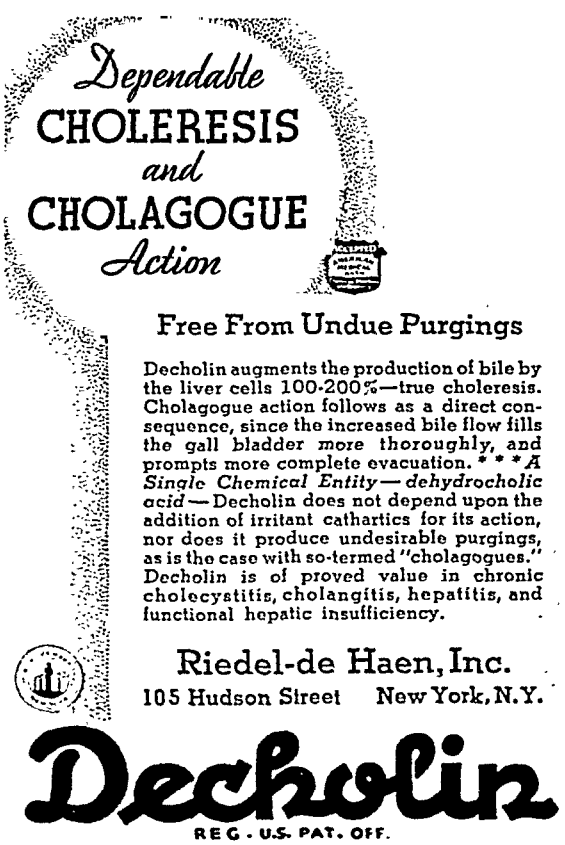
Metastases, especially into the liver and the regional lymph nodes, occurred abundantly in 7 of the 8 cases of carcinoma. The 2 cases of sarcoma showed no secondary growths.

The symptoms and clinical findings are briefly summarized in the report and are of interest. Duration of symptoms before the patients entered the hospital was over 7 months. The clinical picture depended upon the site of the tumor, the type and grade and the presence of metastases. Bloating and epigastric pain after eating, sometimes vomiting or an acute attack of intestinal obstruction occurred. Weakness, loss of weight and strength, altered bowel function and progressive anemia were usually present. The roentgen ray findings in 4 of the 10 cases were dilatation of the stomach with gastric residue without demonstrable gastric lesions and distortion of the duodenum. All were diagnosed as extrinsic tumors or deformities due to adhesions.

N. W. Jones, Portland.

WILDER, RUSSEL M.

Clinical Investigations of Insulins with Prolonged Activity. Ann. Int. Med., Vol. 11 (O. S., Vol. XVI), July, 1937.



This is a very thorough study of the peculiarities of the action of insulins with prolonged activity, and their advantages in insulin hypersensitive diabetics of five years or longer.

The author presents case reports with charts illustrating: (1) the prolonged action of protamine insulin in comparison with the plain, calcium and zinc protamine; (2) studies of prolonged hypoglycemia; (3) the control of glycosuria by diet.

One dose of crystalline insulin (which is quicker acting) will not hold over twenty-four hours, so he recommends crystalline and protamine insulin given at the same time, administered in different syringes, as producing the most evenly balanced results.

An able discussion of protamine insulin to prevent protein waste, and in treatment of diabetic acidosis, completes this very worthy paper.

B. B. Vincent Lyon and Clifford H. Arnold, Philadelphia.

Vi-Syneral for Nutritional Deficiency Conditions

Restricted Diets

FACED with the necessity of removing offending foods from the dietary, the physician well recognizes the serious threat to general metabolism, particularly through the curtailment of the necessary vitamin and mineral intake.

In the case of the obese, or diabetic, a diet low in total calories — with a diminution in carbohydrates and a limitation of fats — inevitably presages a deficiency in most of the vitamins, especially A and D, and the minerals.

In renal disease, characterized by nitrogen retention, the physician must deprive the patient of the larger part of his normal protein consumption — even though he recognizes the concurrent loss, particularly, of vitamin B and many of the mineral elements.

For the gastric ulcer case, or for the patient with colitis with spastic colon, the blue pencil rigorously bars uncooked fruits, vegetables and salads — likely through contained roughage to irritate the gastrointestinal mucous membrane. With them go much of the patient's supply of vitamins A, B, C and E — as well as calcium, phosphorus, iron, etc. — since the vitamin potencies and mineral content of pureed vegetables and fruit juices inevitably suffer serious impairment.

Allergic patients present a particularly difficult problem . . . the foods responsible for the allergic symptoms usually being so important to the normal dietary.

Modern authorities on dietetics emphasize the imperativeness of ensuring an adequate supply of vitamins and mineral salts, and of maintaining a normal acid-base balance, in these restricted diets. Deficiencies are rarely singular, since most foods contain three or four vitamins and various minerals.

It ill suffices, therefore, to supplement the diet by single-vitamin concentrates or specific mineral salts. The interdependence of vitamins and minerals in normal metabolism, and the multiple deficiencies induced by elimination from the diet of any essential food, can be met adequately only by the employment of the original multiple vitamin-mineral concentrate, Vi-Syneral.

This preparation, produced under the direction of Drs. Casimir Funk and H. E. Dubin, the pioneer authorities in the field of vitamin therapy, contains the six definitely known vitamins, fortified with eight essential minerals in balanced proportions and safe dosage.

The employment of this multiple concentrate constitutes an indispensable form of "corrective diet insurance," to forestall the development of those many, often obscure, complications arising from an impoverishment of the body in the vitamins and minerals required for normal metabolism.

Clendening's "METHODS OF TREATMENT"

Great books in medicine are published at rare intervals. Like diamonds, they are hard to find. Clendening's textbook—"METHODS OF TREATMENT"—was acclaimed immediately after publication as such a book. The reviews of previous editions bear out this statement.

Then, too, only the unusual book continues to live. When a book passes into a Sixth Edition there is a reason. A Sixth Edition of Clendening "METHODS OF TREATMENT" is ready now. This book, gone over carefully and brought uptodate, combines in ONE volume ALL methods of treatment—Drugs, Diet, Physiotherapy, Psychotherapy. Furthermore, this is a personal book—with all the charm of a great personality in medicine. It is not a citation of the writing of others. It is Clendening at his best.

"METHODS OF TREATMENT"—By LOGAN CLENDENING. New 6th Edition. 900 pages, 100 illustrations. Price, $10.00.

Up-To-Date!

DIGESTIVE DISEASES—*Kantor*

By JOHN L. KANTOR, Associate in Medicine, Columbia University. 302 pages, 40 illustrations. Price $3.50.

This book presents simply, clearly, and concisely, the essential facts concerning the diseases of digestion. An effort has been made to preserve the proper balance between stress and subordination, inclusion and omission; and to emphasize throughout, the ways in which gastroenterology fits into the larger field of internal medicine. To this end the opening chapter on classification has been designed for early orientation, clinical syndromes common to many diseases have been elaborated as fully as possible, and a final section has been devoted to digestion symptoms in extradigestive diseases.

ANO-RECTAL DISEASES—*Hirschman*

By LOUIS J. HIRSCHMAN, M.D., Professor of Proctology, Wayne University, Detroit, Mich. 288 pages, 174 pages, 6 color plates. Price $3.50.

The technic of diagnosis and of therapeutic measures herein presented requires no elaborate array of costly instruments, nor does it require complicated and expensive electrical or other apparatus. In over one-third of a century's experience in the practice of proctology as a specialty, the author has demonstrated the success of the methods described. These procedures are now presented in this synopsis to guide those who desire to treat that large proportion of ano-rectal diseases which can be treated safely and successfully outside the field of the limited specialist.

Emotional Adjustment in Marriage

The purpose of this unusual book is to increase the sum total of human happiness by seeking to contribute further truths upon which a satisfactory adjustment of the sex side of marriage may be based. The author considers the sexual side of life in its relation to the individual, the family, and society. To the physician interested in the resolution of sexual problems this book will serve as a valuable guide. By LE MON CLARK, M.D., Assistant in Obstetrics and Gynecology, University of Illinois, College of Medicine. 261 pages. Price, $3.00.

Problem: GASTROINTESTINAL DYSFUNCTION

Answer:

CHRONIC constipation, the most prevalent symptom of gastrointestinal malfunction, has continued to challenge the most considered measures of the gastroenterologist for its eradication. Its etiologic significance in cases of dilated colon, in spastic or mucous colitis, or in the aggravation of a multiplicity of complaints through the absorption of toxic metabolic products, has emphasized the imperativeness of developing a means for correction on a sound, physiologic basis.

Cathartics have offered only temporary relief. Preparations of pancreatic enzymes, or of bile salts, or of merely bulk-producing agents, have fallen far short in necessary therapeutic effectiveness. The physician's requirement has been for a multiple agent that would serve simultaneously to reactivate all inter-related elements of the gastrointestinal tract, and restore them to normal functional balance.

SUCH a multiple weapon is now available for the first time in Tri-Costivin . . . the brilliant culmination of extensive research originally initiated by Professor Elie Metchnikoff and prosecuted in collaboration with his colleague at the Pasteur Institute, Professor Boris Sokoloff, and other internationally recognized biologists, physiologists, bacteriologists and clinicians.

In Tri-Costivin these distinguished collaborators have finally succeeded in synthesizing the eight therapeutically indicated ingredients—graphically visualized below—necessary for the effective correction and normalization of the digestive, assimilative and eliminative functions.

This significant product of research thus affords the gastroenterologist an important new therapy. It serves simultaneously to normalize gastric juice secretion; to invigorate gastrointestinal innervation; to increase pancreatic and duodenal activity; to regulate bile secretion and drainage; to restore proper colonic bacterial flora; and to improve stool consistency.

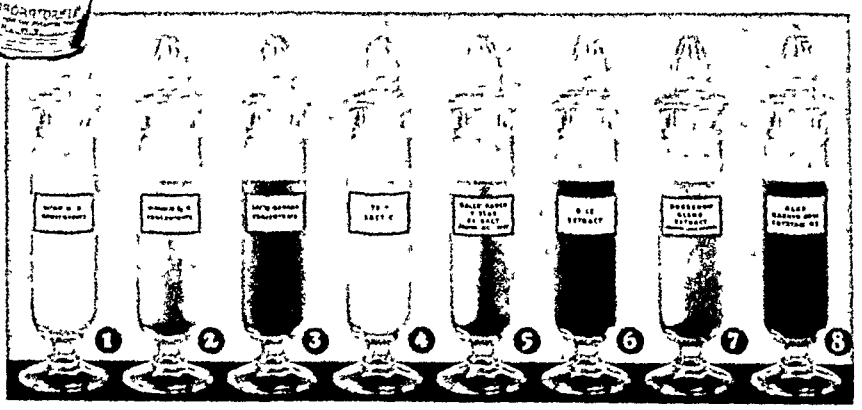
Impressively favorable have been the many clinical reports. Employed in cases in which evacuation has depended for many years on daily cathartic employment, it has restored normal bowel movement without recourse to the further use of irritant laxatives of any kind.

Tri-Costivin constitutes a truly comprehensive therapy . . . for the treatment of *the underlying causes* of intestinal stasis. Its rationale should recommend it to the gastroenterologist for his own clinical evaluation.

Write for samples, and for the book "The New Physiologic Approach," comprising the extensive protocols of laboratory research and clinical investigation prosecuted in its development.

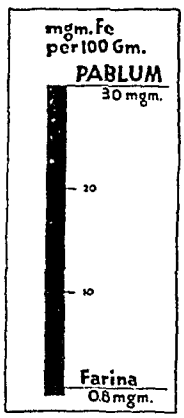
PROFESSIONAL LABORATORIES, INC.
155 EAST 44th STREET NEW YORK, N. Y.

TRI-COSTIVIN



a comprehensive synchronized treatment for gastrointestinal dysfunction as evidenced by constipation.

VISUAL FORMULA



Tri-Costivin contains in fine granule form:

1. Vitamin B_1 Concentrate (650 Chase and Sherman Units Per Daily Dose)
2. Vitamin B_2 (G) Concentrate (125 Sherman Borquin Units Per Daily Dose)
3. Lacto-Banana Concentrate
4. Tri-Lactic (Trade Mark) with Calcium Lactate
5. Gall-bladder Tissue Extract
6. Bile Extract
7. Duodenum Gland Extract
8. AgarKaraya Gum

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.[1] "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1-3] Bibliography on request.

The Influence of the Extrinsic Innervation on the Human Gastric Motor Mechanism

By

LOUIS E. BARRON, M.D.* (by invitation)
NEW HAVEN, CONNECTICUT

THE clinical results of bilateral resection of the splanchnic nerves have inspired new optimism in the treatment of essential hypertension (1) and juvenile diabetes (2, 3, 4). Although the therapeutic value of this procedure is still on trial, nevertheless it has created opportunities for investigating the role of these nerves in the body economy. Our own observations in this field became possible when bilateral resection of the splanchnic nerves was accomplished in an attempt to control juvenile diabetes (5). Further studies on the gastric neuromuscular mechanism were made when abdominal vagotomy was performed on a patient with vagotonia (6), a symptom-complex described by Eppinger and Hess (7). It thus became possible to make comparative studies on the influence of the extrinsic innervation on the motor physiology of the stomach.

METHOD OF INVESTIGATING GASTRIC MOTILITY

In the investigation of gastric motility we used the balloon and kymograph method. The details regarding the apparatus, the criteria for evaluating gastric activity, and the method for ascertaining the location of the balloon in the stomach have already been reported (5, 6). The usual duration of each continuous observation ranged between three and six hours. Observations were made in the morning about fourteen hours after the evening meal. As a preliminary procedure a barium coated balloon was swallowed and its position in the stomach verified by the fluoroscope and X-ray films. The distance from this position to the incisor teeth was measured and kept constant throughout the experiments. Because of the great variability in gastric motility a large number of control experiments were made to facilitate comparative study.

During the kymographic tracings an electric key and signal magnet were incorporated into the system. All patients were instructed to indicate any abdominal distress by pressing the key which produced an informative mark on the record. It then became possible to correlate gastric sensory disturbances with the associated phase of motility. All kymographic records were carefully evaluated and tabulated for comparative study (Table I).

Gastric motility was again studied from five to seven months after operation for the investigation of the late results.

Studies were also made on the influence of the extrinsic innervation on the emptying time of the human stomach. The patients were given a test meal consisting of three ounces of cream of wheat, two ounces of barium sulphate, and sufficient water to form a paste. Frequent fluoroscopic observations were made until barium was no longer evident in the stomach. Occasionally it was difficult to ascertain accurately when the stomach was empty due to the coating of the walls by barium. However this was not a constant artifact.

THE SPLANCHNIC INNERVATION OF THE STOMACH

The anatomical distribution of the splanchnic nerves has been reviewed adequately elsewhere (8, 9). Therefore further discussion is intentionally omitted.

Although numerous experimental observations have been made on the influence of the splanchnic nerves on gastric motility, nevertheless divergent results have been reported. Certain contributory factors such as anesthesia and trauma have frequently obscured the subsequent experimental conclusions.

In spite of this criticism there is sufficient evidence to indicate (10) that resection of the splanchnic nerves in dogs produced an increase in gastric tonus and an augmentation of the contractions. We have concluded from our own observations (5) that this was also true in man, since a marked increase in the duration of periods of gastric motility and a definite increase in the amplitude of the contractions were evident. This was thought to be due to the unopposed action of the vagus nerves.

Following bilateral splanchnic resection we observed great variability in gastric activity. Occasionally the motility was normal and resembled that noted during the control studies. Since the splanchnic nerves contain both motor and inhibitory fibers (11, 12), the results appearing on the kymographic tracings are influenced by the state of the gastric tonus existing at the time of the observation (13, 14, 15).

The immediate effect of splanchnic resection on the gastric motor mechanism was unreliable since the shock of operation, trauma, and anesthesia probably

Presented before the Forties Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7, 1937.
From the Department of Research Surgery, the Ohio State University, Columbus, Ohio.
*Department of Surgery, School of Medicine, Yale University, New Haven, Conn.

influenced the motility. Observations made eight to ten days after unilateral resection revealed very short periods of motility alternating with short periods of gastric quiescence. This was observed for about three to four days and was interpreted as being due to trauma and irritation to the sectioned splanchnic nerves. Subsequently there ensued intense persistent gastric activity. Frequently this continued throughout an observation period of four to five hours. There was a definite increase in the amplitude of the contractions which occasionally measured 14 cm. Many periods of motility terminated in severe gastric tetany. In spite of this increased activity there were no associated symptoms. There was no evidence of colic or diarrhea.

TABLE I

THE INFLUENCE OF THE EXTRINSIC INNERVATION ON GASTRIC MOTILITY

PATIENT	CASE NUMBER	DIAGNOSIS	METHOD OF STUDY	NUMBER OF CONTROL OBSERVATIONS	TREATMENT	NUMBER OF POST-OPERATIVE OBSERVATIONS	RESULTS					
							DURATION OF PERIODS OF QUIESCENCE	DURATION OF PERIODS OF ACTIVITY	CONTRACTIONS			
									NUMBER	DURATION	INTERVAL BETWEEN	AMPLITUDE
EF	345601	Diabetes	Balloon & Kymograph	15	Unilateral (left) Splanchnic Resection	21	Decreased	Increased	Increased	No change	No change	Increased
					Bilateral (right) Splanchnic Resection	25	No further change	No further change	No further change	No change	No change	No further change
					7 months after Bilateral Splanchnic Resection	9	No further change	No further change	No further change	No change	No change	No further change

					Bilateral (left) Splanchnic Resection	17	No further change	No further change	No further change	No change	No change	No further change
RM	350531	Vagotomy	Balloon & Kymograph	13	Atropine medication	9	Slight increase	Slight decrease	Slight decrease	No change	Slight increase	Slight decrease
					Vagotomy	12	Increased	Decreased	Decreased	No change	Increased	Decreased
					5 months after Vagotomy	7	No further change	No further change	No further change	No change	No further change	No further change

One patient was studied seven months after bilateral splanchnic resection (16). The results at this time revealed essentially no change in the motility. The increase in the duration of periods of gastric activity still persisted and lasted from three to four hours. The increase in the amplitude of the contractions was still evident, frequently ranging between 11 and 14 cm. (Figure 3).

Associated with these studies observations were made on the emptying time of the stomach (Table II). Five determinations were made during the control period. The results were fairly constant. The emptying time ranged from four hours and fifteen minutes to five hours and twenty-five minutes and averaged four hours and forty-five minutes.

Five observations were made after unilateral resection. There was practically no change in the average rate of gastric emptying when compared with the results of the control period. The total emptying time ranged from three hours and thirty-five minutes to six hours, and averaged four hours and forty-one minutes, an average difference of only four minutes.

Six observations made subsequent to bilateral splanchnic resection revealed a variation from two hours and forty-five minutes to four hours and fifteen minutes. The average emptying time was three hours and thirty minutes, an average difference of one hour and fifteen minutes.

Contrary to the findings of most observers, Cerqua (17) found that the stomach of most of his experimental animals appeared to be less active after splanchnic resection. However he was able to confirm the findings of McSwiney (18) in that the initial emptying after splanchnotomy was permanently shortened. He also noted a decrease in the total emptying time in some animals, but he did not think that this was permanent.

McCrea (19) found that splanchnotomy resulted in an increase in peristalsis. The stomach also appeared small and tubular. This effect gradually became less marked and it returned toward the normal state. Under these circumstances the initial emptying time remained markedly shortened while there was an appreciable decrease in the total emptying time. Our findings concur with those of McCrea (19) in that the rapid emptying seemed to be due to an increase

in the gastric activity rather than the result of a patulous pylorus.

THE VAGUS INNERVATION OF THE STOMACH

The abdominal distribution of the vagus nerves has already been described in detail (18, 19, 20). McCrea (19) has shown that each vagus sends fibers to both surfaces of the stomach and that stimulation of a single vagus in the neck will cause movements of the whole stomach. Resection of both vagi in the neck has proved fatal since esophageal and laryngeal paralysis results and death subsequently ensues from respiratory infection. Intrathoracic or abdominal vagotomy can be accomplished with a relative degree of safety.

It is believed that the gastro-intestinal manifestations of vagotonia are due to hyperirritability of the vagus nerves. Many of our observations are in keeping with this view. During the untreated stage of this condition intense gastric activity was a common observation (Figure 4). Associated with this there was a corresponding decrease in the duration of periods of gastric quiescence. By means of the signal magnet and electric key it was possible to correlate epigastric discomfort with the associated phase of gastric motility. Such a relationship was observed. During the control period severe contractions were noted occasionally of sufficient magnitude to rupture the balloon. These contractions occurred simultaneous with the upper abdominal distress. The amplitude of the contractions was increased, occasionally to 8 cm. Gastric tetany was common, and frequently was accompanied by temporary periods of discomfort which disappeared with the ensuing period of gastric quiescence. With the resumption of intense gastric motility there was a simultaneous recurrence of epigastric distress. In general there was a definite increase in gastric tonus as detected by the balloon method.

TABLE II

The influence of the extrinsic innervation on emptying time of the stomach

Patient	Case Number	Diagnosis	Emptying Time of the Stomach			
			Average Preoperative Emptying Time	Treatment	Average Postoperative Emptying Time	Difference
M. W.	354581	Diabetes	4 hours, 45 minutes	Unilateral Splanchnic Resection	4 hours, 41 minutes	4 minutes
				Bilateral Splanchnic Resection	3 hours, 30 minutes	1 hour, 15 minutes
R. M.	350531	Vagotonia	6 hours, 49 minutes	Atropine	5 hours, 12 minutes	1 hour, 37 minutes
				Vagotomy	2 hours, 50 minutes	4 hours
				Five months after vagotomy	2 hours	4 hours, 49 minutes

Fig. 1. Segment of a kymographic tracing showing the type of gastric motility observed prior to bilateral resection of the splanchnic nerves.

The results recorded on the kymographic tracings revealed some variation in the duration of periods of motility and in the amplitude of the contractions. Since it has been shown that the vagus nerve contains both motor and inhibitory fibers (21, 22), the results observed depend upon the existing tonus at the time of the experimental observations. McSwiney and Wadge (23) found that in a condition of low tonus, stimulation of the vagus with low or high frequency caused contractions and increased the tone. In a condition of high tonus, stimulation caused inhibition and relaxation. It has also been demonstrated (15) that stimulation of the peripheral cut end of the vagus by means of faradic current will if the organ be in a state of hypotonus either initiate movements in the quiescent stomach, or if movements are present, augment and sometimes accelerate them. The pre-existing state of the peripheral mechanism governs the response to stimulation, the most marked result being obtained with the active organ, the least with the passive.

The effect of vagus stimulation as reported in the literature has been variable. Van Braam Houckgeest (24) reported that stimulation of the cervical vagus caused contraction of the stomach. Bechterew and Mislawski (25) reported inhibition and associated the response with the strength of the stimulus. Bercovitz (26) and Rogers and Bercovitz (27, 28) obtained preliminary contraction followed by relaxation. Laughton (29) demonstrated in cats that stimulation of the dorsal vagus nucleus usually caused contractions, but inhibition also occurred if the tonus was high. Many variations are probably due to the fact that the effects of stimulation are governed by the existing gastric tonus at the time of stimulation.

During the administration of atropine, we observed a slight decrease in the duration of periods of gastric

motility. This was associated with a corresponding increase in the duration of periods of quiescence. The interval between contractions was somewhat increased and the number of contractions, many of which were of low amplitude, was also diminished. Associated with this general reduction in gastric activity, there was considerable symptomatic improvement.

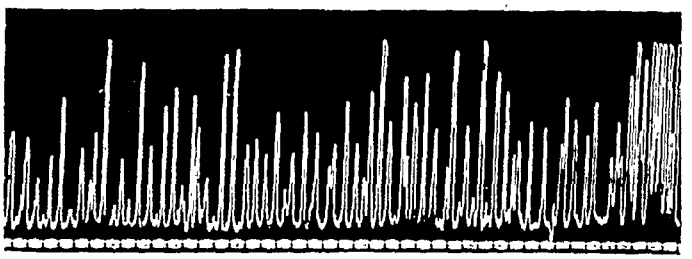

Fig. 2. Kymographic tracing showing intense gastric motility subsequent to bilateral resection of the splanchnic nerves.

Smith (30) and Brown and McSwiney (31), studying the effect of various drugs on gastric motility found that pilocarpine caused contractions of all parts of the stomach which were inhibited by atropine. McCrea and McDonald (32) and Carlson, Boyd and Pearcy (13, 14) also reported that atropine paralyzed the gastric musculature eliminating both vagus and splanchnic control.

There is convincing evidence to show that the left vagus exerts a greater influence on the gastric motility than the right. This was demonstrated by Batelli (33) and also confirmed by May (22). Laughton (29) has shown that faradic stimulation of the cephalic half of the left dorsal vagus nucleus resulted in a more marked effect on the stomach than stimulation of the corresponding part of the right dorsal vagus nucleus. Although McCrea and his associates (34) and McSwiney (18) reported that unilateral vagotomy was without effect, we observed striking changes following anterior (left) abdominal vagotomy. The outstanding feature of our observations was a definite decrease in the duration of periods of gastric motility (Figure 5), associated with a corresponding increase in the duration of periods of quiescence. The number and amplitude of the contractions were markedly decreased.

There was a marked increase in the interval between contractions. In many instances this ranged between nine and twelve minutes in contrast to an approximate average of two minutes during the preoperative control period.

This patient returned to the hospital about five months after left abdominal vagotomy for the investigation of the late results. At this time there was essentially no change in the gastric motility. The decrease in the duration of periods of motility still persisted (Figure 6). Periods of quiescence still remained increased, and the contractions were low grade and many of them feeble.

Our observations indicated that in the untreated vagotonic stomach, there was an abnormal retention of gastric contents. Four determinations on the emptying time made during the preoperative period revealed a variation ranging from five hours and thirty minutes to eight hours and averaged six hours and forty-nine minutes (Table II). It would seem at this time that the probable cause for this abnormal gastric retention was pylorospasm obstructing the outlet of the stomach.

During atropine medication three observations were made. The emptying time ranged from four hours and forty minutes to five hours and forty minutes, and averaged five hours and twelve minutes. Under the influence of this medication the pylorus appeared to be less spastic.

Following anterior vagotomy there was a definite decrease in the emptying time of the stomach. Three observations were made. The emptying time ranged

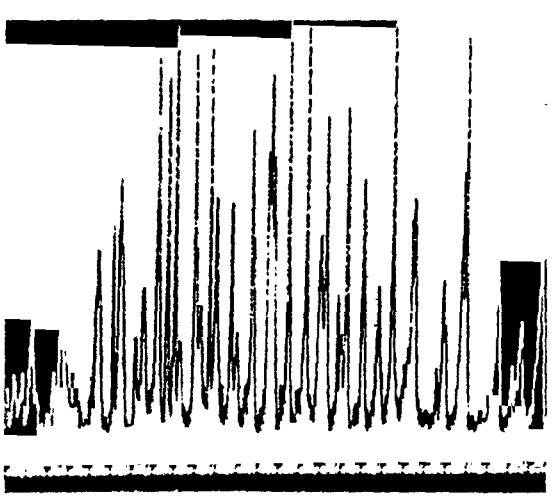

Fig. 3. Kymographic tracing seven months after bilateral resection of the splanchnic nerves. The amplitude of the contractions frequently measured from 11 to 14 cm.

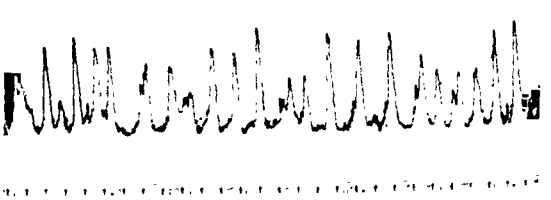

Fig. 4. Kymographic tracing showing persistent gastric motility in a patient with vagotonia. Frequently contractions of this type were observed throughout an observation period of three hours.

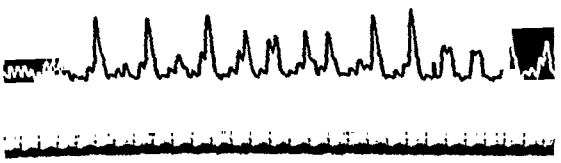

Fig. 5. Kymographic tracing showing gastric motility following vagotomy. There was a definite decrease in the duration of periods of activity and in the amplitude of the contractions.

from two hours and thirty minutes to three hours and fifteen minutes, and averaged two hours and fifty minutes, approximately four hours sooner than during the control period. Five months after vagotomy the emptying time was two hours.

It may at first seem paradoxical that a hypomotile stomach should evacuate its contents sooner than during the hypermotile control period. Our observations indicated that the decrease in the emptying time which ensued subsequent to vagotomy was due to the gravitation of barium through a patulous pylorus. In contrast to this, the increased emptying noted after bilateral resection of the splanchnic nerves was probably the result of increased gastric activity.

McCrea, McSwiney and Stopford (34) have pointed out that the immediate effects of vagotomy were unreliable and probably due to shock. Shortly after unilateral vagus section they observed a temporary paresis and dilatation of the stomach. After bilateral vagotomy there was a marked decrease in the initial emptying time as well as a decrease in the total emptying time which they attributed to a semi-patulous condition of the pylorus. Hughson (35) also observed a decrease in the emptying time. Laterjet, Cluzet and Wertheimer (36) however reported dilatation and atony of the stomach associated with a marked delay in the emptying time.

THE INFLUENCE OF THE EXTRINSIC INNERVATION ON CERTAIN GASTRIC ABNORMALITIES

Numerous investigators have reported various disturbances in the motor physiology of the stomach, subsequent to gastric denervation. Exner and Schwarzman (37) noted pylorospasm and cardiospasm. McCrea, McSwiney and Stopford (34) reported that this was temporary, probably due to irritation of the nerves. It has also been stated (36) that resection of the vagus nerves has prolonged gastric emptying. These findings could not be confirmed by Hughson (35) and Barron and Curtis (6).

The influence of the gastro-duodenal nerve supply in the production of gastric ulcer is still controversial. Lichtenbelt (38) sectioned the vagi under the diaphragm and found that gastric ulcer developed in 70 per cent of his dogs. This work could not be confirmed by Donati (39). Auer (40) also found ulcers in a number of his vagotomized rabbits. Duranti (41) also favored the neurogenic etiology in the production of ulcers. Beazell and Ivy (42) reported an incidence of ulcer in 41.6 per cent of their vagotomized rabbits fed a stock diet, but no evidence of ulcer in vagotomized rabbits which were on a diet of okra. They were unable to find gastric or duodenal ulcers in vagotomized dogs.

We were unable to ascertain any clinical, roentgenographic, or experimental evidence of gastric or duodenal ulcer in our patient subsequent to vagotomy. Numerous observations made until five months after vagus neurotomy revealed an uncomplicated clinical course. Symptomatic improvement continued and there was a sustained conspicuous gain in weight.

Gastro-duodenal denervation has been proposed for the surgical treatment of various gastropathies. From an anatomical study of the splanchnic nerves, Jean (8) recommended supradiaphragmatic resection of the splanchnic nerves in the management of gastric crises of tabes. Pieri (43) also advised this procedure for essentially the same conditions. Gianolla (44) and Pieri (45) performed vagotomy in the management of various gastric disorders and also for gastric ulcer. Encouraging results were noted. Klein (46) reported a series of eight cases upon whom left vagus resection in addition to partial gastrectomy was performed for duodenal ulcer with marked hyperacidity. During the postoperative period he observed anacidity associated with symptomatic improvement. Schiassi (47) also stressed the importance of the nervous element in the etiology of duodenal ulcer.

Contrary to the findings of these investigators, Steinthal (48) performed gastric denervation for gastric ulcer and on the whole formed an unfavorable opinion regarding this operation. Borchers (49) also decided against operations on the vagus nerves. Best and Orator (50) concluded from their investigations that section of the vagus nerves for the treatment of peptic ulcer was of little value.

The lack of uniformity in the results reported in the literature is certainly disconcerting. The failure to establish confirmatory evidence in favor of gastro-duodenal denervation for peptic ulcer no doubt accounts for its cool reception in the minds of many investigators. A critical analysis of many enthusiastic reports leaves us with a multitude of queries. Much of the buoyancy is not substantiated by basic physiological data so that in many instances there is no objective confirmation for certain empirical conclusions. Frequently the duration of investigation before and after operation was too short to evaluate accurately the merits of gastro-duodenal denervation.

Our own observations on the effect of bilateral resection of the splanchnic nerves and of vagotomy revealed no subsequent deleterious clinical complications. We cannot substantiate any views which maintain that pathological dilatation of the stomach ensues after vagotomy. We observed no clinical or roentgen-

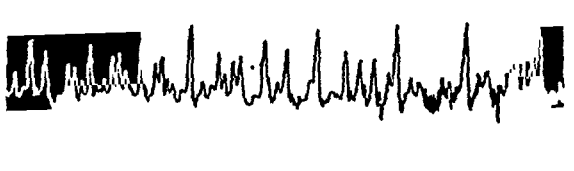

Fig. 6. Kymographic tracing five months after vagotomy. The decrease in gastric activity was still evident.

ological evidence of ulcer. Since so much confusion is already present regarding the role of the extrinsic innervation in the etiology and treatment of peptic ulcer, the present investigation, which deals with the basic physiology of the nervous control of the human gastric motor mechanism, was undertaken with the hope that it might cast some light upon problems which are still obscure.

DISCUSSION

DR. HARRY SHAY (Philadelphia, Pa.): Dr. Barron's data point out certain things that to us are extremely interesting in so far as his findings may be interpreted as showing quite definitely that peristalsis, is not the important factor in gastric emptying. He calls peristalsis what we would rather call motility. We could confine the term peristalsis to the waves of contraction of the stomach, and motility to the actual emptying process. In spite of the increased peristalsis after bilateral splanchnic section, motility was not materially increased, yet, after vagotomy, and a marked decrease in peristalsis, Dr. Barron saw no marked decrease in motility. These findings would fortify the opinion we have often expressed from our own studies that peristalsis per se is not the important factor in gastric emptying.

DR. FRANKLIN W. WHITE (Boston, Mass.): I should like to ask whether atropine in active doses caused less gastric motility, and what doses were used?

DR. LOUIS E. BARRON (New Haven, Conn.) (closing the discussion): I should like to amplify a statement that was made by Dr. Shay. It was our experience that the increased emptying observed subsequent to bilateral resection of the splanchnic nerves was due to the demonstrated increased gastric activity.

The increased gastric emptying observed following anterior or left abdominal vagotomy was due to the gravitation of gastric contents through a patulous or semipatulous pylorus.

In answer to the second question, gastric motility was studied by the balloon and kymograph method. We were observing essentially the contractility of an empty stomach.

The dosage of atropine which we used was 75 minims a day. This patient had been in the hospital about a year prior to our investigation, and apparently had built up a tolerance to atropine so that no symptomatic relief was obtained with smaller doses.

The Effect of Osmotic Changes in the Small Intestine Upon Gastric Emptying in Man*

By

J. GERSHON-COHEN, M.D., D.Sc. (Med.)

and

HARRY SHAY, M.D.

PHILADELPHIA, PENNSYLVANIA

IN previous reports we (1, 2, 5) have shown that the local mechanism controlling gastric motility and pyloric function is activated from the upper small intestine. This has since been confirmed in the experiments of Johnston and Ravdin (3) and of Cerqua (4). We have also demonstrated that the intrinsic agent which stimulates this mechanism is the gastric hydrochloric acid after it has passed the pylorus. Other agents which may be ingested and which may be equally efficacious in modifying gastric and pyloric functions have also been studied. Of these, the effect of fat, milk and cream has already been reported (5). Our present report is concerned with the influence of duodenal osmotic changes upon that same mechanism. The experimental method used was identical with that described in previous publications (1). Briefly, it consisted of frequent roentgenologic observations and roentgenographic records of the gastric emptying of a standard water-barium meal, taken by mouth, while the duodenal stimulant at body temperature was instilled through a duodenal tube. We studied the influence of the various stimulants administered by mouth by adding them to the standard water-barium meal, the volume of the ingested meal being constant. The standardization of the patient and the precautions taken in the study were exactly as those described in previous reports.

Twenty-seven subjects were used for the present investigation. Of these, four had achlorhydria; three, hyperchlorhydria; and twelve had shown a normal gastric acid response to the fractional Ewald Test. The remaining eight patients had had previous gastric operations. Of these, six had had a posterior gastroenterostomy and two had been subjected to a partial gastric resection of the Polya type. All the subjects were apparently in good health during the period of investigation. A total of 221 motor studies was done in this group of experiments. The data obtained with similar test agents were strikingly uniform. A few protocols which show the average findings probably offer the best means of examining our results. We have selected for illustration the data obtained in a patient with achlorhydria.

THE EFFECT OF THE TEST AGENTS ADMINISTERED ORALLY

B. S. evacuated the standard water and barium mouth meal leaving a 10% gastric residue after thirty minutes (Fig. 1). Three times this same result occurred within the limits previously described (1). A normal saline meal was evacuated in like manner in the same interval. A barium—5% glucose meal left a 15% gastric residue at the end of thirty minutes, a response like that obtained with tap water or normal saline. A greater concentration of glucose, however, resulted in definite changes in gastric motility. Thus a 20% glucose meal was emptied more slowly and left a 50% gastric residue at the thirty minute period. A

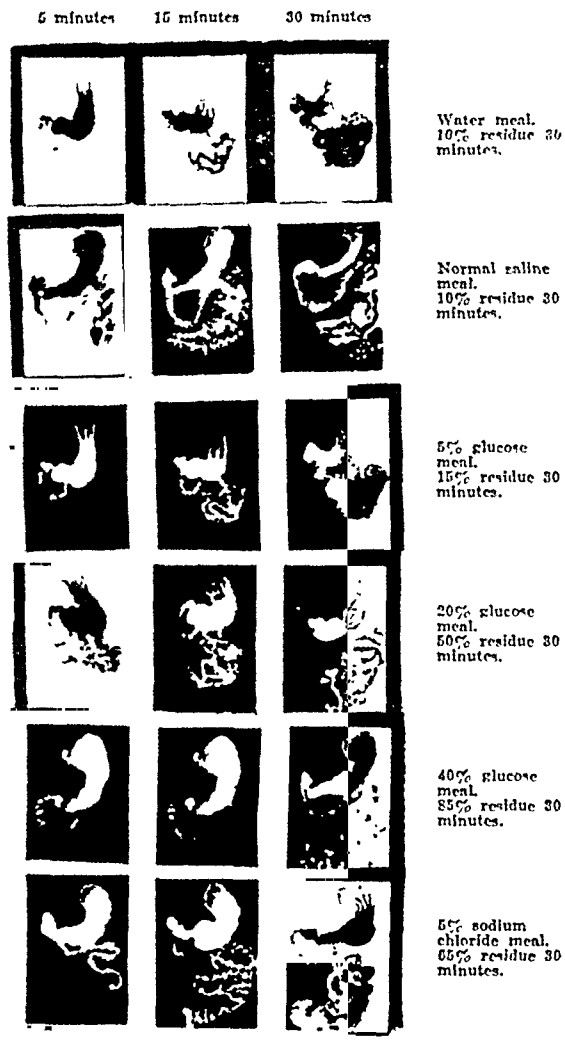

Fig. 1. Evacuation of iso-and hypertonic meals. (Pen and ink drawings of roentgenograms).

*From the Samuel S. Fels Research Fund and the Gastro-Intestinal Division, Medical Service I, Mt. Sinai Hospital, Philadelphia, Pa. Presented at the Annual Meeting of the American Gastro-enterological Association, Atlantic City, June 7th and 8th, 1937.

very striking retention was found in the stomach at the same time interval when a 40% glucose meal was administered. In this instance, 85% of the gastric contents had not yet passed the pylorus at the end of half an hour. A similar marked delay in gastric emptying was obtained with a hypertonic sodium chloride (5%) mixture. Following such a meal, 65% was still present in the stomach at the time interval although the normal saline meal had been practically emptied.

EFFECT OF THE TEST AGENT INSTILLED DIRECTLY INTO THE DUODENUM

Even more striking were the differences in gastric motility from the direct duodenal instillation of agents isotonic and non-isotonic. The intensity of these changes, within certain limits, was proportional to the degree of variation from isotonicity of the test agent used.

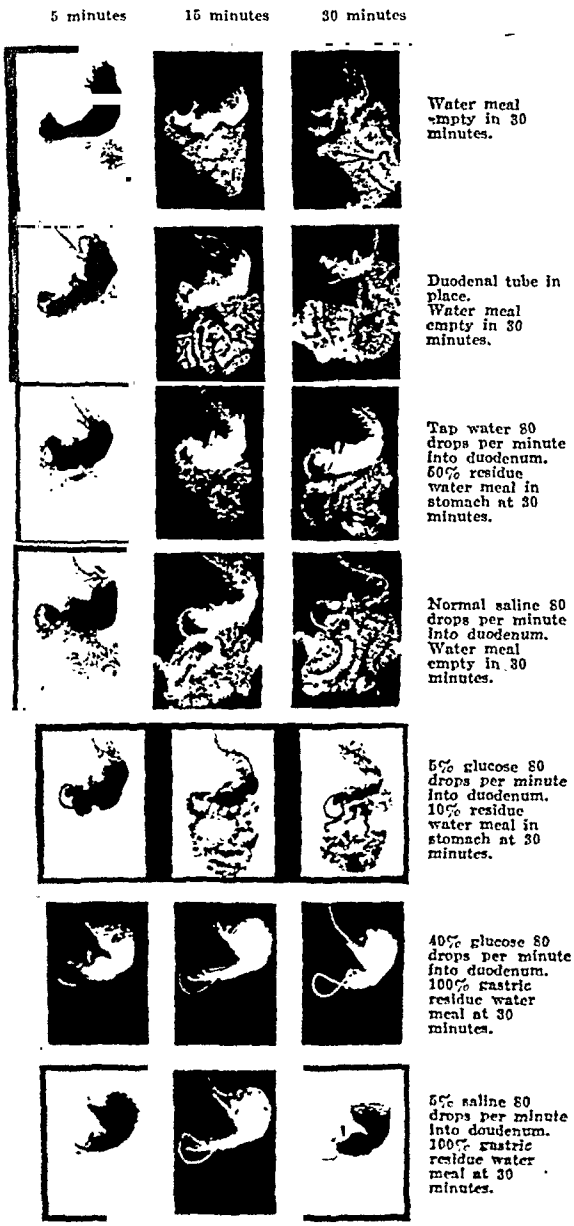

Fig. 2. Effect of osmotic tensions in duodenum on gastric evacuation.

In this group as well as in those previously reported, a possible influence of the presence of the duodenal tube through the pylorus upon gastric motility was sought. Again no change in gastric motility, as a result of the tube alone, was found. It is extremely interesting to contrast the results obtained (Fig. 2) after the duodenal instillations of water and of normal saline. It should be noted that the presence of normal saline in the duodenum did not retard the gastric emptying of the water and barium mouth meal in the slightest. Following the duodenal instillation of tap water there was a marked delay in the evacuation of the barium-water mouth meal (50% gastric residue)—a striking contrast to the 10% gastric residue at the end of 30 minutes when the water and barium meal had been taken by mouth (Fig. 1). These differences, we feel, are adequately explained on the basis of a rapid adjustment of gastric osmotic conditions toward isotonicity and they also stress the extreme sensitivity of the duodenal mucosa to conditions away from isotonicity. Thus Ravdin, Johnston and Morrison (6) studying the concentrations of glucose in the stomach and intestines of the normal dog after intragastric administration, found that the introduction of hypertonic solutions into the stomach was followed by a rapid increase of the volume of the gastric contents and a decrease in their concentration. Our own studies (7) in man resulted in similar changes, there being always an attempt to bring the ingested fluid to the isotonic state. In the same way, ingested tap water tends rapidly toward an isotonic solution because of the salt content of the gastric juice. We see, therefore, very little, if any, difference between the gastric emptying of tap water and of normal saline, when taken by mouth. When, however, the tap water is instilled directly into the duodenum, the sensitive duodenal mechanism is stimulated by the hypotonic tap water thus effecting a change in the pyloric mechanism and in gastric motor emptying.

Again the intraduodenal instillation of 5% glucose (Fig. 2) caused no appreciable change in the emptying of the water and barium mouth meal. When, however, a 40% solution of glucose was substituted for the 5% agent, practically complete pyloric closure was obtained and resulted in a 100% gastric retention of the mouth meal during the usual period of observation. A hypertonic (5%) solution of sodium chloride produced a result identical with that seen following the use of the 40% glucose solution (Fig. 2).

Alkalies, when taken by mouth or instilled directly into the duodenum, produced changes in gastric motility in the achlorhydric subject, which depended entirely upon the osmotic effect of the solution used (Fig. 5 and 6). Thus, a 1% solution of Sodium Bicarbonate (essentially isotonic) had no influence over gastric emptying while a 5% solution had a very marked effect. In the patients with gastric acid secretion, these effects were, of course, modified by neutralization of the bicarbonate through contact with the gastric acid (Fig. 5 and 6). Thus, we see an increased gastric emptying in the normal acid patient following the 1% sodium bicarbonate mouth meal as compared with the water and barium meal alone. This

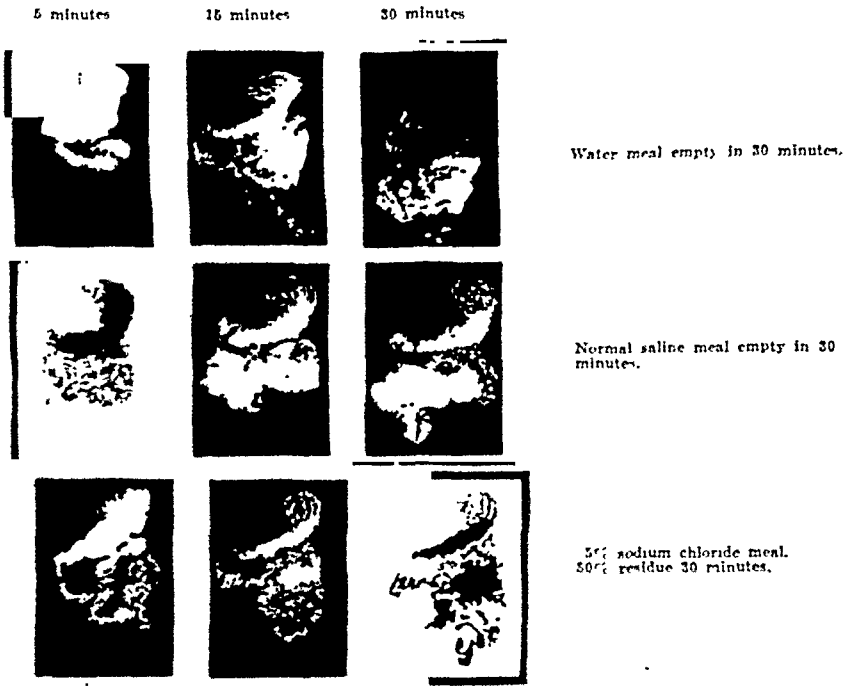

Fig. 3. Effect of osmotic pressure changes in stomach with posterior gastro-enterostomy.

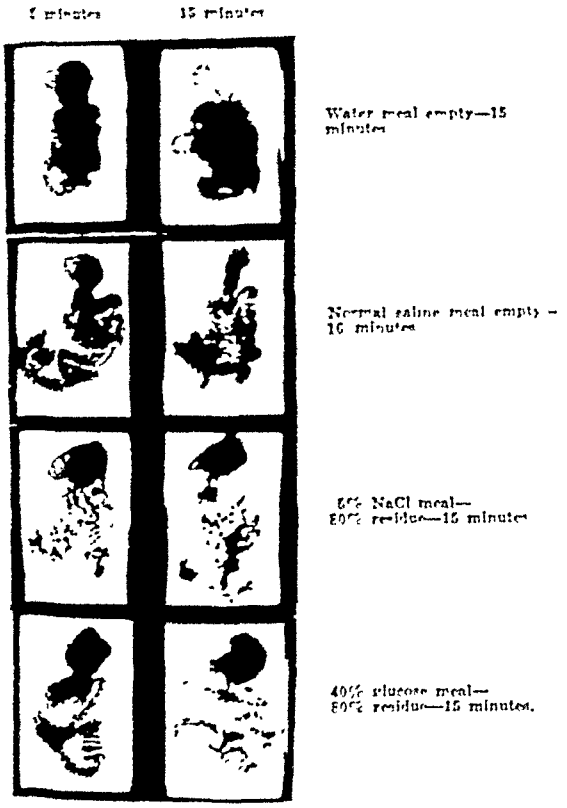

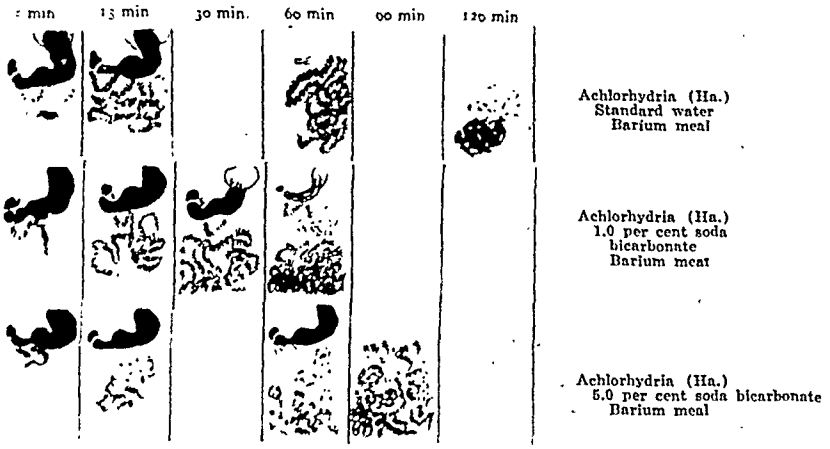

Fig. 4. Effect of osmotic pressure changes in stomach after polya operation.

is also true after the duodenal instillation of the 1% bicarbonate. The 5% bicarbonate solution, however, adds physical factors not offset by the acid neutralization, so that a marked effect on motility is seen even in the normal acid patient. This is especially true when the bicarbonate is instilled directly into the duodenum. Keeping in mind that the osmotic effect of the alkali will be altered by the rapidity of neutralization by the acid in the normal and hyperacid patient, any variations in motor effects will be readily explicable.

The behavior of the operated stomach, whether resected (Fig. 4 and 7) or following gastro-enterostomy (Fig. 3), was similar to that of the intact stomach, except for quantitative differences. The resected stomach, as previously reported (2) for acids, alkalies, and fats, responded to changes in osmotic conditions in the intestines identically as the intact stomach, except that a similar stimulus produced a less marked effect in the operated patient than it did in the non-operated. The behavior of the gastro-enterostomized stomach was similar to that of the resected type. Ravdin, Pendergrass, Johnston and Hodes (8) have observed roentgoenographically the slow gastric evacuation of hypertonic solutions in both dog and man with intact gastro-intestinal tracts, as well as after gastric operations. Probably the earliest detailed studies of the role of osmotic pressure upon gastric emptying were those of Carnot and Chassevant (9, 10) in 1905. In duodenal fistula dogs they found that isotonic solutions of saline or glucose produced a series of pyloric openings which permitted the solutions to course very rapidly by successive jets from the stomach into the intestines without undergoing great modification. If, however, the solutions were appreciably far from isotonicity, the contact of the first portion of the liquid with the duodenum provoked

Response of *achlorhydric* stomach to test substances using mouth meal.

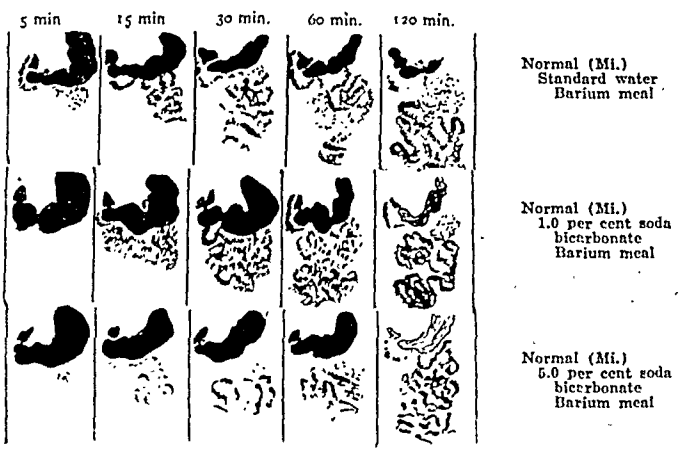

Fig 5

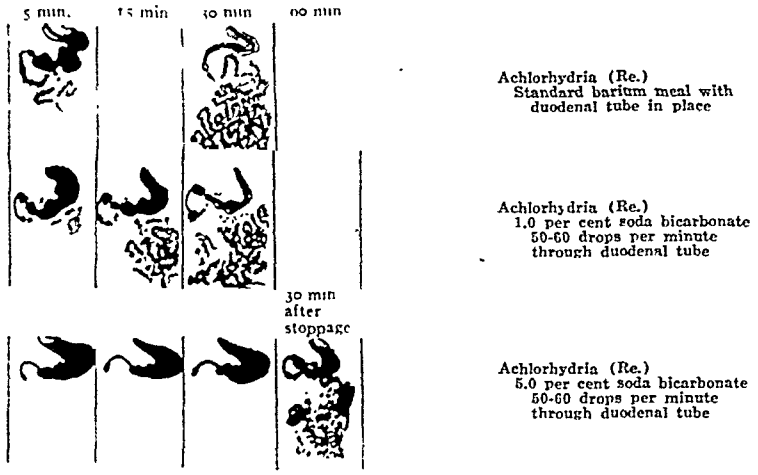
Response of *normal* stomach to test substances using mouth meal.

reflex closure of the pylorus, which did not reopen until proper dilution of this portion had taken place.

More recently McSwiney and Spurrell (11) very carefully studied the influence of osmotic pressure on the emptying time of the stomach. They made very searching calculations of the relationship between the degree of osmotic pressure change and the delayed gastric emptying and concluded that relatively small changes in the former caused very marked delay in the latter. Johnston and Ravdin (3) have stressed the influence of varying concentrations of glucose on the emptying of the normal and operated stomach.

The rapidity with which pyloric closure and cessation of gastric evacuation follow the duodenal instillation of hypertonic or hypotonic solutions, makes the reflex closure suggested by Carnot and Chassevant (10) and later by Wheelon and Thomas (12), a likely explanation for the mechanism involved. Yet the results obtained by Quigley, Zettleman and Ivy (13) in dogs with completely denervated entire stomach pouch preparations, and by Quigley and Phelps (14) with auto-transplanted denervated pouches make a consideration of a humoral factor in the dog at least essential to the understanding of the duodenal mechanism in gastric motor control.



CONCLUSION

For the same reasons that we concluded the pyloric action was motivated locally through duodenal stimulation by chemical action, we conclude that this same mechanism is influenced by physical stimuli as represented by changes in osmotic pressure away from isotonicity. Gastric emptying time alone cannot be used as an index of pyloric function when considering osmotic tension of agents given by mouth because of the migration of fluid which takes place through the stomach wall when the test meals are not isotonic.

We should again like to draw attention to the necessity of considering the type of test meal when measuring gastric motility. Roentgoenologists, especially, must realize that no comparison of gastric motor data can be possible, if the test meals vary either in chemical or physical composition.

DISCUSSION

DR. HARRY SHAY (Philadelphia, Pa.): The first question regarding the position of the tube in different portions of the intestinal tract—we have studied the effect of intestinal instillation of various agents into the duodenum, upper and lower, and into the jejunum as well. The further you get away from the pylorus, the less marked is the effect of similar stimuli.

We are in accord with the concepts of Dr. Thomas and Dr. Quigley, but I am afraid we can't agree to disregard the rôle of the hydrochloric acid in the mechanism concerned. We believe that the hydrochloric acid is the normal intrinsic agent that activates this mechanism, but that other agents added by foods may be equally efficacious. This brings us to some of the points raised by Dr. Eusterman and will explain some of the things that he discussed. We have in previous publications reported the effects of acids and alkalis by mouth and by duodenal instillation. We have there shown that we could radically change the motor function of an anacid stomach by changing the ingested meal from tap water to only .09% hydrochloric acid. I think in this lies the answer to the good clinical results seen from the administration of what chemically are certainly inadequate doses of hydrochloric acid. The good result being an effect on the gastric emptying and a changed intestinal picture. We feel that

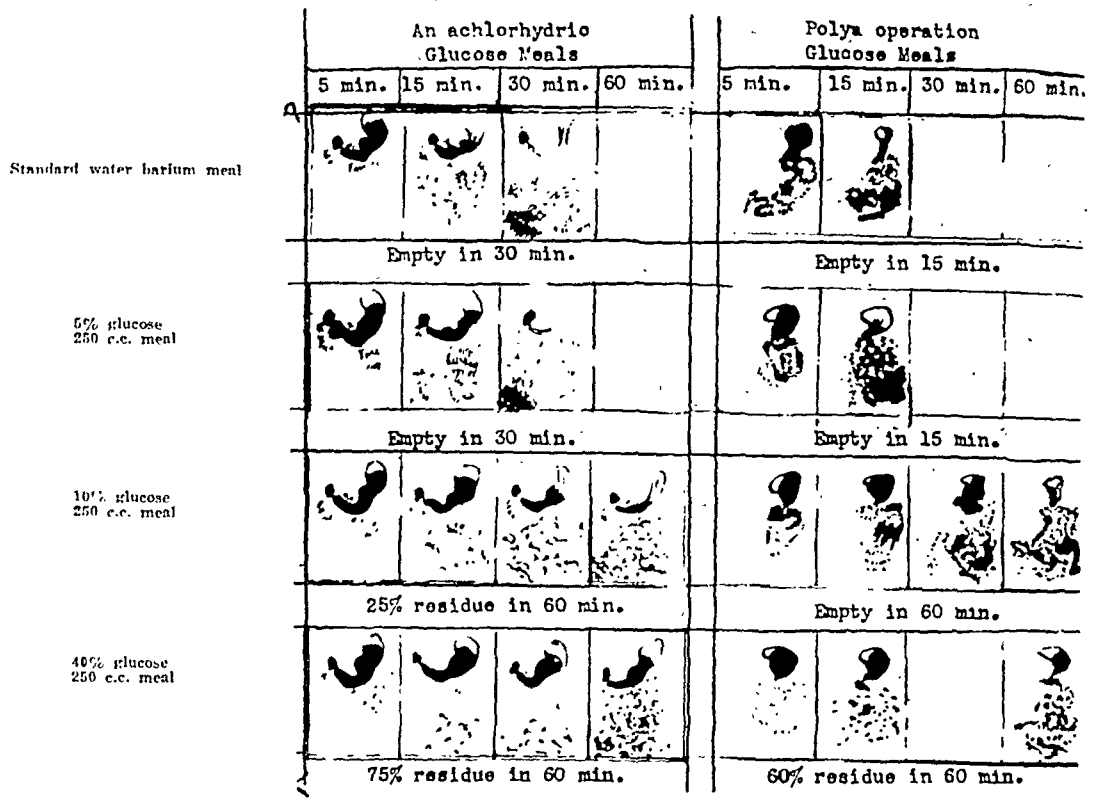

Fig. 7

gastrogenous diarrhea may in many instances be an expression of the rapid gastric emptying.

Regarding the cryoscopic index in the discussion of Dr. Rehfuss, we believe that this again is an expression essentially of the thing we talked about today; namely, the changes in osmotic pressure. We are, in the main, in agreement with the discussion of Dr. Necheles, but he, too, favors disregarding the hydrochloric acid as a factor in the mechanism. To this departure, certainly from a clinical standpoint as well as from our own experiments in the human subject, we cannot subscribe.

DR. J. PAUL QUIGLEY (Cleveland, Ohio): We have been carrying out some experiments which have a direct bearing on the material presented by Dr. Shay. Working with dogs, we have employed the balloon method; individual balloons inserted in the pyloric antrum, pyloric sphincter, and the duodenum by the method of Dr. Thomas which I think is familiar to all of you. With this technic, we have found that hypotonic solutions (represented by distilled water), or hypertonic solutions (represented by 2 per cent sodium chloride solutions), when introduced in the *stomach* had no effect on the three regions mentioned.

When these solutions were introduced in the *duodenum*, they did modify motility, but they always depressed the motility of the stomach, the sphincter and the duodenum. This depression was never very marked, so in comparison with fats and other substances we have investigated, I feel that *modifications in isotonicity are not very important.*

Dr. Thomas' statement that food products actively influence the pylorus and adjacent structures is quite in line with our findings. We are also in agreement with his observation that hydrochloric acid is of less importance. We have introduced at frequent intervals small quantities of hydrochloric acid into the duodenum while recording motility from the pyloric antrum, sphincter, and duodenal bulb. When quantities of 2 c.c. of 0.2% acid were employed practically no significant change occurred in the motility of these structures. If we used larger quantities or higher concentrations (beyond the limits which we consider physiological) we obtained inhibition.

I do not feel that hydrochloric acid is important in controlling the sphincter, antrum or bulb. So far as such studies as we have made can be employed for the interpretation of gastric evacuation mechanisms, hydrochloric acid or moderate variations in osmotic tension of solutions is probably not particularly important in regulating the gastric emptying process.

DR. GEORGE B. EUSTERMAN (Rochester, Minnesota): Several authorities have recently challenged the statement that the achlorhydric stomach does not empty any faster than the one with normal acid content. It has been our experience that the former does empty more rapidly in the majority of cases, granting there is no marked disturbance in the tonicity of the organ and no mechanical obstruction. Some years ago Wheelon, by physiologic studies on the experimental animal, showed that nausea and vomiting are the result of duodenal antiperistalsis. By increasing the pH of the duodenal content he was able to prevent, or reduce, this reversal of peristalsis, with subsidence of nausea and vomiting. He largely achieved this by the addition of hydrochloric acid or sodium chloride. Under certain conditions I have found this chloride or acid therapy to be effectual, and I would like to ask the essayist whether his observations in this field have any bearing on the management of some of our ordinary daily clinical problems.

DR. HEINRICH NECHELES (Chicago, Ill.): We are conducting some experiments just now on the emptying

time of the stomachs of dogs, which I think confirm and complete the observations of Dr. Shay and Dr. Thomas, and Dr. Quigley. We were not satisfied with the small doses of hydrochloric acid that are given (ten to twenty drops of 0.5 per cent solution). We acidified the barium-meal, so that we brought it down to a pH of two to three, or we alkalinized it and we found in a great number of experiments on dogs that this had practically no influence on the emptying time.

On the other hand, I want to remind you of some older work by Kestner and Never, who showed that rather dilute concentrations of hydrochloric acid produce contractions of the intestine. They demonstrated this in a very simple experiment. They took the small intestine of a guinea-pig and perfused its lumen with a very dilute solution of hydrochloric acid—I think it was between N/30 and N/50. There was a marked delay in the passage of this solution as compared to Ringer's solution.

DR. RALPH C. BROWN (Chicago, Ill.): I should like to ask if it made any difference what position the tube was in, whether the tip of the tube was in the first or third portion of the duodenum and as to whether any observations were made on this point.

DR. J. EARL THOMAS (Philadelphia, Pa.): These observations and previous observations of Dr. Shay along the same line are of great interest to the physiologist. They emphasize something which is becoming very important, namely, that substances other than hydrochloric acid can influence the emptying time of the stomach.

The knowledge of such substances is increasing rapidly. We can include fat, which has been known for a long time; carbohydrate, and as shown this morning, hypertonic and hypotonic solutions. Recently it has been observed that the products of protein digestion when placed in the intestine inhibit gastric motility; thus we have included all the three types of food among the materials which, when present in the intestine, may delay gastric emptying.

Why are we interested in substances other than hydrochloric acid? Evidence is accumulating that hydrochloric acid seldom reaches the intestines in quantities adequate to influence gastric motility. I believe it was Dr. Carlson who first remarked that free hydrochloric acid is hardly ever found in the duodenum. pH 3.6 represents the minimum acidity attained in the duodenum even with the foods that develop the greatest acidity. Some incompleted experiments of ours tend to show that the threshold acidity for inhibiting gastric emptying is around pH 2. Those of you familiar with that notation realize that between pH 2 and pH 3 there is a difference of about 1000 per cent, so that it is difficult to believe that in the normal stomach following an ordinary meal gastric emptying is regulated by hydrochloric acid in the intestine, as we have so long believed. It is very useful, therefore, to find these other substances which are capable of inhibiting gastric motility and thus of regulating the emptying of the stomach.

I think we can say now that the bulk of physiological evidence indicates that the products of digestion and the food substances themselves are the main factors in the regulation of gastric emptying by means of stimuli arising in the small intestine.

DR. J. EARL THOMAS (Philadelphia, Pa.): I want to ask whether the motility recorded was peristalsis after meals or merely hunger activity.

A Theory on the Formation of Peptic Ulcer*

By

H. NECHELES, M.D., Ph.D.
CHICAGO, ILLINOIS

THE newer knowledge that stimulation of parasympathetic nerves liberates acetylcholine, and the discovery by Dale and Feldberg (1) that stimulation of the gastric vagus results in the appearance of acetylcholine in the venous blood from the stomach has opened a new approach to the problem of the genesis of peptic ulcer. Although acetylcholine dilates peripheral blood vessels the effect of minute amounts of this substance on the circulation of the stomach had to be investigated. This was done by us on arteries, veins and capillaries isolated from fresh human stomachs as well as on rats' and dogs' stomachs (2-4). It was found that acetylcholine produces a diminution of flow through isolated vessels. In perfusion experiments on the rats' stomach acetylcholine practically always effected marked vaso-constriction while controls, namely the legs of the same rat, responded with vasodilation to the same quantities of acetylcholine. In order to test an animal whose stomach resembles more the human one, the dog was used. The stomach of one animal was viviperfused by another larger dog and blood flow through that stomach was measured. In another series of experiments the stomach of a dog was prepared so that the blood flow through the gastric vein could be measured. In a third series of dogs oncometry of the entire stomach was performed. The results showed that in the greater number of experiments small doses of acetylcholine comparable to those liberated when the vagi are stimulated, produce diminished blood flow through the stomach, the diminution amounting to from 60-96% in some of the experiments (4). We may conclude, therefore, that over-production and, more particularly, a continuous production of acetylcholine in the stomach will produce an anoxemia of its tissues. Such an anoxemia will be more severe in those regions in which most branches of the vagus nerves are distributed and will be more fateful in such parts where end arteries occur, namely, on the lesser curvature of the stomach and in the duodenal bulb.

Devitalized gastric and duodenal tissues are digested rapidly by the gastric and duodeno-pancreatic juices. We have found that these tissues are dissolved also by weak HCl and sodium bicarbonate solutions without the presence of enzymes (unpublished). In experiments on frogs we have seen that alternating exposure to active trypsin and pepsin solutions effects

*Presented at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7-18, 1937.
From the Michael Reese Hospital, Chicago, Ill.

much faster and much more thorough digestion than active pepsin alone (7).

In the light of the experiments and facts cited above, one might expect to obtain the greatest incidence of ulcers in the duodenal cap and next to it on the lesser curvature, where alternating exposure to active trypsin and pepsin takes place regularly, where at the same time end arteries occur and where most branches of the vagus nerves are found, i.e., where most acetylcholine is produced.

A fundamental question in the above theory is whether persons with peptic ulcer really produce more acetylcholine in their stomachs than normal persons. Many facts support this assumption. Acetylcholine is able to produce powerful contractions of the stomach and intestine as well as acid secretion of the stomach (4-6, and unpublished experiments). Gray, from Ivy's laboratory, reported in Memphis (16) that small amounts of acetylcholine raise gastric acid secretion and that larger amounts suppress it. In a number of tests on Heidenhain dogs we have been able to confirm Gray's findings against those of the Boston group (17). In addition to this, we have found that acid secretion produced by histamine is first stimulated and then decreased by acetylcholine.

Confirming Winkelstein we have shown that patients with duodenal ulcer have a higher appetite secretion than normal subjects (8, 9). This points to greater vagus effect in ulcer patients. A higher and more constant acid secretion after meals and during the interdigestive phase, that is, during the night points to the same fact. Hypermotility of the stomach, which we have found even in ulcer patients after sub-total gastric resection, and which we find is more or less common to all patients with duodenal ulcer may be due to a greater activity of the vagus or of Auerbach's plexus (10). We have not found a change in dermographic reaction time in ulcer patients as reported by others but we do find a jump in the dermographic reaction time around the age of 30 which may point to capillary changes at this age, at which period, coincidentally, ulcer begins to occur more frequently (11).

One fact, which we find difficult to class with the above consideration, is our finding that peptic ulcer patients secrete less saliva to pilocarpine stimulation than a comparable group of normal subjects (13). This is somewhat opposed to the findings of Winkelstein (14). It is probable, however, that in persons with peptic ulcer only certain centers in the mid-brain may be hyperactive and others not. It also may be that the overactivity in one center may depress other centers. The above observations favor the concept of "autonomic imbalance" in ulcer patients.

It may be unnecessary to add that most ulcer patients are persons of the worrying and high strung type. A fact that favors the assumption of a constitutional factor in peptic ulcer can be seen in our results on the gastric secretion in the normal relatives of ulcer patients (12). In 82 such healthy male and female relatives of ulcer patients not having any gastro-intestinal complaints, distinctly low values for free acid were found after an Ewald meal while the residue of the fasting stomach in the greater number of instances, contained a high degree of free acid. From these findings the question arises whether peptic ulcer begins as a gastritis and whether the hyperacidity of the duodenal ulcer develops later.

There is another question, namely, whether the decreased amount of visible mucus which we have found after pilocarpine stimulation in persons with duodenal ulcer (15) as well as the decreased amount of dissolved mucus which Fogelson reported in ulcer patients is due to an accompanying gastritis or to the effects of acetylcholine on the mucus glands of the stomach. This is under investigation.

With regard to ulcer therapy not much can be said at present except this: The only two agents known to counteract acetylcholine effectively are acetylcholine esterase and atropine. The concentration of acetylcholine esterase in the blood has not been found to be diminished significantly in peptic ulcer. It is a rather constant value and apparently changes only in wasting diseases. We have found one organ which secretes it in large amounts, namely, the pancreas, but pancreatectomized dogs did not show a diminished blood esterase and in acute experiments loss of pancreatic juice after secretin stimulation did not effect the esterase level of the blood (18). Yet if one could find means of raising the concentration of esterase in the blood it might be very much worth while to try this on persons with peptic ulcer.

Concerning the use of atropine in the therapy of peptic ulcer, it is apparent that if this drug is expected to relieve vasoconstriction possibly existing in the stomach of ulcer patients it must be given in such a way that it is effective for 24 hours of the day, a problem which does not seem to be unsurmountable.

CONCLUSION

I want to say that I have not put forward the above theory for the sake of itself, but because many experimental facts speak in its favor and because it may lead us further in the field of research and therapy. I gratefully acknowledge the help of my collaborators, whose names I have not been able to mention in this short account of our work.

DISCUSSION

DR. EDWARD S. EMERY (Boston, Mass.): This theory which Dr. Necheles has put forward certainly deserves serious consideration because by it one can correlate many clinical and laboratory findings. It involves two problems, one the pharmacology of acetylcholine; the other, clinical observations. So far as the pharmacology is concerned, I do not feel capable of discussing it. I talked to some of the pharmacologists before coming down here and there seems to be some difference of opinion as to the normal concentration of acetylcholine in the body.

So far as the clinical side is concerned, I can agree with what the speaker has said concerning the increased secretion in patients with ulcer.

I should like to say just a word about the neurogenic theory. It seems to me that clinically we should be cautious as to how we interpret our findings. The neurogenic theory has received great impetus in recent years as a result of Harvey Cushing's statements, but nervousness is a complication of any chronic disease. When one talks with the asthma or the arthritic specialists, they speak also of nervousness as one of the important complications of the disease in which they are interested. We know that the gastric acidity plays a definite role in peptic ulcer, yet it is often difficult to evaluate the influence which the acidity exerts on the behavior of an ulcer in any one patient.

The same is true of nervousness. It is undoubtedly true that nervousness is a common cause of the recrudescence of symptoms in these patients, but we see a not inconsiderable number who are not unusually nervous. Therefore, with our present evidence, it is impossible to say that peptic ulcer is a neurogenic disease.

For the last few years we have tried, because of the work of Williamson and Mann and other experimentors, feeding ulcer patients with bile, without any success. More recently we have been trying feeding raw pancreas to these patients. To date the number of cases is very small, but so far we have not been able to demonstrate any value from this treatment.

DR. B. M. BERNSTEIN (Brooklyn, N. Y.): For the past two years Dr. Matzner and Dr. Windwer, in our department have been working on the production of experimental ulcer in the rat. My participation has been that of an observer and adviser. A number of important facts have been brought out which we are continuing to study and hope to present at a future time.

In the first place we produced ulcers in the rats by feeding and starving on alternate days. We found when we fed the rats hydrochloric acid in excess on the fasting days, we produced ulcer lesions in 10 per cent of the rats. When we gave pepsin, we found in the same way lesions in 85 to 90 per cent of a large number of rats. The problem arose as to whether we couldn't prevent the formation of these ulcers by in some way inhibiting the effect of pepsin.

We first thought we would use the ordinary food stuffs and this is most interesting, particularly in the light of Dr. Shay's paper. We found that when we fed these rats on the fasting days, fat or olive oil, and on other days carbohydrate as glucose solution, and other days on other group rats, protein, the following findings appeared: The rats that had fat with the pepsin and hydrochloric acid, developed ulcers in 70 per cent of the number used. Those with glucose developed ulcer in about 50 per cent; and those with protein developed them in a small percentage of cases.

How to evaluate these findings is rather difficult because we have several factors to deal with. Shall we say that the protein simply absorbed the pepsin, and in that way inhibited its action? That is one possibility. Hypoproteinemia can produce ulcers as has been shown by other workers.

Another theory comes to our minds this morning in the light of this paper and that is that fat and carbohydrate retard the emptying time of the stomach; protein apparently does not and, therefore, permits the pepsin to get in its effect over a longer period of time and produces ulcers more frequently and more routinely.

We haven't started yet on our clinical work. We hope to do so in the fall.

DR. GEORGE B. EUSTERMAN (Rochester, Minnesota): I feel that modesty should characterize any discussion of the pathogenesis of ulcer, for after all we may not know anything about the real fundamentals. The mechanism of its formation is somewhat more clear. What actually starts it and destines the acute lesion to become a chronic one still remains obscure. However, the Society is to be congratulated on having such competent workers and members as Doctors Necheles, Shay, Ivy, Mann and others, present the results of their investigators for our elucidation and consideration.

In discussing the problem of etiology with one of my associates, Doctor Mann, who has done such fruitful work in this field, one soon realizes that he is not a proponent of the vascular theory of ulcer genesis, which I think originated with Virchow. In Mann's extensive experimentation on animals he never was able to produce a chronic ulcer by interfering with the arterial supply to portions of the gastric mucous membrane, even though such interference was often very extensive. On the contrary, he maintains, and his results plainly show, that such lesions begin on the mucosal side, the result chiefly of chemical and mechanical factors. No work has been so outstanding or so generally accepted as that of Mann and Williamson in this respect, and other investigations by his colleagues of a similar nature.

One other successful way of producing the chronic lesion experimentally is by the injection of toxic doses of cinchophen. But such procedure is more or less out of line with human experience, and surely the latter is a constant reminder of the overwhelming importance of the acid or chemical factor in ulcer genesis, irrespective of how it may be brought about. This combination of maximum concentration, spasm, hypersecretion and concomitant retention of secretions through spasm, is the great mischief maker in the majority of cases, to my way of thinking. In this connection proponents of the psychogenic theory, that is, the effect of certain emotions on visceral function mediated by the sympathetic nervous system, have an increasingly strong argument. But the experimental physiologist, like Mann, will strongly disagree with you as regards the importance of the vascular role in ulcer genesis.

DR. HEINRICH NECHELES (Chicago, Ill.): As to the question asked by Dr. Emery about concentration of acetylcholine in the body, there is probably no acetylcholine whatsoever in the circulating blood except when the esterase is inhibited, which probably does not occur under physiological conditions.

Apparently the main point in this question is whether at the focus of production the acetylcholine is active or not, and I am convinced that it is, that the blood cannot destroy it as fast as it is produced at the endings of the vagus nerves. If we inject acetylcholine intra-arterially, we obtain violent contractions, in fact, the most violent contractions of stomach and intestines. If we give it intravenously, there are hardly any contractions, hardly any effect, except when we give it continuously and in huge doses, because it is destroyed so quickly.

As to the question of sympathicotonus, I think that we may favor the concept of autonomic imbalance; that is to say, a prevailing effect of the vagus center, either in the way of lack of inhibition or of overactivity, and I think that this view is sustained by a number of experiments which I cannot mention now.

Gastric acidity in ulcer, as I tried to explain, probably plays a small role, because, first of all, we know that ulcers may heal while gastric acidity is very high, or that ulcers may develop in patients with a very low gastric acidity. Very little acid and very little pepsin are needed for digestion of a devitalized spot in stomach or duodenum.

To Dr. Bernstein's argument, I agree, except that the rat has a pro-stomach and a stomach, and that it is difficult to draw conclusions from most animals except the dog and monkey, because the stomachs are so different. I was well aware of this difficulty in the question of hyperacidity of duodenal ulcer and the normal or subnormal acidity of gastric ulcer which Dr. Winkelstein mentioned. I did not want to go into it because it would take too much time. I just want to mention the possible effects of an accompanying gastritis as well as reflexes from the duodenum or from the lesser curvature which may explain such differences. I am not convinced yet, however, that duodenal and gastric ulcer are produced exactly by the same causes, although my experiments tend to indicate this.

Dr. Eusterman mentioned experiments which have been done long ago. I know the literature on ligation of arteries to the stomach of the dog. I think when we deal with end arteries, ligation of the big branches which we can get on the lesser and major curvature will not teach us very much because there are sufficient collaterals before the end arteries. Besides, I do not know of any work that shows that vascular-anatomic conditions in the dog's and in the human stomach are the same. Maybe Dr. Eusterman can answer that.

Dr. Rehfuss's work has interested me very much. I didn't know some of the facts, and I will be very much interested to consider all this.

In conclusion, I should like to mention one more fact which I forgot to bring out. The group of workers in Boston have shown that injection of mecholyl inhibits gastric acidity. A worker from Ivy's laboratory has reported that small doses given continually produce high acid secretion of the stomach and larger doses inhibit secretion. We have been able to confirm this latter result in a great number of experiments, and we have found that histamine increased the volume of this secretion, and then depressed it, a fact which may be of some importance in the physiology of secretion.

Again in conclusion, I want to stress that I have not put out this theory as a proven thing but rather as a guide to further research on the physiology and on the pharmacology of duodenal ulcer.

DR. ASHER WINKELSTEIN (New York, N. Y.): Dr. Necheles's ingenious hypothesis brings up a possible explanation both for the decrease in the resistance of the tissues to ulceration and the increase of the acid. His idea would explain both factors simultaneously.

I should like to discuss briefly the acid factor. I have demonstrated that in duodenal ulcer the psychic or nervous secretion, produced by the chewing of an orange, is very high as compared to normals.

There is a marked difference in this respect in duodenal ulcer and in gastric ulcer. It is well known that a high percentage of duodenal ulcer patients have hyperchlorohydria; gastric ulcer patients on the other hand have a low or normal acidity. This striking difference has to be explained. Either the two diseases are different or two different mechanisms may be involved.

Dr. Ivy has performed some interesting experiments in dogs. If he cut the sympathetics and gave a rough diet, he got marked hypermotility with a dumping action into the duodenum and duodenal ulcer. When the vagus was cut, stasis in the stomach occurred followed by a gastric ulcer. It would prove interesting to study the difference in constitution in both types of ulcer. We know that gastric ulcer rarely occurs in the hypersthenic stomach.

If you do a partial gastrectomy in a patient with a duodenal ulcer who has a high acidity before the operation, in approximately half of the cases free hydrochloric acid persists and recurrent ulcer occurs in 3% of these acid cases. If you add anterior vagotomy to the partial gastrectomy in duodenal ulcer patients who have a high acidity before the operation, you get an achlorhydria in nearly 100 per cent of the cases and no recurrences.

In sixteen out of nineteen cases who had this operation, i.e., vagotomy plus partial gastrectomy, performed by Dr. A. A. Berg, we found an achlorhydria which persisted throughout the follow-up period of 5 to 9 years.

Peptic Ulcer Emergencies

A Study of Massive Hemorrhages and Acute Perforations Treated During the Diagnosis of 916 Private Cases Suffering from Peptic Ulcer*

By

JOHN M. BLACKFORD, M.D., ALFRED L. SMITH, M.D.
SEATTLE, WASHINGTON
and
DEAN H. AFFLECK, M.D.
TWIN FALLS, IDAHO

A REVIEW of representative recent literature (2, 4, 6, 7, 8, 10, 11, 14, 15) shows that in patients admitted to large charity hospitals because of hemorrhage from peptic ulcer the mortality rate varies between 15 per cent and 30 per cent. Goldman's (15) recent report from the San Francisco General Hospital gives a mortality of 15 per cent.

A few variations of this mortality rate are noted: Finsterer (14) of Vienna, reports a mortality rate of 5 per cent following emergency surgery on all bleeding ulcers; Gordon-Taylor (12) believes that many patients should be operated upon during acute bleed-

*Read at the Annual Meeting of the American Gastro-Enterologic Society, Atlantic City, June 7, 1937.
From The Mason Clinic, Seattle, Washington.

ing and reports a lower rate following operation than with medical treatment; Lahey expects a 5 per cent mortality from hemorrhage; and Hurst (13) reports a mortality of 4.8 per cent from Guy's Hospital; he states "the danger of hemorrhage from ulcer has been grossly exaggerated in a number of papers recently appearing in British Journals." Hurst feels that in private practice the mortality from hemorrhage is between 1 and 3 per cent.

The extremes of opinion seem to be shown by (1) Finsterer (14), who feels that immediate operation for bleeding ulcer is always indicated and that no case should be refused immediate operation on account of exsanguination, and (2) Hurst (13), who feels that operation is never indicated, or should be reserved for "very rare cases." In his series one case was operated upon and the result was fatal. Between these extremes are many opinions, but a review of articles shows that immediate emergency surgery is rarely undertaken. The idea is repeatedly recorded that cases which will result fatally cannot be separated by clinical evidence from those that will survive; and that surgical mortality is much higher than that from medical supportive treatment; hence, we should not increase mortality by emergency attempts at surgical control of hemorrhage.

Such wide variety of opinions has led us to investigate the private patients at The Mason Clinic and the Virginia Mason Hospital. Our Clinic consists of a group of men in private practice who exclude the fields of obstetrics and pediatrics.

This report is based upon the study of 916 patients on whom the diagnosis of peptic ulcer was made, using all ordinary methods for diagnostic study and laying great emphasis on clinical history and roentgenologic findings. As formerly reported (1, 3), we feel confident in a diagnostic accuracy approaching 95 per cent.

The Clinic has examined approximately 65,000 patients during the time these ulcer cases were collected, an average ulcer incidence of 140 per 10,000 (1.4 per cent). However, the incidence of acute perforation is approximately 9 per 10,000 (.09 per cent); of massive hemorrhage it is 5 per 10,000 (.05 per cent); and of fatalities from hemorrhage from peptic ulcer it is 1 per 10,000 (.01 per cent). These figures justify the frequent assertion that many busy general practitioners have never seen a fatal ulcer hemorrhage and hence consider that the mortality rate must be very low.

The 916 cases have been recently tabulated in great detail; and from them we have segregated those (1) with a history of previous gross hemorrhage, (2) with active massive hemorrhage and, (3) with acute perforation.

HISTORY OF HEMORRHAGE

I. One hundred sixty-two cases, or 18 per cent, have a history of previous hemorrhage. Less than half have had severe clinical ulcer symptoms, and in the large majority the gross hemorrhage has not been a critical affair. Not infrequently hemorrhage has been the first definite clinical symptom of ulcer that has made the patient consult a physician. Recurrent hemorrhages are frequently noted. A tabulation by age at the time of the first hemorrhage shows that 75 per cent of first gross hemorrhages occur under the age of fifty.

MASSIVE ACTIVE HEMORRHAGE

II. Massive active hemorrhage has brought thirty-six of these patients to the hospital, twenty-two with their first hemorrhage. These patients do not include all admissions with active bleeding, but only those that have had severe symptoms from loss of blood. The active massive hemorrhages have occurred in cases with relatively mild clinical histories in more than half; and have occurred in a relatively or absolutely quiescent period in the great majority. Yet in the six fatalities (18 per cent) which occurred from hemorrhage while in the hospital three were having severe ulcer pains. Two of the six patients died with their first hemorrhage.

Age seems to be the greatest factor in mortality from hemorrhage. Of thirty patients surviving active hemorrhage, twenty-two were under the age of fifty years. Of six fatal cases, three were under fifty years old, and two of these were surgical deaths not due to

hemorrhage. Of six fatalities in the hospital from hemorrhage, four were due to loss of blood; and three of these patients were above fifty years old.

ACUTE PERFORATIONS

III. A few years ago we reported before this Society (5) our experience with acute perforations of peptic ulcer. Large series of cases suffering from acute perforation had been reported by various other

observers. General agreement is found that immediate emergency operation is indicated, that the operation within the first twelve hours carries a low death rate, and that closure of the perforation apparently is followed by a cure of the disease in many of the patients who survive operation.

We now have treated sixty-two perforations. Two-

62 Acute Perforations	41 during quiescent symptoms
	21 during active symptoms

4 only with previous diagnosis

thirds of acute perforations occurred during silent periods of ulcer symptoms. Massive hemorrhage has occurred at the time of perforation in only three instances. Four patients out of sixty-two had been previously diagnosed or treated for ulcer. Twenty-five were below fifty years of age, thirty-seven above fifty; and we are unable to say that the patient's age has made any definite difference in surgical mortality. The sex ratio was fifty-six males to six females, again showing the infrequency of acute perforation in women.

GENERAL CONSIDERATIONS

These findings have led to considerable thought in an attempt to recognize the clinical type of peptic ulcer that is likely to cause critical hemorrhage or to perforate.

Mann's studies on experimentally produced chronic duodenal ulcers of dogs are most enlightening. He finds two types of bleeding: First, in the healing of an ulcer the epithelium grows over the base of the ulcer, and is smooth and very loosely attached to the base — so loosely in fact that it is difficult without special precautions to demonstrate this epithelium at autopsy. The epithelium may be brushed off or even washed off under a faucet. In life this should be followed by bleeding in certain instances, a venous or granulation bleeding which should never cause critical loss of blood. Second, he finds that in an active ulcerating stage of experimental peptic ulcer the erosion may eat into the wall of an artery, technically known as *arrosion*, causing extensive or even fatal hemorrhage. Naturally Mann cannot evaluate the clinical subjective symptoms in the dog leading up to arrosion.

These two types of hemorrhage seem to us to offer a plausible hypothesis for what we see happen in certain patients. As already shown, the majority of recognizable hemorrhages occur in ulcer cases with milder symptoms; hypothetically it seems to us likely that these cases are milder because they are repeatedly and frequently healed. The "silent hemorrhage," so often seen and not so critical in younger people, occurs in a healed or healing stage. On the other hand arrosion bleeding should occur with active symptoms of ulcer. Hypothetically, silent hemorrhage should occur in a healed or healing stage and hence is likely to come at a time when the patient is not suffering clinical symptoms of ulcer. By contrast, if active symptoms are present at the time of hemorrhage, we should suspect arrosion and critical or fatal hemorrhage.

Actually we have found in our series that severe ulcer symptoms apparently precipitated massive hemorrhage in five instances, two of which were fatal. Arrosion, however, is clinically by no means confined to cases with active symptoms. Of thirty patients surviving critical hemorrhages, twenty-seven were relatively free from symptoms at the time that massive bleeding occurred. We have operated in two instances where a fatality seemed inevitable because of prompt recurrence of massive hemorrhage; and in both instances we feel that the operations were actually lifesaving.

The fatalities following surgery were all on cases treated for days, transfused repeatedly, and then operated. One death resulted from failure to control hemorrhage (age sixty-one), one from technical postoperative complications, and one from exhaustion with an acute postoperative psychosis. Finsterer feels that operative risk is greatly increased by delay for days of treatment and for transfusions, and then surgery undertaken before recovery of general health; our experience seems to coincide with his.

The most outstanding fact in this study seems to be that age is the first consideration as regards prognosis with massive hemorrhage; that any serious hemorrhage in a patient beyond fifty years old (and probably beyond forty-five) is a very dangerous symptom, nearly ten times as dangerous as in a patient under fifty years old.

Apparently a lesson may be learned from the Massachusetts General (7), where they believe that medical treatment is always to be given thorough trial in cases of massive hemorrhage — 138 critical ulcer hemorrhages treated with a 14.5 per cent mortality. Eight patients were, however, operated upon after "all hope had been lost for a spontaneous recovery," and all eight died. Manifestly that is not the way to handle such situations.

Acute perforations, according to our records, almost always occur (93 per cent) in those who have not even suspected ulcer or had symptoms serious enough to induce them to consult a physician or to take any kind of treatment. It seems clear that perforation of chronic duodenal ulcer through the anterior wall of the duodenum is far more common, and that such an ulcer produces very mild symptoms or none that are ascertainable. The usual perforation is essentially a "blow out," a very sudden and dramatic event. Only a small portion of acute perforations are the result of deep erosion and have massive hemorrhage from arterial bleeding from a branch of the pancreaticoduodenal artery in the posterior wall. Perforation of gastric ulcer is more likely to take place during active ulcer symptoms.

VITAL STATISTICS FROM SEATTLE

We have not found in current literature any clinical deductions regarding hemorrhage or perforation based on vital statistics. It seemed to us likely that efficient health department records might give valuable information.

In Seattle we have the King County Hospital with a tributary city and county population of nearly 500,-

000 people. The Hospital mortality rate during 1935 and 1936 from massive gastric hemorrhage from peptic ulcer was 20 per cent, and the Hospital has approximately half of all deaths from peptic ulcer recorded in the city and county. They have an active

VITAL STATISTICS FROM SEATTLE (400,000)

42 Massive Hemorrhage	11	31
20 Other Causes	10	10
	55	69

54 autopsies

autopsy service and for this reason we feel sure that vital statistics from Seattle are fairly accurate, and are proven by nearly 50 per cent autopsy records.

With the cooperation of the Seattle Health Department we have reviewed all death certificates for the years 1935 and 1936. These vital statistics show that during two years massive hemorrhage from ulcer was the assigned cause of death in forty-two instances, and acute perforation as cause of death in sixty-two instances, out of a total of 124 deaths attributed to peptic ulcer. The diagnosis was substantiated in fifty-four patients by autopsy.

The vital statistics show that thirty-one patients died without surgical interference for hemorrhage, and eleven patients died following surgical interference. Of the forty-two deaths, eight occurred below the age of fifty and thirty-four above the age of fifty.

The vital statistics also show that of sixty-two perforations, twenty-eight died medical deaths, thirty-four died following surgical intervention. Twenty-four of these patients were under fifty years old and thirty-seven were above fifty years old.

Interesting deductions may be made because, as we

VITAL STATISTICS FROM SEATTLE

have shown, gross hemorrhage is very much more frequently found under fifty years old, yet the death rate from hemorrhage in older patients is ten times higher. No such statement can be made in connection with age and acute perforations.

Ten patients died, according to death certificates, following operation in which neither perforation nor hemorrhage was recorded, and ten died from medical conditions which presumably were considered by the attending physician as the immediate cause of death, with peptic ulcer as the chief cause of death.

SUMMARY

Our studies then seem to indicate that in private practice in Seattle the immediate mortality rate from massive hemorrhage from peptic ulcer is 18 per cent—if all deaths are recorded—or 11 per cent if we exclude two postoperative deaths not due to hemorrhage. Much the greatest mortality factor is age, for deaths from hemorrhage under fifty years old are relatively rare; though our records show that most hemorrhages occur in patients under fifty.

Arterial disease must be the explanation of the remarkable importance of the age factor in the prognosis of massive hemorrhage. Younger arteries will contract much more efficiently; in older people with marked sclerosis it may be impossible for the artery to contract sufficiently to promote clotting and stop the hemorrhage. This probability may account for the hesitancy on the part of surgeons in operating on cases of massive hemorrhage, and in their uncertainty as to what procedure is best undertaken at operation. However, surgical procedures are not part of this discussion.

It would seem that conservative treatment is always to be instituted. However, if the hemorrhage is in an older person, and particularly if it recurs promptly in the presence of active ulcer symptoms, one should assume that arrosion has taken place. The mortality with such cases is very high—from the literature and from our experience about 50 per cent. *Prompt* expert surgical intervention will undoubtedly reduce this extraordinary death rate—yet intervention a few days later because of failure to improve with medical treatment, gives an average surgical mortality of 47 per cent in seventy-two cases, as shown by six representative institutions (2, 7, 8, 10, 11, and loc cit).

CONCLUSIONS

1. In private practice in Seattle the hospital mortality of massive peptic ulcer hemorrhage is 18 per cent—and if we exclude deaths not due to loss of blood, it is 11 per cent.
2. King County Hospital in Seattle shows a mortality rate of 20 per cent on admissions for massive ulcer hemorrhage.
3. King County Vital Statistics and our figures in private practice there show that age is the greatest factor in mortality from hemorrhage.
4. Most severe hemorrhages are likely to occur during quiescent symptoms of an ulcer.
5. "Bleeding ulcers don't perforate; and ulcer perforations don't bleed."
6. The majority of histories showing ulcer hemorrhage relate a relatively mild severity of clinical symptoms of ulcer.
7. Severe symptoms of ulcer leading to hemorrhage strongly suggest arrosion, and in an older person may indicate a life-saving emergency operation.

8. Emergency surgery has its place in the treatment of certain cases of massive gastric hemorrhage before "all hope is lost for spontaneous recovery."

9. The large majority of acute perforations occur during quiescent symptoms—and in patients who have never had severe ulcer symptoms.

The Differential Diagnosis of Gastro-Intestinal and Cardiac Disorders*

(The Alvarez Lecture)

By

PAUL D. WHITE, M.D.

BOSTON, MASSACHUSETTS

LIDDELL and Scott's Greek Lexicon gives the following definitions *Kardia*, heart, stomach, and *Kardiakos*, of the heart or stomach, dyspeptic. No wonder we have been confused ever since.

Neuburger of Vienna, the medical historian, in writing of the opinions of the Greeks and Romans in Galen's day and before quotes from their works as follows: "The sense of hunger depends upon cold and dryness and has its seat in the 'cardiac orifice' (the expression cardia or stomachos stands for the esophagus; the cardia was supposed to be very rich in sensory nerves and thus the starting-point of many morbid conditions)." Neuberger goes on to say that "the so-called 'morbus cardiacus'—frequently mentioned by the ancient medical authors, and probably a neurosis—was considered by Galen to be an acute illness originating in the stomach."

The opinions held through the middle ages are summarized at their termination by the great physician Fernel who in 1554 wrote his masterpiece of medicine. At the beginning of Chapter III of the sixth book of the section on pathology and symptoms Fernel said (I shall give the literal translation): "Many symptoms vex the ostium at the beginning of the stomach. Some of these result from the fact that this structure is endowed with an extraordinary degree of sensation and is connected with great affinity to the principal parts of the heart and to the brain. To these other organs indeed, it is generally agreed, it may communicate its troubles and provoke them in various ways: the heart to cause swooning, syncope, and pain which has been labelled cardialgia; the brain to cause lethargy, catalepsy, brooding, unsociability, melancholy, and delirium, the reasons and causes of all of which are adequately explained thereby." Fernel also said that palpitation and abnormalities of the pulse may be caused by indigestion, in particular excess of food or drink.

In 1749, Senac, physician to the court in Paris wrote "The stomach is one of the commonest causes of palpitations; but this cause is not always an immediate cause or one acting on the heart without other influences; it is sometimes only an incidental cause. If there is, for example, a lesion in the ventricles, in the auricles, in the vessels, or in some other viscera, if that lesion by itself causes palpitations, the stomach will be able to activate that other cause. When it is filled, for example, it pushes up not only the diaphragm and bothers the respiration but it also compresses the belly and the aorta. . . .

"But the nerves too can be put into action by the stimulation which follows the filling of the stomach"—and may induce palpitation. Also indigestion and bad food and gas can induce palpitation. Belching and passing wind may give quick relief.

Senac went on to say that certain foods may cause palpitation. Coffee may do so. "I know a man who is so attacked when he eats lentils; he resembles in this respect Malpighi whose heart was agitated when he ate peas or beans. Simon Pauli reports that he was affected by palpitations in the autumn when he ate raw apples." . . . "The intestines produce palpitations just as does the stomach; such symptoms arise sometimes after violent purgation. . . . Some persons feel violent beating in the region of the heart when the belly is compressed and are relieved when it is free. . . .

"Among the affections of the intestines which cause palpitations we can place hemorrhoids. . . .

"The liver, which is one of the great organs of the animal machine can without doubt excite palpitations. Its lesions may cause dyspnea and often give pain in the region of the clavicles and in the back and front of the chest. . . .

"The spleen was regarded by the ancients as the principal cause of palpitations; it was, according to them the seat of melancholy. The black blood, to which they gave this name, was formed, they thought in this viscerum whose use was unknown." Senac ended this discussion by noting that Willis more recently had discarded this idea but had blamed the splanchnic nerves instead.

In 1761 Morgagni had no knowledge of any direct relationship between pathological structural changes in heart or digestive tract but he did cite the case of a very old man who showed at autopsy both gall stones and an unsuspected calcified stenosed aortic valve.

Finally, to illustrate the very modern point of view that was held by James Hope of London, 105 years ago I shall read from the introduction of his important "Treatise on the Diseases of the Heart and Great Vessels."

*Read at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7, 1937.

"Again, there are few more common and certain exciting causes of palpitation and difficulty of breathing in disease of the heart, than derangement of the stomach. What happens to the patient in this case? Tracing the attack, in perhaps every instance, to a dyspeptic fit, he naturally concludes that the latter is the cause: that it is 'all indigestion.' 'Good air and plenty of exercise' are the remedies recommended: the result is an apoplectic seizure. The circumstance that before the introduction of the new mode of exploring diseases of the heart (auscultation), they could rarely be detected in their early stages, contributed to the error in question. For, as patients frequently recover from the early stages, the recovery was regarded by those who assumed this class of diseases to be incurable, as a proof that the affection was merely dyspeptic. Hence dyspepsia acquired the reputation of producing certain symptoms, particularly in the head, which are in reality foreign to it, being exclusively the results of a co-existent disease of the heart.

"There prevails another error, the converse of the above—that of mistaking nervous, or really dyspeptic palpitation, for disease of the heart. The frequency of cases of this kind, especially amongst men of studious habits, (and more particularly, I have noticed, among those of my own profession), is truly surprising; and, as it has always been considered difficult, and by many impossible to distinguish the two affections, the alarm created is sometimes distressing. Having thought this subject of so much importance as to demand a separate article, I shall here only say, that, so far as my own experience enables me to judge, the discrimination may be made with ease and certainty."

"There is scarcely a disease of the heart, accompanied with obstruction of the circulation for any considerable period, which is not productive of enlargement of the liver, and, sooner or later, of its ordinary consequence, abdominal dropsy. Yet there are few common facts in medical science less generally known than this intimate connection between the heart and the liver. The dropsy is ascribed to the latter; the treatment extends not beyond this organ; the unknown cause continues to reproduce its effect, and the patient, if he obtain relief at all, only obtains it to undergo a speedy relapse."

In recent years considerable advance has been made in the localization of activity of and sensation from the gastro-intestinal tract through the pioneer work of Walter Cannon and Walter Alvarez, in whose honor this lecture is named, and also through the work of your president, Chester Jones, among others. Among these studies has been the demonstration, particularly by Cannon, of the important effect of emotions on the action of the gastro-intestinal tract associated reflexly with disturbance of other organs especially the heart, but we have still much to learn about the details and inter-relationship of both cardiovascular and gastro-intestinal symptoms.

The differential diagnosis of gastro-intestinal and cardiac disorders is a subject of never-ceasing interest and importance. In the accumulation of experience one goes through a cycle of changing impressions. I can recall the assurance with which I started my own experience. There were handy rules to differentiate heart disease from stomach trouble and gall stones. But it was a time when we were acquiring much new knowledge and some of this was based on the errors we were making. I shall never forget being called in the summer of 1920 to see an elderly surgeon who was found to have an acute pericarditis, for some unknown reason complicating an attack of severe prolonged epigastric pain which had been diagnosed by himself and his medical friends as being the result of acute cholecystitis. Characteristic coronary T waves in electrocardiograms a few weeks later were ignored. It is easy now in retrospect, of course, to diagnose extensive myocardial infarction secondary to coronary thrombosis. Errors similar to that one shook our confidence in those days but gradually we regained our assurance in the course of the next decade by dint of careful analysis of clinical, postmortem, electrocardiographic, and X-ray studies. Several years ago we again felt masters of the situation but a few humbling experiences since then have indicated the folly of a cocksure attitude in doubtful cases, even with all the resources at our command at the present day. There are almost certainly rare cases in which a clear differential diagnosis between cardiac and gastro-intestinal disorders is impossible and likely to remain so, but our diagnostic acumen is still so amenable to improvement that it is bound to improve with further experience.

To illustrate some of the more common, important, and difficult problems in this field I shall cite briefly several cases that I have myself encountered.

Case 1. Esophageal pain or coronary insufficiency—which? A salesman, 37 years old, nervous and a heavy smoker, came to me complaining that for about ten months he had been occasionally troubled by a substernal burning sensation radiating equally to both shoulders, never very severe, lasting fifteen to thirty seconds and subsiding when he belched gas after taking a drink of water. This sensation usually came on when he was sitting quietly at home in the evening shortly after dinner, about once in two or three days. It never was induced by effort; in fact, exercise such as golf, stair-climbing, and even running seemed to help him. The reduction of tobacco from 20 cigarettes or more a day to 2 or 3 was attended by complete relief of his trouble. Otherwise he had been well. Physical examination, electrocardiogram, and fluoroscopic examination of the thorax revealed no abnormalities whatsoever. Much gas was noted fluoroscopically in the stomach and colon raising the left leaf of the diaphragm.

DISCUSSION

This story can be duplicated time and time again. Usually it is evident at once that the trouble lies in the gastro-intestinal tract and not in the coronary circulation, but occasionally careful study is needed clearly to determine the etiology, and rarely an erroneous diagnosis of angina pectoris due to coronary disease is made. The history alone usually suffices for diagnosis, but it is sometimes very helpful to have also electrocardiographic and roentgenological evidence.

There are three more common types or circumstances of esophageal pain. The most common is probably "heartburn," a burning sensation like that described in the patient noted above and due in many cases probably to the eructation of acid gastric juice or contents into the lower esophagus. The second is actual spasm of the esophagus at its lower end, the so-called *cardiospasm*, which may sometimes be seen roentgenologically when barium is swallowed. The esophageal peristaltic waves may be disturbed in their function, prolonged, or even reversed. The globus hystericus has been ascribed to the meeting of contraction waves traveling in opposite directions at the upper end of the esophagus. The third type of esophageal pain is the result of the pressure

of air or food entrapped in the esophagus as in aerophagia. Here there is the combination of the pressure of the esophageal contents and the spasm of the esophagus above or below. Air swallowing or cribbing is very common and may be observed in operation with relief of discomfort on belching up the air or in passing it on into the stomach.

In the differential diagnosis of coronary and esophageal pain the history of the occasion of the pain is of chief importance. The position and radiation of esophageal and gastric pain is likely to be the same as that of angina pectoris and even its character may be similar; as a rule however the pain of coronary insufficiency is that of a heavy oppression or choking (as indicated by the word angina itself, which means strangling) while gastric or esophageal pain is more often burning or sharp and is well characterized at times by the designation "heartburn." Either pain may be epigastric or low, intermediate, or high in position behind the sternum. Coronary pain is more likely to radiate into the left arm but often it doesn't radiate at all. Effort is almost invariably the exciting factor of the pain of coronary insufficiency, while eating is more commonly the occasion for the occurrence of esophagospasm or cardiospasm or heartburn. Also the excessive use of tobacco is especially likely to favor the occurrence of esophageal or gastric pain. Excitement may induce either type of pain, gastro-intestinal or coronary. A common accompaniment of the substernal pain of gastric origin at its termination is the belching or eructation of gas that attends the release of the spasm of the lower end of the esophagus or of the cardiac sphincter of the stomach.

Three further considerations are of great importance: First, the nitrites tend to relieve the pain of esophagospasm or cardiospasm as well as that of coronary insufficiency, though as a rule more slowly, and so are not a satisfactory therapeutic test for differential diagnosis. Second, quite often coronary insufficiency and esophageal irritation or irritability coexist in the same individual. The patient may have angina pectoris on effort and esophageal pain or "cardiospasm" after meals or an attack of angina pectoris may induce "cardiospasm" sympathetically with almost simultaneous relief of the two mechanisms by resting or nitrites. When such simultaneous occurrence and relief of the two conditions occur the case may be difficult of analysis; it is doubtless the apparent relief of angina pectoris by the belching of gas that has caused confusion and even led to the idea that the pain of coronary insufficiency is in reality wholly due to the "cardiospasm" that is induced reflexly by it. An especially observant patient who has both kinds of pain can usually distinguish between the two: this fact, the occasion of the occurrence of the pain, its character, and the fact that atropin or belladonna tends to prevent "cardiospasm" but not angina pectoris indicate that they are in fact two separate conditions. And third, an increased heart rate and more forceful heart action following food or certain drinks, especially coffee, tea, and alcohol, may readily be interpreted by the patient as painful; it tends, however, to be precordial aching rather than substernal oppression or burning.

We must remember that there are a number of different causes for pain in any part of the chest, superficial and deep. This includes the retrosternal region which is too often regarded by each specialist as his own particular province, by the cardiologist as the site of the angina pectoris of coronary insufficiency, by the gastro-enterologist as the site of esophageal or gastric pain, and by the pulmonary expert as the site of the pain of tracheal and bronchial disease or of mediastinal tumor. Almost any pathological change in the mediastinum can cause retrosternal pain which may or may not radiate to arms, back, or neck.

Before leaving this discussion, mention should be made briefly of the infrequent cases of esophageal ulceration, tumor, or diverticulum with pain high up substernally, closely resembling in site the angina pectoris of coronary insufficiency and likely to be wrongly diagnosed. The pain is, however, more related to eating than to exertion and more prolonged in its attacks. When in doubt careful fluoroscopic observation of the esophagus during the swallowing of barium and esophagoscopy should be carried out. Other causes of obscure retrosternal pain are that occasioned by a central diaphragmatic hernia and that occurring on swallowing by the esophageal obstruction caused by a congenital right sided aortic arch or anomalous right subclavian artery.

Case 2. Coronary disease with angina pectoris complicated by aerophagia and cardiac neurosis. A housewife, 55 years old, enters the hospital on April 13, 1937, with a history of having first noticed substernal oppression three and a half years ago when walking in the evening after eating. Associated with this there was "indigestion" characterized especially by the belching of gas. Upon resting and upon belching gas the substernal discomfort was relieved within a few minutes. One year later her mother died as a result of angina pectoris. Shortly after this the patient began to notice pain in the upper anterior chest in association with an increased amount of distension from gas and of belching of gas. The pain occasionally radiated to the left arm and to the back of the chest on the left side near the scapula. Eight months before her entrance to the hospital she had a prolonged attack of substernal oppression and precordial pain, lasting for hours, and attended by prostration. Ten weeks before admission, after the removal of a corn beneath the nail of the right second toe, she began to have pain in the toe with slow healing, and later infection. She had noticed some numbness in the right foot for a year. Slight hypertension and diabetes had been discovered at the age of 43, but the glycosuria was readily controlled by moderate restriction of diet.

On examination the patient was found to be slightly obese. There were no abnormalities expect for very slight hypertension, the blood pressure ranging from 145 to 160 and about 90 diastolic. There was a decrease in the arterial pulsation in both legs. There was no evidence of congestive failure.

The various laboratory tests were all normal except for the electrocardiogram which showed low, diphasic T waves in Lead 1, and abnormal T waves in the precordial or chest lead, X-rays of the legs which showed extensive calcification of the blood vessels of the legs and ankles, and a high blood sugar.

Under observation it was evident that the patient, especially when nervous, was very much inclined to gulp and belch gas, complaining of the discomfort in the chest therefrom.

DISCUSSION

This patient is a good illustration of the combination of coronary disease with slight angina pectoris complicated by aerophagia and cardiac neurosis. Her

coronary symptoms had subsided completely by the time of her entrance to the hospital for study, but her aerophagia and the discomfort therefrom had become more marked and were easily detected. The only abnormalities on examination were the electrocardiographic evidence of coronary disease and the X-ray evidence of peripheral vascular arteriosclerosis. These findings, however, are of great importance in the complete study of a patient suspected of having cardiovascular disease.

Case 3. Circulatory collapse incident to gastro-intestinal disease. A professor, 49 years old, always highly nervous and recently under severe mental strain, had been seized five days before I saw him by very severe epigastric pain which kept him awake all night and which was followed by tarry stools. He had had heartburn and other evidences of indigestion for twenty years or more and roentgen ray examination showed a small duodenal ulcer. He improved rapidly on Sippy powders and diet but late the night before I saw him while he was listening to the radio he was seized by a desire to go to the stool. He went to the bathroom and had a copious bowel movement. In fear he looked to see if it contained blood. When his fear was confirmed he grew greatly alarmed and at once began to feel faint. He dragged himself back to bed and collapsed. There his wife found him semicomatose and a doctor who was summoned discovered him in a cold sweat with impalpable pulse at the wrist and a very slow heart rate of about 20. After a few minutes he recovered and the next morning when I examined him I found nothing at all wrong except for the story of the recent bleeding from the gastro-intestinal tract. An electrocardiogram showed no heart block. The important history was elicited of an exactly similar collapse twelve years before after an indigestible meal late at night.

DISCUSSION

This case illustrates the frequent occurrence of circulatory depression that may attend any illness or fright, whether incident to gastro-intestinal trouble, or to heart disease (for example, coronary thrombosis), or to other complaint. There may be a marked depression of the sinoauricular nodal pacemaker as well as of general vascular tone without any organic heart block at all, despite the bradycardia.

Case 4. Peptic ulcer diagnosed as coronary disease with angina pectoris decubitus. The wife of an army officer, 46 years old, had begun to have nocturnal attacks of severe sharp low substernal pain, nonradiating, attended by nausea, and lasting several hours at a time, five and a half months before I examined her. This had recurred nightly for several weeks but finally subsided after bed rest. For some months thereafter she felt fairly well, being free from pain. Then she overdid in preparing for Christmas and the nocturnal attacks recurred. Ten days later when I examined her there was evidence of hypertension (systolic blood pressure 165 and diastolic 120) and slight cardiac enlargement. The electrocardiogram was essentially normal and the Wassermann and Hinton reactions were negative. Gastro-intestinal roentgen ray examination revealed the presence of a peptic ulcer and treatment by rest and diet was instituted. She has been free from symptoms since this treatment was started. Her blood pressure has continued to be moderately elevated.

DISCUSSION

Although angina pectoris decubitus is possible in a middle aged woman with hypertension it is very unlikely in the absence of a previous history of angina pectoris on effort or of evidence of luetic aortitis. Also of course paroxysmal angina pectoris is at once excluded by the duration of the attacks of pain; coronary thrombosis which might explain the duration of an individual attack would not recur night after night, leaving her in fair comfort and health in the daytime. The electrocardiogram too would almost certainly have shown evidence of coronary disease had the latter been the occasion of such frequent severe pain. Fortunately the treatment of the peptic ulcer is about as suitable as anything we know of for the treatment of the hypertension and its effect on the heart.

Case 5. Gall stones erroneously diagnosed as coronary thrombosis or pulmonary embolism. An obese housewife, 60 years old, had always been well until her present illness except for pneumonia at the age of 29 and varicose veins for many years culminating in an ulceration in the summer of 1935, one and a half years before I first saw her; this ulceration had finally healed in the course of some weeks. On December 26, 1935, she was awakened in the middle of the night by a very severe choking pain across the front of the chest radiating into the neck and left arm, attended by nausea and vomiting, lasting for hours, requiring morphine, and followed by several days of fever. She gradually improved and was fairly well through the spring. In June, 1936, she had a similar attack with vomiting. Through the summer there were several milder spells and then in October another very severe attack with collapse. She then remained in bed nearly two months and was only just beginning to sit up in January, 1937, when I first saw her, a year after her first attack of pain. There had been two mild spells in the fortnight before my examination. I found no abnormalities of heart, lung, abdomen, or blood pressure. The electrocardiogram was essentially normal. A few weeks later another severe attack occurred with persistent vomiting and tearing substernal pain. There was marked tenderness with spasm in the epigastrium. Bile appeared in the urine the next day, and the stool was clay colored. The diagnosis was now obvious.

DISCUSSION

Here is a good example of the difficulty of the early differential diagnosis of gall bladder disease and coronary thrombosis. In the first place the sex and absence of previous angina pectoris and hypertension favored the former condition. Later the constant occurrence of vomiting with the attacks, the frequent repetition of the pain, and the absence of characteristic electrocardiographic findings practically ruled out coronary thrombosis. At one time the repeated attacks of chest pain and the old history of varicose veins and phlebitis suggested the possibility of recurrent pulmonary embolism but there was nothing to support the diagnosis. Nausea and vomiting always favor the diagnosis of trouble below the diaphragm unless they are induced by morphine given for the relief of pain or by excessive dosage of digitalis given because of real or fancied myocardial failure. Often these drugs are responsible for nausea ascribed to indigestion of some sort. Much better evidence than vomiting is that yielded by the occurrence of persistent hiccoughing. Obstinate hiccoughs may result from diaphragmatic pleurisy secondary to a large pulmonary infarct but it is far more common from irritation subdiaphragmatically and is exceedingly rare in coronary thrombosis. I have myself never encountered it as a complication of coronary thrombosis; the one time I did make such an interpretation I was in error, the chest

pain and absence of signs of trouble in the abdomen being caused by an unique position of a pus-filled gall bladder situated high, almost like an intrathoracic organ, under the right leaf of the diaphragm which had become inflamed by contact.

Case 6. Gastro-intestinal disease complicated by silent (?) coronary disease. A housewife, 54 years old, had had for many years an ill defined indigestion and for a few years a variable slight hypertension. Eight days before I was asked to see her she had had an attack of severe epigastric pain with nausea. Twenty-four hours later the pain had shifted to the right lower quadrant of the abdomen where there were tenderness and spasm. The temperature was 101 degrees and continued elevated for two or three days. The blood pressure was 150 systolic and 90 diastolic. A week later, on the morning of the day I examined her, while she was being prepared for appendectomy she had another attack of severe epigastric pain with pallor and a drop in blood pressure to 100 systolic and 50 diastolic. An electrocardiogram showed inversion of the T waves in the classical leads, upright T waves in the precordial lead, and a prolonged P-R interval of 0.21 second. The Q wave was present in Lead 4. The operation was postponed. Repeated electrocardiograms during the next few days showed no change. The epigastric pain subsided but some right lower quadrant tenderness persisted. Finally, thirteen days after my examination laparotomy was performed and an inflamed appendix was removed without incident. The abnormality of the electrocardiogram persisted. There was no more pain.

DISCUSSION

Here was a case of gastro-intestinal disease complicated by real heart disease which apparently was incidental, revealed by electrocardiogram. It is quite certain that the electrocardiographic abnormality and the underlying coronary disease were not produced by the acute appendicitis. It is true that gastro-intestinal disease, especially gall stones, may induce functional cardiac and general circulatory disturbances, especially premature beats, paroxysmal tachycardia (even in the form of auricular fibrillation), and vascular collapse but that it can actually and directly produce organic myocardial, endocardial, or coronary disease is extremely unlikely. Heart failure or angina pectoris or electrocardiographic anomalies may, however, be precipitated and perhaps for the first time brought to light by disease below the diaphragm but no more than by any other strain, and certainly not fundamentally caused thereby.

Case 7. Coronary thrombosis and "silent" gall stones. A surgeon, 41 years old in October, 1936, had been well except for a liver abscess following appendectomy in 1917, and pneumonia following influenza in 1929 until January, 1935, when he began to have mild substernal oppression on vigorous effort. This symptom increased in frequency and severity until March 20, when he was seized by a terrific substernal and bilateral arm pain lasting several hours and requiring morphine. Typical clinical and electrocardiographic evidence of coronary thrombosis ensued and he remained in bed three months. When I examined him in October, 1936, he was still incapacitated by the typical angina pectoris of coronary insufficiency. The electrocardiogram was still abnormal. A routine gastro-intestinal X-ray examination a few months before had revealed two gall stones and he asked if these should be removed. We advised against the operation, at least at that time. Further treatment of the coronary disease was recommended.

DISCUSSION

Gall stones are common and often silent. Only occasionally must they be removed. Operation always carries some risk and in the presence of serious coronary disease as in this patient it may kill. There is very little likelihood that the gall stones were a source of aggravation of the heart trouble in this particular case.

*Case 8. Paroxysmal tachycardia, wrongly interpreted as angina pectoris, the result of reflex irritation of the heart from gall bladder disease.** A 54 year old housewife entered the Massachusetts General Hospital on April 5, 1933, to have treatment for persistently recurring nocturnal heart attacks by paravertebral alcohol injection of the sympathetic nerve ganglia and rami. Five years before she had begun to be troubled by momentary attacks of sharp, shooting pain originating just over the heart to the left of the sternum and radiating across the chest to the right and occasionally up over the left chest, almost to the clavicle. These transitory pains were not associated with exertion but seemed to come more when she was resting after a hard day and in the evening when in bed. She consulted her doctor who gave her tablets of nitroglycerine for the attacks, which seemed to give relief. This was at the time of the menopause. Ever since then this trouble had recurred at intervals, more frequently during the few weeks prior to her admission to the hospital, when she also noticed almost constant heartache, some dyspnea on hurrying, and blueness of her fingers and lips. Her ankles seemed to swell slightly at the end of the day. Her doctor digitalized her but she said that she had to omit the drug because of her inability to retain it.

About one year before entrance to the hospital she was troubled by another and more important symptom, consisting of precordial and substernal oppression in attacks at night, awakening her and causing her to sit up, lasting for a few minutes at a time, and not responding quickly to nitroglycerine. On one occasion she was given morphine for relief. During the three weeks before entrance to the hospital these nocturnal attacks had increased in frequency and severity, and had been accompanied by a feeling of impending death, cold sweat, and rapid heart beat. She had, however, continued to do her housework as before.

Her past history revealed no important illnesses. She had six healthy children. Her mother and one sister had died of tuberculosis.

Physical examination showed a well developed and well nourished middle-aged woman with good color, normal breathing, no edema, and no abnormal neck pulsations. Her heart was normal in size, sounds, rate, and rhythm. There were no murmurs. The pulse rate was 80. The blood pressure varied from 154 to 165 millimeters of mercury systolic and from 90 to 100 diastolic. The lungs were normal.

Electrocardiogram showed normal rhythm, and total inversion of Lead 3.

X-ray examination showed some increase in the transverse diameter of the heart, which was recorded as greater than the long diameter.

The urine and blood were normal except for very slight albuminuria and slight secondary anemia. There was no bile in the urine. The stool was normal. The Hinton reaction was negative and the basal metabolic rate was minus 10 per cent.

On April 5, the day of her admission to the hospital, I

*This case has already been reported in "Errors in the Interpretation of Cardiovascular Symptoms and Signs. *"Annals of Internal Medicine*, 9:1703, 1936.

saw her for a few minutes and wrote the following opinion: "Brief questioning does indicate the apparent occurrence of severe angina pectoris (decubitus) dating back three weeks (mild for two or three years before that). Examination shows no abnormalities except for slight hypertension. Further study—more careful history, electrocardiogram, roentgen-ray, Hinton reaction—are essential before final diagnosis. Paravertebral alcohol injection may well be indicated but I would advise postponing it for a few days until studies are completed. Try amyl nitrate for attacks." The surgeon wrote the following note on the record: "I believe that this patient is a suitable case for paravertebral alcohol block as her cardiac pain is so severe and she is getting so little relief from her medical measures. The only difficulty is the bilateral nature of the pain."

On April 7, 1933, we questioned her more carefully, realizing how rare severe angina pectoris is in a middle aged woman with little or no hypertension and no story of substernal oppression on effort, and we gave the following verdict: "Further history this morning reveals the vitally important fact that rapid regular heart beating at more than twice the usual speed always accompanies the anterior chest discomfort and apparently precedes it. This is extremely significant for it changes the diagnosis from coronary disease with angina pectoris to paroxysmal tachycardia with little or no heart disease. . . . She is already better in here resting. Sedatives and quinidine sulphate (3 grains three times daily) will be much more likely to help her than any other drugs. I expect the Hinton reaction will be negative. For completeness we shall have a basal metabolic rate determination. Certainly there is no need at present for paravertebral alcohol injection unless the paroxysms grow very much worse and are refractory." One week later on the new therapy she was feeling very well, completely free of heart attacks. She was discharged from the hospital much improved on April 15.

Three months later, on July 3, 1933, she came to my office with no complaints except for very slight heart twinges for a second at a time on two days the previous week. She was taking quinidine. Examination including electrocardiogram and fluoroscopy showed nothing amiss except for slight hypertension (170 mm. systolic and 95 diastolic).

In October she reported the occurrence of a spell of racing of the heart lasting a half hour after a recent fatiguing day. She had omitted the quinidine but thereupon resumed it. She no longer was afraid of the attacks, they had become simply disagreeable. Her blood pressure was 155 systolic and 90 diastolic.

She continued in good health (with infrequent palpitation) except for a series of acute attacks of typical gall stone colic with vomiting from August to November, 1935, completely relieved by the uneventful removal of her gall bladder containing a large stone. She continued to have infrequent brief paroxysms of tachycardia up to the time of operation but none thereafter. The blood pressure continued to be slightly elevated (170 systolic and 95 diastolic on February 10, 1936). The electrocardiogram, including the chest lead, has been normal.

DISCUSSION

It is probable that in this case the gall stones were responsible for the paroxysms of tachycardia. It is unlikely that some other disturbance may have been the chief factor. Some of the precordial pain in these nocturnal attacks from which she suffered may have been due to the gall stones and not wholly to the discomfort from the paroxysmal tachycardia.

Case 9. Heart failure and cirrhosis of the liver. A strenuous fat lawyer, 63 years old, who had used alcohol to excess, was found to have considerable hypertension (blood pressure 180 systolic and 122 diastolic) at the time of acute congestive heart failure in July, 1932. Intense breathlessness had been followed by dependent edema. His liver was found to be somewhat enlarged. The heart rhythm was normal. After a long rest and digitalization he improved and continued in fair health for two years. Then in July, 1934, he became breathless again. Treatment relieved him but in February, 1935, he once more developed severe congestive failure following an acute respiratory infection. Gradually this yielded but in May intractable ascites appeared and he required abdominal paracentesis every three weeks. There remained little dependent edema. Because of the unusual situation this patient excited much interest. On examination in April, 1936, he showed a very large heart with diastolic gallop rhythm, accentuation of the pulmonary second sound, moderately loud precordial systolic murmur maximal at the apex, absolute arrhythmia at a heart rate of 72, blood pressure of 170 systolic and 105 diastolic, slight engorgement of the neck veins, soft edema of both lower legs, considerable enlargement of the liver with hard edge, and an abdomen much distended by ascites. The urine was normal, the Wassermann reaction was negative, and the electrocardiogram showed auricular fibrillation with a ventricular rate of 65, abnormal left axis deviation, and inverted T waves in Lead 1. Improvement followed a considerable restriction in fluid intake and the continuance of digitalis and diuretic therapy.

DISCUSSION

This case illustrates the deleterious effect that one abnormal condition may have on another. Although the hepatic cirrhosis might eventually have caused trouble itself its effect was certainly precipitated by the severe heart failure. Congestive failure alone would not have produced such obstinate ascites unless chronic mitral stenosis of high degree were present; there was no evidence of mitral stenosis here. Two other cardiac lesions can cause a preponderant obstruction of the portal circulation with obstinate ascites; these two conditions are tricuspid stenosis and chronic constrictive pericarditis. There was no indication of either of these conditions here. Cirrhosis of the liver as an uncomplicated cause of ascites is not attended by engorgement of the neck veins, that is, an increase in systemic venous pressure. When there is the combination of preponderant ascites with overfilled neck veins we must look for one of the four conditions mentioned above: (1) either the combination of cirrhosis of the liver and congestive heart failure as in Case 9, or (2) high grade chronic mitral stenosis, or (3) tricuspid stenosis, or (4) chronic constrictive pericarditis.

Case 10. Upper abdominal pain due to liver enlargement secondary to mitral stenosis with right ventricular failure. A housewife, 38 years old, with rheumatic heart disease, mitral stenosis and auricular fibrillation of long standing, complained of a new symptom coming on during the three years prior to my examination of her in September, 1932. This symptom consisted of fullness and aching in the upper abdomen especially on the right side. Physical examination showed a woman somewhat overweight, with slight dyspnea, and engorgement and pulsation of the cervical veins in the upright position. There was clear evidence of mitral stenosis with auricular fibrillation and considerable enlargement of the heart. There were moderate enlargement and tenderness of the liver. The heart rate was 110. The blood pressure was normal. The electrocardiogram showed auricular fibrillation with

slight right axis deviation and inverted T waves in Leads 2 and 3. Fluoroscopic examination showed a very large, mitral shaped heart.

After rest and full digitalization she improved a good deal. There was less congestion of the abdomen.

A year and a half later she reported again complaining of having been much worse with increased congestion of the abdomen with some nausea and vomiting. Rest and diuretic therapy helped somewhat but because of the persistence of her marked limitation of reserve she underwent the operation for total thyroidectomy in February, 1934. Following the operation she improved rapidly, and in the next few weeks lost all sense of congestion in her upper abdomen. Her heart action was better and the liver was distinctly smaller. Her appetite was good. She continued in improved health with less evidence of engorgement of the liver which was responsible for her abdominal discomfort and fullness and nausea, during the next two years.

Finally, in the spring of 1936, she failed rapidly with congestive failure and died May 27, 1936.

DISCUSSION

In this patient the failure of the right ventricle was undoubtedly responsible for the engorgement of the liver and gastro-intestinal tract causing her discomfort. When there was relief of this failure there was also relief of the symptoms of abdominal discomfort and anorexia and nausea. It is in such cases that it is often difficult to know whether the abdominal discomfort and nausea may be the result of too much digitalis or too little. All the evidence available, including the electrocardiogram, is essential in the analysis of the problem. Besides the evidence and symptoms of the congestion of the liver and stomach, there sometimes may be associated with the congestion ulceration of the stomach, either fresh or recurrent due to the chronic congestion, and also hemorrhoids resulting from chronic congestion of the rectum.

Case 11. Liver enlargement and ascites due to chronic constrictive pericarditis. A healthy, active Irish lad, 12 years old, began to notice prominence of his abdomen three months before our examination. This abdominal swelling had slowly and steadily increased and recently had been so extensive that it had extended into his flanks. He had been active despite this and had had no shortness of breath or pain. There was no jaundice or urinary symptom. Four days before admission to the hospital his abdomen had been tapped, and straw colored fluid was removed. X-ray examination at that time showed calcification of the pericardium.

His father died of tuberculosis three months before the patient was born. His mother was living and well.

In the past he himself had had pneumonia at the age of 4 when he was critically ill for four weeks. He had measles, mumps, and chickenpox between the ages of 4 and 6. His tonsils and adenoids had been removed at the age of 2.

Physical examination showed a well developed and nourished boy, greatly put out at having to enter the hospital. There was slight general adenopathy. The chest flared at the costal margin to meet the protuberant abdomen. The lungs were clear. The heart was normal in size, and did not shift with change in position. There were no murmurs or thrills. The pulmonary second sound was loudly reduplicated. The pulse was regular at 90. The blood pressure was 90 systolic and 60 diastolic. The veins of the neck, arms and upper chest were dilated. The respiratory rate was 20. The abdomen was distended. The liver edge was felt three fingers below the costal margin, nontender. There was shifting fluid dullness. There was no edema of the legs. The reflexes were active. The respiratory rate was 20.

The blood was normal except for slight anemia, and clear reduction of the serum protein to 4.8 per cent. All other laboratory tests were normal except for slight reduction of the liver function and abnormality of the T waves in the electrocardiogram. The T waves were very low in Lead 1, diphasic in Lead 2, and slightly inverted in Lead 3. X-ray examination of the heart showed the measurements at the upper limits of normal, with a lateral area of calcification extending around the entire lower half of the heart. The lung hilus shadows were slightly enlarged, and there was slight thickening of the axillary and apical pleurae.

He entered the hospital June 30, 1933. On July 7, salyrgan intravenously resulted in a fair diuresis with the loss of two pounds.

On July 12, Dr. E. D. Churchill performed a pericardial resection, cutting away thick, hard pericardium over the anterior surface of the ventricles and over the right auricle to the cavae. Most of the diaphragmatic pericardium was removed.

There was an uneventful convalescence after the first two or three days, which were somewhat stormy. Then came a spontaneous diuresis beginning about the 7th day, and continuing for twelve days, at which time he was entirely free from evidence of surplus fluid. He has been perfectly well since this operation with no evidence of increased venous pressure; he is now fully active.

DISCUSSION

This case is an excellent illustration of congestion of the liver due to chronic constrictive pericarditis preventing the blood from entering the heart in sufficient amount. The onset was insidious. There was some discussion at first as to the probability of the diagnosis of primary cirrhosis of the liver. The factors which established the definite diagnosis were the accompanying engorgement of the neck veins, that is, the increase in systemic venous pressure, and the abnormality of the electrocardiogram, which are not found with an uncomplicated cirrhosis of the liver, and of course in addition the X-ray evidence of calcification of the pericardium. However, the diagnosis can easily be established without the X-ray; furthermore, it is to be noted that X-ray evidence of pericardial calcification is sometimes obtained without any constrictive pericarditis or liver enlargement or ascites.

Case 12. Jaundice due to extensive pulmonary infarction complicating rheumatic heart disease with mitral stenosis, auricular fibrillation, and congestive failure. A housewife, 49 years old, known to have had rheumatic heart disease with mitral stenosis and slight aortic regurgitation for many years entered the hospital because of recurrent rheumatic infection, arrhythmia consisting of paroxysmal auricular fibrillation and flutter, and congestive failure. There were associated attacks of chest pain and dyspnea with clear indication of recurrent pulmonary infarction, now in one lung, now in the other, and now in both. She grew much sicker, entered the hospital, and there developed jaundice, though not of high degree. Under full digitalis therapy, oxygen, and morphine she slowly improved but was still desperately ill. To the surprise of all concerned she gradually recovered, and has been in excellent health during the last year, although she

still shows clear evidence of the rheumatic heart disease and mitral valve involvement.

DISCUSSION

The point of particular interest in this case is the fact that jaundice may rarely complicate heart disease without primary disease of the digestive tract. It is quite likely that three factors played a role simultaneously in the production of the jaundice in this patient: one of these was the damage to the liver resulting from the rheumatic infection past and present. More and more evidence of this is being revealed in rheumatic fever studies at the present time. The second factor is congestive failure which adds to the burden of the already damaged liver, and finally the third factor, which is the precipitating one, is that of pulmonary infarction which adds to the blood stream a surplus of blood pigment, at the time of resolution of the infarct, which cannot be taken care of by the inefficient liver. This results in hematogenous jaundice.

Although the symptom of jaundice is rare in cardiac cases, its possibility should be borne in mind and the condition should not be interpreted as obstructive jaundice, unless there is clear proof thereof.

Case 13. Coronary thrombosis erroneously diagnosed acute indigestion. A clergyman, at the age of 48 years, had an attack of severe epigastric pain radiating substernally, and a little into both arms equally, lasting several hours, requiring morphine for relief, and attended by vomiting after the morphine injection. A diagnosis of "acute indigestion" was made and he remained in bed one week. Three years later he had a similar attack awakening him at night. A third spell of "indigestion" came eight years after that and finally a fourth just prior to my examination another four years later when the patient was 63 years old. All four attacks were almost identical. The clinical course of the fourth attack and the electrocardiogram were typical of coronary occlusion with myocardial infarction. The patient survived for another nine years and finally died of congestive heart failure more than twenty-four years after his first attack. His heart at autopsy showed extensive coronary occlusion and the scars of multiple infarcts.

DISCUSSION

I have included this case of coronary thrombosis because of its importance despite the fact that nowadays such an error is made much less often than ten years ago. In fact, the diagnosis of coronary thrombosis is made too often now. Nevertheless, every few weeks I still encounter acute coronary occlusion that at its onset was not recognized. The value of the electrocardiogram in such acute cases cannot be overemphasized.

Here it is appropriate to say a word about the so-called abdominal angina (angina abdominis). Coronary pain may be epigastric in position whether paroxysmal in type or due to coronary thrombosis, but otherwise the term as applied to heart disease is unwarranted. It is true, of course, that disease of the abdominal aorta either in the form of a dissecting aneurysm or of a large obstructing sac, and occlusion of lesser arteries in the abdomen can give rise to severe prolonged abdominal pain, but such pain is not comparable to that of angina pectoris except perhaps in rare cases of partial vascular occlusion; such cases need further study.

Thus, pain, collapse, nausea, jaundice, liver enlargement and other physical signs, and X-ray and electrocardiographic abnormalities are all symptoms and signs that must be carefully evaluated in the differential diagnosis of cardiac and gastro-intestinal disorders. A careful history is the first essential and generally establishes the diagnosis. Pain and collapse, and liver enlargement and tenderness may attend either of the two groups of diseases, but it is usually possible easily to analyze the difference. Nausea, vomiting, hiccoughing, and jaundice rarely result from heart disease but are common in gastro-intestinal disorders. The electrocardiogram is invaluable since it is generally abnormal in heart disease. The X-ray is usually more helpful in gastro-intestinal disease. The greatest difficulty arises when both kinds of disorders occur together. Unfortunately such a concurrence is common; then the keenest diagnostic acumen may be none too keen. This particular field is still a fertile one for further cultivation. The last word has not yet been said.

Hemorrhage From Gastritis---A Gastroscopic Study*

By

EDWARD B. BENEDICT, M.D.
BOSTON, MASSACHUSETTS

THAT varying degrees of hemorrhage may occur from gastritis has long been recognized by a number of European authors. In this country, however, little attention had been paid to chronic gastritis until very recently, when interest was stimulated by the development of the flexible gastroscope (1). In the ten year period 1924-1933 a diagnosis of gastritis with hemorrhage was made in only five cases in the Massachusetts General Hospital. In the four year period 1933-1937, however, since the common use here of the flexible gastroscope (2), this diagnosis has been made in twenty cases. In other words we are now making a diagnosis of gastritis with hemorrhage ten times as frequently as formerly.

Among the earliest writers to consider gastric erosions as a cause of hemorrhage was Langerhans (3) (1891) who, in a case of eclampsia, reported severe bleeding from erosions in the stomach. Death was hastened by the bleeding, and autopsy showed catarrhal gastritis with hemorrhagic erosions. Nauwerck (4) (1897) noted small superficial hemorrhagic erosions in the stomach of a patient who died of a perforated gastric ulcer. Einhorn (5), Pariser (6) and Mintz (7) should also be mentioned among the early

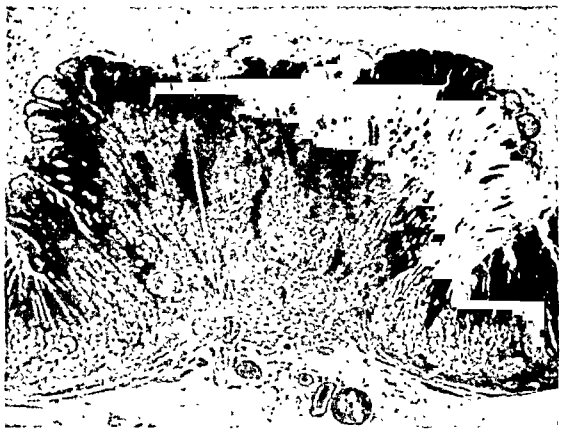

Fig. 1. Low power photomicrograph showing erosion typically located on crest of fold.

writers on this subject. Recent authors include Faber (8), Schindler (9), Moutier (10), Korbsch (11), Henning (12), Delore (13) and the present writer (14). Faber, in pointing out the clinical significance of chronic gastritis without ulcer, says, "The next symptom to discuss is hemorrhage, which from early days has been regarded as a sure sign of ulcer. But hemorrhage, even sometimes very severe, as fresh hematemesis or melena, also appears to be a very frequent symptom of these gastritis cases. Torben Anderson found hematemesis 5 times and melena 3 times among his 21 cases; 3 of Nicolaysen's 7 cases had a large hemorrhage, and 5 of Bj. Dahl's cases had hematemesis. Nearly all the cases had periodic occult hemorrhage. As all the cases exhibited advanced gastritis with erosions, it is not surprising that hemorrhage occurred. As already mentioned, Dieulafoy formerly observed even fatal hemorrhage after what he called *exulceratio simplex* in gastritis, in other words, after gastric erosions." Schindler, Ortmayer and Renshaw (9) likewise have discussed hemorrhage from gastritis and have pointed out that "gross, sometimes fatal, hemorrhages from gastritis have occurred." Korbsch (11) too has said, "It is certain that

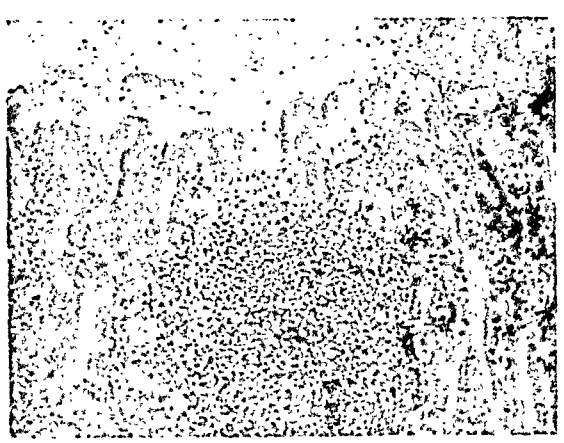

Fig. 2. High power photomicrograph of chronic gastritis showing slight erosion, fibrinoid necrosis, and marked lymphocytic infiltration.

gross bleeding can occur in chronic gastritis and that hematemesis is no longer to be considered a sure sign of ulcer." Henning (12) believes "that gross gastric bleeding in gastritis is not secondary in frequency to bleeding from tumors and ulcers." We thus have ample corroboration of our own experiences in hemorrhagic gastritis.

Hemorrhage from gastritis may be mild or severe. Any classification as to the degree of hemorrhage is necessarily somewhat arbitrary. In our twenty-five cases of gastritis with hemorrhage nine showed red counts below three million and were classed as severe hemorrhage. Three of these had red counts of 1.3 to 1.7 million, were almost moribund on admission, and required intravenous fluids and transfusions. One patient, with a history of very severe hematemesis following a large intake of bay rum and rubbing alcohol, died of hemorrhage from acute gastritis a few hours after admission to the hospital. Autopsy showed the only source of the bleeding to be multiple gastric erosions.

The signs and symptoms of chronic gastritis have

Fig. 3. Photomicrograph of gastric mucosa from patient with severe hemorrhage from chronic gastritis. Note erosion, fibrinoid necrosis, marked cellular infiltration, and lymph follicle formation.

been discussed in a previous paper (14). They are indefinite and inconstant. They may simulate peptic ulcer. In the twenty cases of acute and chronic gastritis confirmed by gastroscopy the age ranged from 30 to 60 years. There were 14 men and 6 women. There was a history of excessive use of alcohol in 5 cases, moderate intake in 5, rare or no intake in 10. Hematemesis occurred in 15 cases, and in most of these melena was also present; melena without hematemesis occurred in 5. Gastric analysis was done in 11 cases, and in 2 showed no free hydrochloric acid one-half hour after histamine. The other 9 cases showed 40 to 86 c.c. of N/10 NaOH one-half hour after histamine. Hence it appears that the degree of acidity is very variable. X-ray examination was done in all cases. A diagnosis of hypertrophic gastritis was made by X-ray four times, and confirmed by gastroscopy every time. A positive roentgen diagnosis of hypertrophic gastritis is significant, and is usually confirmed by gastroscopy. Negative X-ray findings are, however, quite common in hypertrophic gastritis.

The pathological picture in chronic gastritis shows

that bleeding takes place from an erosion in the mucous membrane. That such erosions commonly occur on the crests of the rugae is borne out gastroscopically and histologically. In Figure 1* the histological appearance of such an erosion is well illustrated. Note that the break in the epithelial lining is on the crest of the fold. Many of the mucous glands are darkly stained and contain no mucus. Hence the protective layer of mucus normally present is markedly diminished in and near the eroded area. Figure 2 is a high power photomicrograph showing chronic gastritis with marked lymphocytic infiltration of the mucosa, and a layer of fibrinoid necrosis covering a small erosion. These photomicrographs were taken from a stomach resected for duodenal ulcer. Figure 3, however, shows the histologic appearance of chronic gastritis not associated with ulcer or carcinoma. This patient had severe bleeding from gastritis alone. Because of tarry stools and a hungry feeling in the epigastrium he had had a gastroenterostomy performed at the age of sixteen at another hospital. Tarry stools continued intermittently, however, for thirteen years with severe hematemesis the day before admission to this hospital. Alcoholic history was negative. On entry the red count was 1.7 million, hemoglobin 40 per cent. One month later, after medical management and transfusion, hypertrophic gastritis was demonstrated by X-ray and gastroscopic examination. Because of the hemorrhage resection of the pylorus and duodenum was done, but failed to disclose the source of the bleeding. Pathological examination of the resected specimen showed no gross lesion present on either the gastric or duodenal surfaces. Microscopic examination (Fig. 3), however, confirmed the gastroscopic and X-ray diagnosis of chronic gastritis. Note the loss of epithelial surface, marked cellular infiltration and lymph follicle formation.

Fig. 4. Case 1. Gastroscopic appearance of erosion on crest of fold. Mild bleeding from hypertrophic gastritis.

The appearance of the mucosa as seen through the gastroscope is variable, depending on the degree of the hemorrhage and the time interval after the bleeding. Sometimes in the mild cases there is only a superficial gastritis with mottled areas of edema and reddening. Usually, however, there is more definite evidence of a long-standing chronic gastritis with a verrucous appearance of the mucosa and reddening of the crests of the rugae, sometimes with marked edema. Small erosions or shallow ulcerations may be demonstrable. If the examination is undertaken early, bright red blood may occasionally be seen lying in the dependent portion of the stomach, or trickling away from an inflammatory area or an erosion. Moutier (10) describes the gastroscopic appearance in hemorrhagic gastritis, and shows colored illustrations. He says all stages are seen from the simple congestive forms to the hemorrhagic lesions, in the latter cases the folds being generally large, swollen, and brightly colored, and sometimes spotted with whitish placques. Moutier feels that such an altered mucosa presents a special fragility, gastroscopy demonstrating a thin leakage of blood high up on the lesser curvature.

The treatment of gastritis includes rest in bed, intravenous fluids and transfusions for the severe cases, regulation of diet, dental attention, and elimination of alcohol and tobacco for all cases. Undue mental strain should be avoided. Gastric lavage has not been found necessary.

The following are detailed reports of a few cases of gastritis with varying degrees of hemorrhage:

Case 1. J. McC., M. G. H. No. 17046. Female, 55, entered the hospital February 11, 1937, complaining of epigastric pain, hematemesis and melena of one and a half years' duration. Alcoholic history was negative. A year and a half ago following hematemesis and syncope she was admitted to another hospital, transfused, and a diagnosis of duodenal ulcer was made by X-ray. Tarry stools continued intermittently. There was considerable epigastric distress with some relief by feed. On admission to this hospital the red count was 5.5 million, hemoglobin 75 per cent. Gastric analysis showed normal acidity. X-rays of the esophagus, stomach, duodenum and colon were negative. Gastroscopy showed normal pylorus, normal peristalsis, antrum smooth, red, and glistening. The rugae in the body of the stomach were particularly red, edematous and tortuous, with an erosion (Fig. 4) on the crest of one fold on the greater curvature which was deep red in color and appeared like clotted blood. In the upper part on the posterior wall, the appearance was markedly verrucous with two saucer-shaped depressions about ½ to 1 cm. in

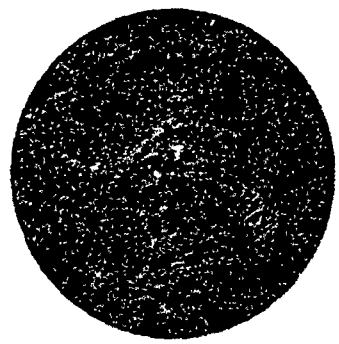

Fig. 5. Case 1. Showing verrucous appearance indicating hypertrophic gastritis.

*I wish to acknowledge with thanks the cooperation of Dr. Tracy B. Mallory and Dr. John I. Bradley in obtaining these photomicrographs (Figs. 1 and 2).

Fig. 6. Case 2. Small erosion of antrum in chronic gastritis with hemorrhage. Note raised collar of swollen mucosa with warty appearance, formed by heavy infiltration of inflammatory exudate and presence of connective tissue.

diameter (Fig. 5). Diagnosis by gastroscopy: hypertrophic gastritis with erosions. Definite improvement was obtained on a bland diet, but occasional tarry stools were observed.

Comment: Here we have a history of a moderate degree of melena of over a year's duration with conflicting X-ray reports regarding peptic ulcer. Very soon after a period of melena X-ray examinations by our own senior roentgenologists failed to show any ulcer or other abnormality of the gastro-intestinal tract. Gastroscopy, however, showed definite hypertrophic gastritis with erosions, apparently the only source of bleeding at the present admission.

Case 2. M. I. B., M. G. H. No. 329407. Female, 37, entered the hospital March 12, 1934, because of gas, sour eructations, nausea, vomiting, epigastric pain relieved by food or soda, and tarry stools. All symptoms had been intermittent for twelve years. Alcoholic history was negative. On admission the red count was 4.9 million, hemoglobin 80 per cent. Two stool examinations were negative for occult blood. Gastric analysis showed no free hydrochloric acid half an hour after histamine. X-ray examination showed no evidence of organic disease of the esophagus, stomach, or duodenum. Barium enema was negative except for diverticulosis, which, in view of her symptoms and the rarity of bleeding from diverticulosis, was regarded as an incidental finding. Gastroscopy showed pinpoint red erosions on the anterior wall of the antrum (Fig. 6) in an area which was granular in appearance and showed small elevations and depressions. On the greater curvature in the body of the stomach the rugae were abnormally prominent and showed clubbing with an erosion on the crest of one such fold (Fig. 7). The mucosa showed a verrucous appearance. Diagnosis by gastroscopy: hypertrophic gastritis with erosions. On a bland diet with mineral oil and belladonna there was improvement.

Comment: This case illustrates a mild degree of bleeding coming almost certainly from the upper gastro-intestinal tract. X-ray examination of this region was negative but gastroscopy showed hypertrophic gastritis with erosions.

Case 3. E. F. H., M. G. H. No. 350190. Male, 41, entered the hospital on December 10, 1935, complaining of heartburn, anorexia and nausea of one year's duration. For six months there had been an empty, gnawing feeling in the epigastrium about four hours after meals, relieved by food. Two months before entry he had passed a black stool and had vomited some material containing black specks. There had been a loss of about thirty pounds in weight. Alcoholic history was negative. Physical examination showed moderate pallor, red blood count 3,900,000, hemoglobin 70 per cent, smear normal. X-ray examination of the gastro-intestinal tract showed a low dilated stomach, containing a moderate amount of fluid. All the rugae were very markedly thickened. Duodenal cap appeared definitely normal. The findings were those of hypertrophic gastritis. Gastroscopic examination a few days later was reported as follows: "The gastroscope passed easily, the patient cooperated well, and the view was very good. The pylorus was well seen, and there was normal peristalsis passing over it. The rugae of the greater curvature were perhaps slightly thickened and did not entirely disappear on inflation. In the valleys between the folds were numerous very bright red streaks, indicating a superficial gastritis. On the posterior wall and lesser curvature there were numerous rounded hillocks and a somewhat verrucous appearance, indicating hypertrophic gastritis. There was no fresh bleeding and no erosion or ulceration could be demonstrated. The findings were those of superficial and hypertrophic gastritis." The patient was placed on a bland six-meal diet with ferrous sulphate and liver extract, and discharged improved. Six months later, after neglecting treatment, his symptoms had recurred.

Comment: In this case we have moderate hematemesis and melena, explained by X-ray and gastroscopic diagnosis of hypertrophic gastritis.

Case 4. M. W. G., M. G. H. No. 30520. Male, 53, first entered the Medical Out Patient Department in October, 1933, complaining of dull, gnawing epigastric pain of one

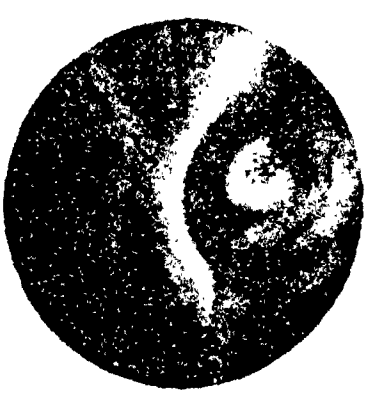

Fig. 7. Case 2. Erosion on crest of club-shaped fold in chronic hypertrophic gastritis with hemorrhage.

year's duration. X-ray examination at that time showed no evidence of organic disease of the esophagus, stomach, or duodenum. Improvement was noted on a six meal bland diet, to which, however, he adhered for only a few months.

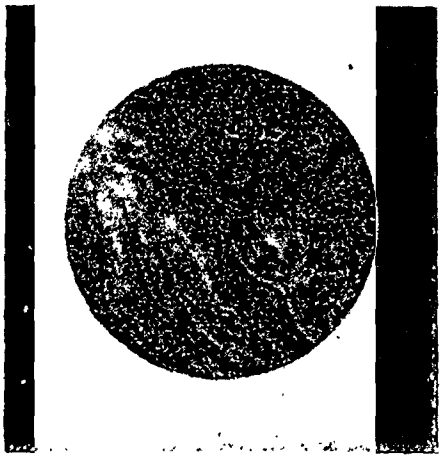

Fig. 8. Case 4. Marked inflammatory verrucous appearance of greater curvature and posterior wall in chronic alcoholic with moderate hematemesis. Chronic hypertrophic gastritis.

In March, 1937, he again entered the Medical Clinic because of intermittent recurrence of gnawing epigastric pain of five months' duration and vomiting of one pint of blood two weeks prior to entry. Alcoholic history showed heavy intake of whisky as a young man, none during prohibition, then heavy drinking again during the past four years. Two X-ray examinations of the upper gastrointestinal tract failed to show any organic disease that would account for the hematemesis. A diverticulum of the third portion of the duodenum was regarded as an incidental finding. Gastroscopy showed a normal antrum and pylorus, with normal peristalsis. The rugae were small and beaded and the mucosa reddened with an inflammatory verrucous appearance, particularly along the greater curvature and posterior wall (Fig. 8). The findings were those of hypertrophic gastritis. Improvement was noted on a six-meal bland diet with the elimination of alcohol and tobacco.

Comment: This history records a moderate degree of hematemesis, prolonged intake of alcohol, essentially negative X-ray findings on three examinations, but definite evidence of hypertrophic gastritis by gastroscopy.

Case 5. S. M.*, B. M. No. 32246. Male, 60, entered the hospital March 20, 1937, because of pallor and dizziness of three days' duration, hematemesis and melena of ten days' duration. There was a history of excessive alcoholic intake for many years, consisting of several daily drinks of whisky or gin. On admission physical examination disclosed extreme pallor and dehydration, with a blood pressure of 94 systolic, 35 diastolic. The red count was 1.5 million, hemoglobin 35 per cent. The patient was stuporous and in a very critical condition. After repeated transfusions, however, there was marked improvement. Two X-ray examinations about two weeks after admission showed the esophagus normal, the stomach unusually high in position and therefore hard to visualize. The duodenum was running posteriorly and was seen in profile only in the lateral view. No ulcer craters or filling defects were seen in the stomach, pyloric valve, or duodenum. Films of the small bowel taken at frequent intervals revealed no positive evidence of disease. Barium enema was negative. Gastroscopy was reported as follows: "The antral sphincter remained partially closed throughout the examination but a partial view was obtained into the antrum, which appeared normal. The rugae throughout the body and especially in the fundus of the stomach were not hypertrophied but were definitely beaded and reddened along their crests (Fig. 9), and in some places presented a slightly tortuous appearance. Some areas between the folds showed very marked inflammatory reddening and there was one small erosion on the crest of several converging rugae. This erosion was healing. It had a whitish base and appeared about 3 to 4 mm. in diameter and 2 mm. deep. In the acute stage of this gastritis a few weeks ago I believe profuse hemorrhage could have occurred. Much healing has undoubtedly taken place since the hemorrhage. The findings indicate a marked hypertrophic gastritis with erosions."

Comment: In this case we have massive hemorrhage from the upper gastro-intestinal tract, a long history of excessive use of alcohol, a critically ill patient who recovered by repeated transfusions, negative X-ray examinations, but gastroscopic evidence of hypertrophic gastritis with erosions.

CONCLUSIONS

Gastritis is a very important cause of bleeding from the stomach.

Varying degrees of hemorrhage from chronic superficial or hypertrophic gastritis may take place in the absence of other demonstrable pathology in the gastrointestinal tract.

Twenty cases of acute and chronic gastritis with hemorrhage have been studied by gastroscopy. The only likely and demonstrable source of bleeding in these cases was a superficial or hypertrophic gastritis, often with one or more erosions in the gastric mucosa.

As an etiological factor in massive bleeding from gastritis excessive use of alcohol is the most important.

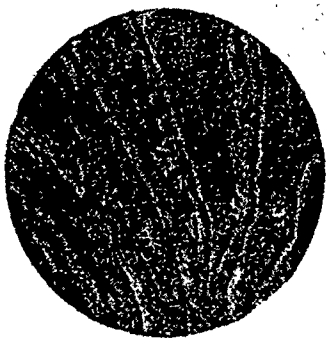

Fig. 9. Case 5. Beaded appearance of rugae and reddening of crests of rugae with erosions in chronic alcoholic with severe hematemesis and melena. Chronic hypertrophic gastritis.

*I should like to acknowledge the courtesy of Dr. William P. Thompson in granting permission to report this case.

For accurate diagnosis of gastritis gastroscopy is indispensable.

DISCUSSION

DR. JULIUS FRIEDENWALD (Baltimore, Md.): Massive gastric hemorrhage is always alarming. Fortunately the incidence of this complication is not very frequent. Gastric hemorrhage occurred in 22 per cent of our ulcer cases. Of these, 38 per cent were single and 60 per cent were multiple. Of the 22 per cent in which hemorrhage occurred, but 14 per cent were massive in type. Among our cases melena was twice as frequent as gastric hemorrhage.

In our experience profuse hemorrhages occur most frequently in the latent periods of ulcer when the other symptoms have subsided or even when the ulcer has been considered healed. I am firmly convinced that blood pressure readings play a more important role in the prognosis of gastric hemorrhage than the low hemoglobin readings, which may even fall as low as 35, with subsequent recovery. A fall of blood pressure to from 80 to 85 systolic, without being followed by a rise, is always an alarming sign. The prognosis ordinarily to life in gastric hemorrhage is good. There were but three fatal instances in our series of one thousand ulcer cases.

Hemorrhage usually ceases under the usual medical management; however, there are recurrences of massive bleeding occasionally in spite of active treatment. In these, surgical intervention should be considered even in spite of the great danger entailed in such a procedure. With improved surgical preparation and technic, resection of the bleeding area may be undertaken with a hope of a satisfactory outcome.

The following case has recently been seen in consultation: A man of fifty-three years gave a definite history of ulcer extending over a period of two months. He was suddenly seized with successive massive hemorrhages which recurred notwithstanding most careful medical management including transfusions. His red blood cell count fell to 1,600,000, his hemoglobin to 30, and his blood pressure was 80. As there seemed no hope of preventing further recurrences, operation was undertaken. A large indurated cartilogenous-like ulcer, two and one-half centimeters in diameter, was discovered high up on the lesser curvature several centimeters from the esophagus. One margin of the ulcer was bleeding profusely and a large open-mouthed vessel was seen. The ulcer was resected. It was perfectly evident that the bleeding could not under any condition be checked from a vessel of this size by medical measures.

DR. HORACE W. SOPER (St. Louis, Mo.). Since my paper on the subject of hematemasis some six years ago, I have had more experience in the treatment of massive hemorrhage.

The expectant method of treatment is almost universally employed by physicians who see these patients. The blood is allowed to remain in the stomach. This incites vomiting the next day and the physician fears a recurrence of the hemorrhage. In brief, he is in the dark and does not know what is happening in the stomach.

In the method which I advocate, I term the "direct attack." A No. 16 Levin soft rubber catheter is passed into the stomach and the stomach lavaged by means of a large piston syringe. It is easy by this method to break up large blood clots without unduly disturbing the patient. When the stomach contents have been removed, continuous syphonage is instituted. I do not employ the suction apparatus but allow whatever secretion forms to pass out into a container by the side of the bed. If bright red blood continues to flow through the tube it means that the hemorrhage is arterial and immediate surgical operation is indicated. At all times the physician is in complete control of the situation.

Furthermore, keeping the stomach secretion free initiates early and rapid healing of the ulcer. The chlorides you remove are replaced intravenously. By the third day one is able to begin feeding egg albumin water and gelatine water, and usually by the end of the week the high calorie milk-egg mixture. During this feeding time, the tube remains in place, clamped off, but allowed to remain open from time to time to test the secretion with congo red paper.

The retention of the tube in the stomach does not incite gastric secretion nor contracture.

DR. PAUL M. ASCHNER (New York, N. Y.): Mr. President and Gentlemen: I believe it was about four or five years ago that I presented before this Association a study of some 120-odd specimens of resected stomachs in which subtotal resection had been done for various gastric lesions of the gastric group. We concluded from those studies, both clinical and pathological, that ulcer does not occur in a normal stomach; that ulcer is a stage in the disease of the gastric mucous membrane, and we have had illustrated here very beautifully today, with the gastroscopic method of examination, the type of lesions which we found pathologically in our resected specimens.

From this type of patient we have two distinct groups of cases. We have the type of case in which there is extensive microscopic erosion of the duodenous mucous membrane with or without a co-existent actual macroscopic ulcer. These cases are not infrequent and can bleed very profusely and fatally.

These types of lesions are likely to occur in the younger individuals. The older patients who have had ulcer disease over a great period of years and arrive at the age of fifty or over with their ulcer waxing and waning are likely to have a calloused type of ulcer of the duodenum, or the stomach which erodes gradually into one of the large vessels. This type of patient has an enormous hemorrhage which usually, as has been mentioned, requires surgical intervention. The first type of erosion may respond to the medical treatment which one of our discussers has just described.

In regard to symptomatology in these patients, there is another factor that enters and that is the factor of sensitivity to pain, which has been reviewed for many years by Dr. Libman and dilated upon by Dr. Crohn, which is a valuable point to bear in mind. While it is true most

patients with ulcer disease have a neurotic constitution, neurosis and sensitivity to pain do not go parallel. You may have patients who are insensitive to pain and whose lesions go on developing to a marked extent with very little symptomatology and these are the patients that get so-called unexpected perforations and hemorrhage.

DR. LEMUEL C. McGEE (Elkins, W. Va.): Mr. President, inasmuch as the acute massive hemorrhage is a medical problem for the most part, rather than a surgical one, we still have, after the patient has recovered from the immediate hemorrhage, the question of what shall be the future management. There are very few objective criteria to help one decide the proper procedure.

The young individual's prognosis is good if he will follow advice, and for that reason I suspect a large number of us do not advise resection after the first hemorrhage in the younger group of patients. In the group past fifty years of age we see the mortality has increased to such an extent that it becomes advisable to resect the ulcer soon after checking the first massive hemorrhage. After the patient has been made suitable for major surgical procedures the importance of this course is emphasized by the pathological specimen presented here and the discussion by Dr. Friedenwald. Since the mortality of the older group is as much as 10 per cent, as mentioned by Dr. Blackford, we may assume that the condition of the arterial wall is the important factor. If we could have some way of determining the condition of the arterial wall directly by the gastroscope or by the condition of arteries externally, it would be a great help to us.

I should like to ask Dr. Blackford if he has attempted any correlations between objective measurements, such as the degree of sclerosis of the retinal arteries, and the occurrence of repeated hemorrhage in ulcer patients of various ages.

DR. ALBERT F. R. ANDRESEN (Brooklyn, N. Y.): Both speakers have shown the reason why, in general, medical treatment for massive gastric hemorrhage is safer than surgical. Our experience, in patients who have been subjected to operation on account of persistent hemorrhage or who have died and have had a necropsy performed, has shown that the bleeding either came from multiple erosions over large areas, as demonstrated by Dr. Benedict, or from deep ulcers, involving large vessels and held open by large, tough, horny masses of induration, as described by Dr. Friedenwald. The large bleeding areas are obviously not amenable to surgical care, and the horny masses are friable, almost impossible to suture and not safe to excise in a patient suffering from the effects of hemorrhage.

The indications in gastric hemorrhage are simple: 1. Shock should be treated by rest, by morphine and by maintaining body heat, especially by the avoidance of ice internally or externally. 2. Complete rest, in bed, with physiologic rest of the stomach by means of frequent small feedings, preferably containing gelatin, to avoid violent and possibly dangerous hunger contractions. 3. The protective effect of the low blood pressure, preventing dislodgement of the thrombus which stops the hemorrhage, must be encouraged by avoiding sudden increases in blood volume or pressure. This involves the avoidance of stimulants and of intravenous or subcutaneous injection of fluids. Even transfusion may often cause a recurrence of active bleeding and should be avoided except in cases of actual air hunger, when usually 150 or 200 c.c. of blood will be sufficient. Blood regeneration is usually very rapid after cessation of bleeding.

DR. WILLIAM A. SWALM (Philadelphia, Pa.): I believe that this presentation brings out the fact that gastritis of the erosive type is a definite entity and that many hemorrhages occur in cases that are not of the true, peptic ulcer type. The Europeans have told us that the superficial musculature beneath the glandularis structure is the dividing line between ulcerative gastritis and peptic ulcer. May in collaboration with Müller has noted in pathological studies that if he finds hemorrhagic infarct, deep into the glandularis, rather than on the superficial muscularis mucosa, hemorrhage is likely to occur, and I think that is an important observation.

I think another important observation is that Christensen found gastroduodenitis in a great many of his so-called peptic ulcer cases. They had duodenal defects and, on operation they found gastroduodenitis and not true peptic ulcer.

DR. DANIEL N. SILVERMAN (New Orleans, La.): I should like to make mention of our recent experience in the treatment of persistent hemorrhage not alone from peptic ulcer, but also from severe cases of chronic ulcerative colitis and dysentery, and that is following the method recently devised by Marriott, of London, who showed single transfusions 500 c.c. of blood, which were instrumental in elevating the hemoglobin only 5 to 10 per cent, while with his method of continuous transfusion he had been able to elevate it much beyond the single transfusion, and keep that elevation, and had given as much as 3000 to 5000 c.c. of this citrated blood mixture within a short period of forty-eight hours.

In our experience, of course, which was with just a few cases, whereas Marriott is ready to publish some five hundred cases so treated, we were able to get results in these few cases in which previously repeated massive transfusions were given daily in the amounts of some 500 c.c. of blood without improvement.

We do know that in other diseases than peptic ulcer, hemorrhage is sometimes death dealing and single transfusions have not been as beneficial in those few cases previously mentioned as the so-called continuous drip blood transfusion of Marriott.

DR. MAX EINHORN (New York, N .Y.): I think this is a matter of clinical importance and I congratulate the two gentlemen, Dr. Blackford and Dr. Benedict upon their important papers.

I wish to make only a few remarks with regard to treatment. First, what is called hypertrophic gastritis is not always a real gastritis but hypertrophy of the mucous membrane, which is a secondary condition due to hyperacidity which results in hypertrophy of the glands.

With regard to erosions, which I described many years ago, they usually do not give rise to very much hemorrhage. We find in these cases small pieces of mucous membrane in the wash water—fasting condition, as a constant phenomenon. They have to be treated and can be treated very effectively by nitrate of silver spray—not washing but really spraying the stomach. Besides this galvanic current given intragastrically is also beneficial. I have had very good results with the above two means of treatment.

Very rarely it happens that an erosion can lead to a massive hemorrhage. That is the type described by Dieulafois as very important and in such cases an operation may be necessary.

In regard to the treatment of massive hemorrhage, I would like to say that the principle of rest is of the greatest importance, no matter what you do. Many years ago I introduced during the hemorrhage, or an hour or two later, the duodenal tube, and could see by aspirating very gently whether there was blood, and then let the tube go further, and, if it is in the duodenum, start with nutrition, giving them milk.

I do not speak now of a few cases, but I will mention my experience, which covers a very big field. In the severe cases I would say we can have good results—simply the rest treatment. The ice bag I am in favor of, then adrenalin, opiates when necessary, and thromboplastin we can

give, but I don't think that is the main thing, but resting of the stomach and keeping the patient quiet, no visitors, no talking, an ice bag, a little bit of water by mouth, and the rest by the duodenal tube.

DR. RUDOLF SCHINDLER (Chicago, Ill.): Mr. President and Members of the Association: This table (Table I) gives a classification of the gastric hemorrhagic phenomena other than those of ulcer, syphilis and tumors.

TABLE I

Classification of the gastric hemorrhagic phenomena other than those of ulcer, syphilis and tumors

I. MUCOSAL HEMORRHAGES	II. GROSS HEMORRHAGES
A. in the normal not inflamed gastric mucosa	A. Profuse parenchymatous bleeding in chronic hypertrophic gastritis (only one observation)
1. without other organic disease (often combined with pigment spots or *hemorrhagic erosions*)	B. caused by ulceration having eroded a blood vessel
2. in ulcer-bearing stomachs	1. without inflammation (hemorrhagic erosion)
3. in all kinds of general hemorrhagic diatheses	2. in chronic nonspecific ulcerative gastritis
B. in the inflamed gastric mucosa	a. in chr. superficial ulcerative gastitis
1. in acute gastritis	b. in chr. hypertrophic ulcerative gastritis (most common form)
2. in chronic nonspecific gastritis	
a. in chr. superficial g.	
b. in chr. atrophic g.	
c. in chr. hypertrophic g.	

It is, in my opinion, to the great merit of Dr. Benedict that he has directed our attention to a phenomenon which is well known but rarely sufficiently appreciated; namely, the fact that gross and even fatal gastric hemorrhages occur, the origin of which is not ulcer or carcinoma. What is the cause of these hemorrhages?

We usually subdivide chronic gastritis into three groups, two of them having a certain relationship to each other; namely, chronic superficial and chronic atrophic gastritis, while the third form, the chronic hypertrophic gastritis is a different entity. Most of the profuse hemorrhages in gastritis occur in the chronic hypertrophic form from an ulceration eroding a small blood vessel; the same occurs, but very rarely, in the superficial form.

To call a gastritis a hemorrhagic gastritis because an erosion of a blood vessel causes gross hemorrhage, does not agree with the generally accepted definition of a hemorrhagic inflammation. In a hemorrhagic inflammation, the inflammatory exudate contains more or less red blood cells; the hemorrhage is part of the inflammatory process.

Such mucosal hemorrhages in gastritis are frequent. I have described and pictured them in 1922. They are found in all forms. Some occult blood may be present in the stools; however, until a short time ago I believed that these true inflammatory mucosal hemorrhages never would lead to gross gastric hemorrhage, but a few months ago I observed a case at Cook County Hospital, Chicago, which seemed to me to prove the contrary. A white man, thirty-eight years of age, had several times had severe attacks of vomiting of blood and wished to be operated on. When I emptied the stomach with an Ewald tube, thin, light-red blood came out of the tube. Gastroscopically almost the whole stomach showed the most severe hypertrophic gastritis, velvety swelling, formation of nodules and verrucae. No ulceration was seen, but blood was oozing constantly from the inflamed, swollen area into the cavity of the stomach. This was a parenchymatous bleeding, a true chronic hypertrophic hemorrhagic inflammation causing gross hemorrhage.

It is evident that the described gross hemorrhages coming from ulcerations with eroded blood vessels do not belong to this group. They may be called chronic hypertrophic (or superficial) ulcerative gastritis, causing gross hemorrhage.

The fact that there are gross hemorrhages without ulcer, carcinoma, and so forth, but also without inflammation, is almost always forgotten. I am referring to profuse hemorrhages caused by non-inflammatory hemorrhagic erosions (1). They are rare. I have observed only three cases.

The following is characteristic: A white woman, fifty-six years of age, had had several gross hemorrhages. X-ray examination with the compression technic did not reveal any evidence of gastric disease. The gastroscopic impressions were:

(1) Numerous mucosal hemorrhages without inflammation;
(2) Multiple pigment spots; and
(3) Two *hemorrhagic erosions.*

Two days later the patient had again a severe but not fatal gross hemorrhage.

The knowledge that profuse gross hemorrhage occurs frequently from other conditions than ulcer and carcinoma must decisively influence our therapeusis.

DR. EDWARD B. BENEDICT (Boston, Mass.): I want to thank Dr. Schindler, Dr. Einhorn, Dr. Swalm, Dr. Andresen and Dr. Aschner for discussing the paper. It seems to me that a classification of chronic gastritis with hemorrhage is difficult. I called my paper "Hemorrhagic Gastritis," but in the publication I shall call it "Hemorrhage from Gastritis," because I think hemorrhage may occur in chronic superficial or chronic hypertrophic gastritis. I am trying to use Dr. Schindler's classification. I have not seen hemorrhage in atrophic gastritis, although I believe it may occur.

Cine-Fluorographic Studies of Lesions of the Gastro-Intestinal Tract*

By

WILLIAM H. STEWART, M.D.

and

DEWITT STETTEN, M.D.

NEW YORK, NEW YORK

CINE-FLUOROGRAPHY, as the name indicates, is the making of a motion picture record of the image seen on the fluoroscopic screen. Attempts to accomplish this purpose were begun by McIntyre (1) in Glasgow soon after the discovery of the roentgen ray. These efforts met with little success, however, when applied to the living patient. In this country, the late Dr. Eugene W. Caldwell conducted a series of such experiments beginning about 1906 and continuing for about fifteen years without any published success. Gastric motor phenomena were demonstrated more than twenty-five years ago by a motion picture film made from serial radiographs. In 1909, Kaestle, Rieder and Rosenthal (2) made thirteen successive radiographs of the stomach in twenty-two seconds. These were reproduced on a motion picture film, which, when projected, showed the passage of a peristaltic wave toward the pylorus. In 1910, Cole (3) demonstrated a method of making serial roentgenograms on a machine of his own design which employed a continuous X-ray film eight inches wide; he exposed areas of this film at regular intervals. Then, by a process of reduction and selection, combined with animation he was able to manufacture a film as a cinematogram. From 1921 to 1925, Reynolds (4, 5) of London, made extensive experiments leading at last to a successful motion picture of the fluoroscopic image of a thorax and various joints of the human body. More recently, Reynolds in England, Belot in Paris and Janker in Germany, employing greatly improved apparatus have successively made motion pictures of the fluoroscopic image.

REQUIREMENTS OF THE PROBLEM

The recording of a motion picture film of the movements of organs and joints of the living human being, is attended with considerable physical and mechanical difficulty. Any method which can be regarded as a solution of the problem must provide a technic which is safe, simple, convenient and inexpensive. Two methods may be suggested, namely, the direct and the indirect.

The direct method is the repeated exposure of any part of the human body to the X-ray beam recorded on a moving continuous X-ray film, as in the usual technic of making separate simple roentgenograms. This method is beset with many difficulties, is expensive and impracticable for routine examinations.

The indirect method makes a motion picture record of the fluoroscopic image. This method is obviously simpler, more accurate and less expensive.

DIFFICULTIES AND LIMITATIONS

Aside from the inherent mechanical difficulties this method is restricted by definite physical limitations. In solving the problem, which, after all, is that of focusing the greatest amount of light on the most highly sensitive photographic film, the following factors govern the result:

(1) The amount of energy in the incident X-ray beam. This is limited by the capacity of the X-ray tube and by the tolerance of the patient's skin.

(2) The light producing power of the fluoroscopic screen. This varies qualitatively and quantitatively according to:

(a) The chemical composition of the screen.

(b) The color of the fluorescence produced by the screen.

(3) The light-gathering power of the camera lens system.

(4) The photographic sensitivity of the film as related to the fluorescence of the screen.

As the limits of each of the above factors are widened, the greater is the scope of the method and the greater is the chance of success.

X-ray Tube: The X-ray tube we have found most satisfactory for this purpose is the G.E. 10 R.W. This tube can be safely operated at 100 KV with a current of 110 milliamperes for five seconds.

Skin Tolerance: When this tube is operated at 100 kilovolts, 110 milliamperes, at 40 cm. target-skin distance, with 1 mm. of aluminum and 5 mm. of wood filter, the estimated dose of radiation reaching the patient's skin is 500 roentgens per minute. This would be sufficient to produce an erythema in 48 seconds. The average time for each simple exposure has been five seconds which is repeated two or three times in each case. There is a rest period for the tube of 15 seconds between each five second exposure. This is well within the limits of safety. It is, therefore, apparent that the capacity of the X-ray tube is much more a limiting factor than is the tolerance of the patient's skin. If it were necessary, however, a further reduction in the amount of exposure of the patient could be brought about by synchronizing the excitation of the X-ray tube with the camera shutter so that the X-rays strike the patient only during those instants when the camera shutter is open. Although this is the arrangement employed by Reynolds we have not found it necessary because in five seconds a complete cycle of any moving organ of the body except the stomach can be recorded.

Fluoroscopic Screen and Photographic Film: The brilliance of the fluoroscopic image varies with the chemical composition of the screen while the photographic results depend upon the sensitivity of the film to that particular wave-length of light emitted by the screen. After many experiments made with all types

*Read at the Annual Meeting of the American Gastro-enterological Association, Atlantic City, June 7 and 8, 1937.

of available screens and photographic film we have found that the most desirable combination is a special screen emitting a yellow green fluorescence used in combination with Eastman Super X Film. This screen is made from a preparation of zinc sulphide developed by Dr. Leonard Levy and Mr. Donald West of London, Engand. It compares with a type B Paterson Screen.

Lens System: The lens employed is a Zeiss R-Biotar, with an aperture of 0.85 and a focal length of 5.5 cm. In order to cover the fluoroscopic field of 30 x 50 cm. it was necessary to place the lens at a distance of seven feet from the screen. This lens is fitted with a focusing mount and because it is used wide open no diaphragm is employed.

Camera: The Bell & Howell Filmo 70-D, 16 mm. camera, fitted with a special finder has been found to be most satisfactory.

Technic: Employing the above mentioned factors and the normal camera speed of 16 frames per second 80 pictures could be obtained in the exposure time of five seconds. This is sufficient to record the motions of such rapidly moving organs as the heart, lungs and diaphragm as well as to demonstrate the mechanism of swallowing. Films made of the esophagus require at least 12 frames to the second or a total of 60 frames to each exposure. If the camera speed is reduced to 8 frames per second the exposure time per picture is doubled and the apparent motion of the organs is proportionately increased to twice the normal speed.

In suitably thin patients the camera speed may be increased to 24 pictures per second, so that when the film is projected the apparent motion is slowed down proportionately, and permits more careful study and analysis of the film. Within narrow limits the speed of the apparent motion may be further diminished by reducing the rate of projection. Beyond this point, however, further slowing of the projection speed produces a flickering image.

CINE-FLUOROGRAPHY OF THE GASTRO-INTESTINAL TRACT

The investigation of the organs below the diaphragm is attended with considerable difficulty. This portion of the body is so opaque that the fluoroscopic image is much fainter than that seen in the examination of the chest. Since the total continuous time of exposure cannot be extended beyond a maximum of five seconds with the tube which we are using, the only way to increase the exposure per picture is to diminish the distance between the screen and the film and to reduce the camera speed to 8 frames or less per second. At this rate a clear picture can be obtained in a suitably thin patient. The time required for a normal peristaltic wave to pass downward along the full extent of the stomach has been estimated as averaging forty seconds. For that reason even a five second exposure is limited in its recording of movement.

In our efforts to obtain a film of the gastro-intestinal tract below the diaphragm we have shortened the screen-lens distance to five or even to 3.9 feet and reduced the camera speed to 4 to 8 frames per second. This has increased the amount of light which reaches the film from any unit area of the screen. With the shorter screen-lens distance the size of the field has necessarily been proportionately reduced so that only a part of the screen image can be photographed. It is therefore necessary to focus the camera accurately on the pathologic lesion.

With the equipment and technic described above, we have been able to obtain excellent films of the functioning in health and disease of the esophagus, stomach, duodenum and gall bladder, although the phase of gastric activity revealed by the film is so short that only a little of the real physiological activity of the stomach or duodenum can be demonstrated. Films of the act of swallowing show the manipulation of the opaque bolus in the pharynx and its peristaltic descent through the esophagus. The entire action is contained on a strip of film containing 40 to 60 frames, the projection of which would provide visible action for only a few seconds. By repeatedly printing this short film on a roll of film twenty-five to fifty feet in length the cycles of action may be projected over and over again for many minutes. This provides ample time for study of the physiologic action of the organs under investigation. Having obtained a good film it is necessary to have a projectoscope which will give the maximum amount of light and one in which the speed of the shutter can be cut down to a minimum without a flickering of the image. A Bell & Howell 1000 watt machine has proven to be most satisfactory.

FIELD FOR FURTHER IMPROVEMENT

At its present stage of development, the greatest needs in the field of cine-fluorography are:

(1) A method of prolonging the exposure so that a record of twenty to thirty seconds of action may be made at one time.

(2) A more brilliant fluoroscopic screen.

(3) X-ray tubes of greater capacity for longer periods.

(4) More sensitive films.

(5) Better correspondence between the sensitivity of the film and the light production of the screen.

Improvements in screen, X-ray films and tubes must await dvelopments by the chemists and physicists. Until they are available we must learn to make the best possible use of the remarkable materials and equipment which they have already placed in our hands.

ADVANTAGES OF CINE-FLUOROGRAPHY

By means of cine-fluorography a permanent record may be made of the functioning organs and parts such as the esophagus, diaphragm, stomach and duodenum, intestines and gall bladder, both normal and pathological. This motion picture record can be studied at leisure without danger of excessive exposure to the patient or examiner. It provides a means of comparing the state of the functioning organs or parts with previous motion picture records, thus demonstrating the results of operative, X-ray, radium or other therapy or the progress or recession of the disease. It furnishes, also, a means for building up a library of excellent teaching material. These motion picture films can be shipped to distant places for consultation and opinion on the condition of the patient at the present time or at any time in his previous history as represented on the films.

The method is simple, convenient, safe and relatively inexpensive. With further experimentation and improvement its scope doubtless will be broad-

ened, and it is probably destined to become an important division of roentgenological study.

DISCUSSION

DR. CHESTER M. JONES (Boston, Mass.): I should like to make one comment. If ever I saw an excellent demonstration of aerophagia and "gas in the stomach," it has been shown here. I think this film could well be used for teaching purposes.

DR. A. C. IVY (Chicago, Ill.): I should like to congratulate Dr. Stetten and Dr. Stewart on the wonderful demonstration they have made. Those of us who are physiologists and have worked in the laboratory on animals have frequently prayed for an apparatus of this kind. For example, we have seen reversed waves on the esophagus with the fluoroscope and with the esophagus exposed through an opening in the chest. We have never been able to demonstrate them the way this film does. Never have we had available such a beautiful way of demonstrating how evacuation of the duodenal cap occurs.

It would be very interesting to extend such a study as this to the evacuation of the distal ileum, and also to the colon.

In conclusion, I hope that Dr. Stewart will be able to make copies of this film available to teachers of medical students at a cost that is not prohibitive.

DR. JOHN L. KANTOR (New York, N. Y.): We might add a vote of thanks to Dr. Einhorn, who has shown such a wonderful way of perpetuating his investigations from the earliest years of our specialty right up to the threshold of the future, as it were.

PRESIDENT JONES: That is a very justifiable remark.

DR. MAX EINHORN (New York, N. Y.): Mr. President, I wish to congratulate Dr. Stewart and Dr. Stetten on their very important work. There is a saying "Seeing is believing," and I think this demonstration helps a great deal to clarify the particular situation and that is the reason I am interested in it. I should like the two gentlemen to follow it up further, down the whole intestinal tract.

The Interdependence of Gastric Secretion and the CO_2 Content of the Blood and its Significance in the Alkali Treatment of Peptic Ulcer*

By

EVERETT D. KIEFER, M.D.

BOSTON, MASSACHUSETTS

THE usefulness of alkalis in the treatment of duodenal ulcer has been fully established by the fact that Sippy powders and other forms of alkalis are still in use many years after they were first introduced. Some clinicians attempt to achieve complete neutralization of the gastric contents while others are content to use alkalis only in sufficient quantities to control pain.

The hypersecretion of hydrochloric acid and the activity of peptic ulcer are so closely associated clinically that regardless of whether one or the other is the primary factor, effective neutralization of the gastric juice is a rational procedure which has yielded good results in many cases. While an ulcer may be so mild that comparatively little alkali is necessary to control symptoms and promote healing, patients with severe active lesions tend to produce such large quantities of acid that only heroic doses of alkali are effectual. Nevertheless, it is common experience that the patient with the most active ulcer, the most severe symptoms and the highest acid is the one who shows the least tolerance to alkalis, so that frequently, in the case with the greatest need for neutralization, the use of alkalis is limited by the increased tendency to alkalosis. Under these circumstances, a therapeutic dilemma develops, the explanation of which involves physiologic as well as pathologic considerations.

A tendency to alkalosis has been shown to be indicative of a severe ulcer. Jordan and Kiefer (1) have presented statistical evidence that intolerance to alkali therapy is an unfavorable prognostic sign in the medical management of ulcer. Additional observations include the fact that patients who are quickly upset by alkalis during the active phases of their ulcer, can often take the same dosage after the hypersecretory phase has passed without unduly raising the blood CO_2. These clinical observations suggest that the occurrence of alkalosis may be largely dependent upon the secretory activity of the gastric glands and associated changes in the electrolyte balance in the blood and body fluids.

Previous reports (Wilkinson (2), Hardt (3), Ellis (4), Gatewood (5)), have cited impaired renal function as a major etiologic factor. This is undoubtedly true in many cases, but it does not explain either alkalosis occurring in patients without evidence of kidney disease or the increase in tolerance to alkalis observed in some cases when there is no evidence of improvement in the condition of the kidneys. There is apparently some additional mechanism which determines the amount of load thrown upon renal tissue, which is the chief regulatory organ governing the acid-base balance of the blood.

Read at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7 and 8, 1937.

Sodium bicarbonate, which is the most important antacid used in alkali therapy from the standpoint of the production of alkalosis, is a soluble salt readily absorbed from the gastro-intestinal tract and readily secreted unchanged by the kidney. Investigations (Kast (6), Jordan (7), Gatewood (5)) of the blood in the alkalosis state have disclosed an appreciable rise in the plasma pH, a marked rise in the CO_2 content and a decrease of the chlorides of the plasma. If the mechanism responsible for these changes, particularly the elevation of CO_2, is an accumulation in the blood of sodium bicarbonate absorbed as such and present because of delayed excretion by the kidneys, blood analysis should show an increase in sodium as well as bicarbonate. Actual measurements of the total base reported in this paper show that alkalosis may be present without an accumulation of base in the plasma.

When the total base, chlorides and CO_2 content are known, it is possible to construct a diagram of the electrolytes of the blood expressed in comparable units, i.e. mille-equivalents per liter (Figure 1). The total height of the column is determined by measuring the total fixed base which tends to remain constant at about 160 mille-equivalents per liter. The total anions are represented by a column of equal height. The bicarbonates and the chlorides are measured separately and the remainder which consists of protein, organic acids, sulphates and phosphates, is obtained by subtracting the sum of the CO_2 and the chlorides from the total base. In the normal, the bicarbonate is equivalent to about 30 mille-equivalents per liter, the chlorides to about 101 and the undetermined radicals account for about 29 mille-equivalents per liter. See Subject 1 (Figure 1).

Subject 2 (Figure 1) was a case of alkalosis with typical symptoms except there was no vomiting. The pH was elevated and the plasma bicarbonate was increased with almost identical lowering of the chlorides. The total base remained constant, showing that alkalosis can occur without an appreciable accumulation of base in the blood.

A reduction of the chlorides was found to be a regular concomitant of an elevated CO_2 content so

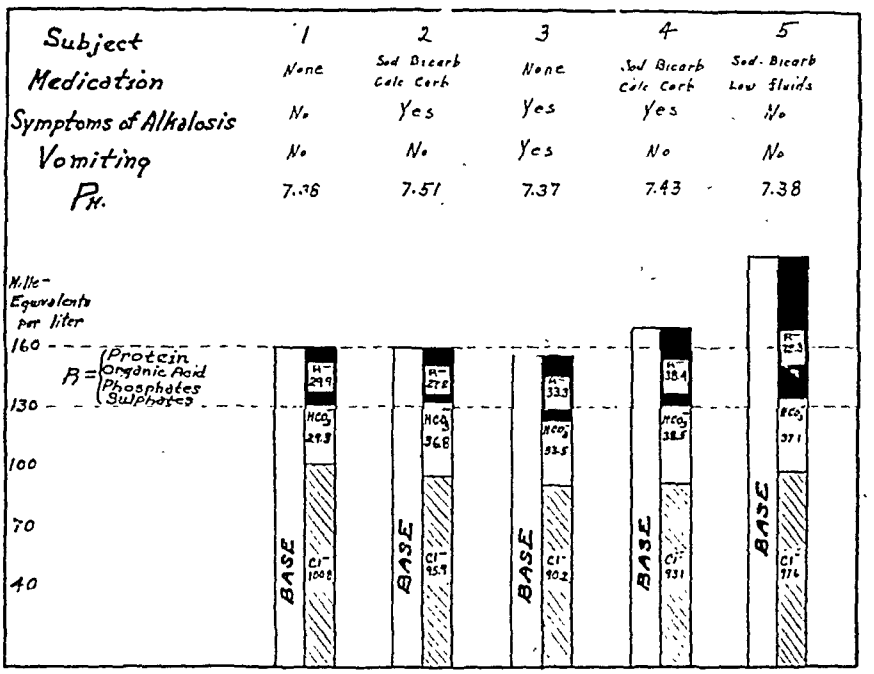

Fig. 1

that in every condition studied, an increase in the bicarbonate ion resulted in the displacement of an equivalent amount of chloride ion. It is to be noted that regardless of the changes demonstrated by the diagrams in Figure 1, the sum total of chloride and bicarbonate remains remarkably constant. The role of the chlorides, therefore, appears to be an important one.

The relationship of gastric secretion may be represented schematically by Figure 2. During gastric secretion, particularly during the stages of hypersecretion associated with ulcer, the parietal cells are actively engaged in manufacturing large quantities of hydrochloric acid which is a strong, highly dissociated acid. Under ordinary circumstances the acid is neutralized by food, products of digestion and the alkaline secretions present in the intestine. The chloride is reabsorbed to adjust the slight temporary relative increase in base, known as the alkaline tide.

If an excess of sodium bicarbonate is introduced into the stomach, neutralization of hydrochloric acid takes place and the chlorides pass into the intestine as sodium chloride. Here they are reabsorbed as in normal conditions with the exception that they carry into the blood sodium ion, which instead of coming from the blood by way of liver and pancreatic secretions, originates outside the body. The chloride ion therefore makes the circuit of being passed out of the

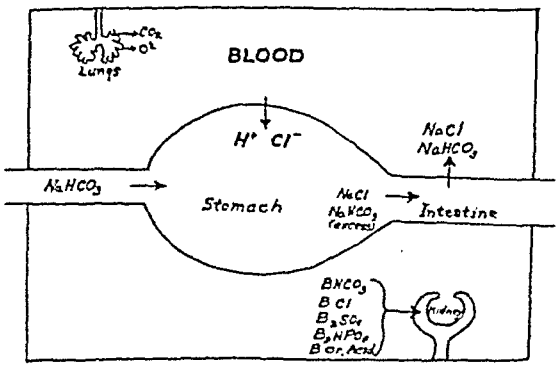

Fig. 2

blood into the intestinal tract and back into the blood, but the net result is that sodium is quantitatively added to the body. Further gain in sodium takes place as the excess sodium bicarbonate is absorbed as such, but this portion carries with it an acid radical (HCO_3) which also originates outside the body and permits the kidney to excrete sodium bicarbonate in the urine. Since it is necessary to conserve the chlorides. The real problem for the body is to find acid radicals to combine for excretion with the sodium ion which was absorbed as sodium chloride. Sodium appears in the urine combined with sulphates, phosphates, carbonates and organic acids, but in addition considerable chloride is lost. To compensate for the chloride depletion, the bicarbonate concentration of the plasma increases, resulting in a rise also in the free CO_2, which is part of the buffer system which prevents more than minimum changes in blood pH. This concept is offered as an explanation of the mechanism by which the blood CO_2 is elevated and the clinical observation that alkalosis occurs more readily when gastric hypersecretion is present because the quantity of sodium absorbed without the introduction of an equivalent acid radical is dependent upon the amount of hydrochloric acid neutralized in the stomach.

In a case of alkalosis caused by vomiting, as in Subject 3, Figure 1, there is some loss of base, but a much larger depletion of chlorides which operates in the same way to produce a relative increase in the combined CO_2 of the blood. This explains the clinical observation that patients with vomiting show the least tolerance for alkalis.

Dehydration is a prominent feature of alkalosis and tends to occur when there is a large excretion of sodium, since this element cannot be excreted without the loss of water. Subject 4, Figure 1, represents the changes in the blood when the water balance is upset in the presence of alkalosis. There is a definite increase in total base but the increase in the acid radicals occurs in the undetermined portion which consists largely of protein and organic acids. Subject

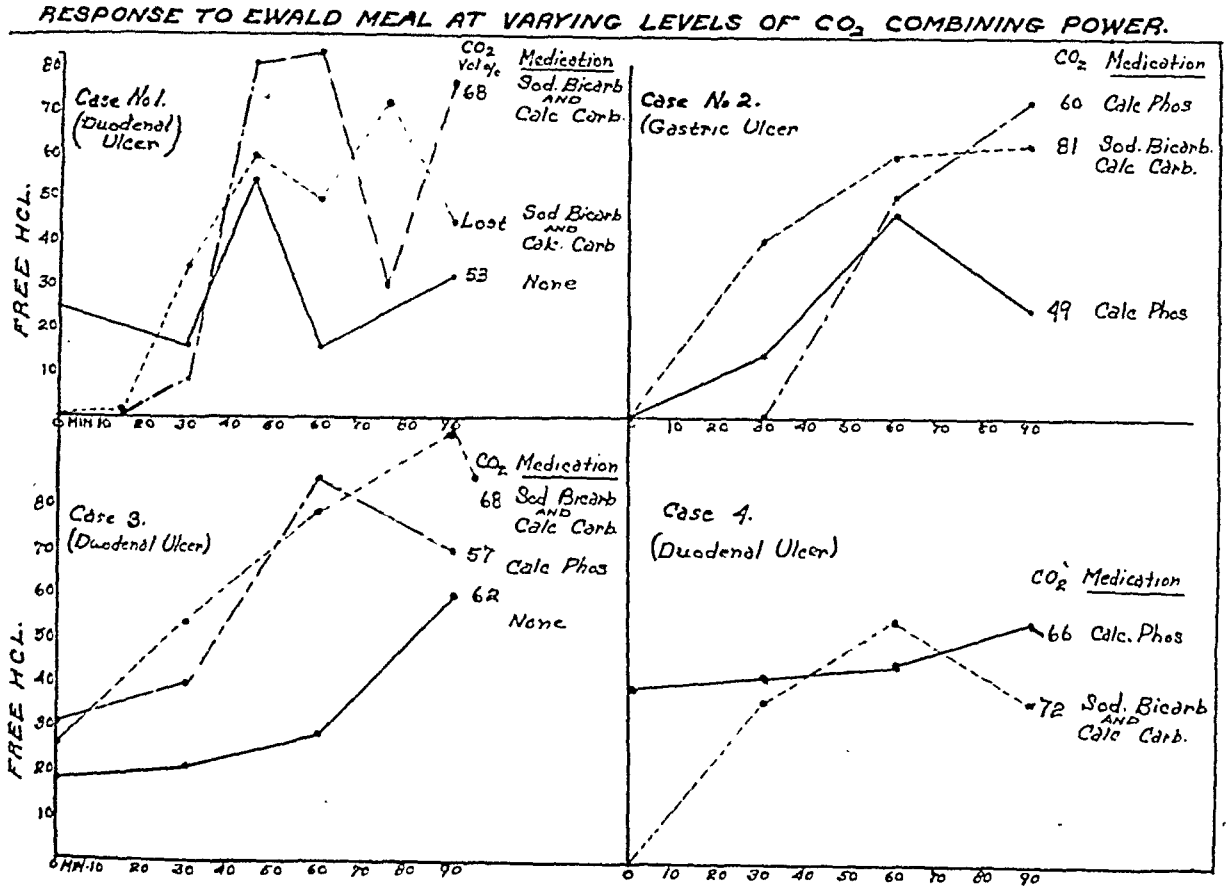

Fig. 3

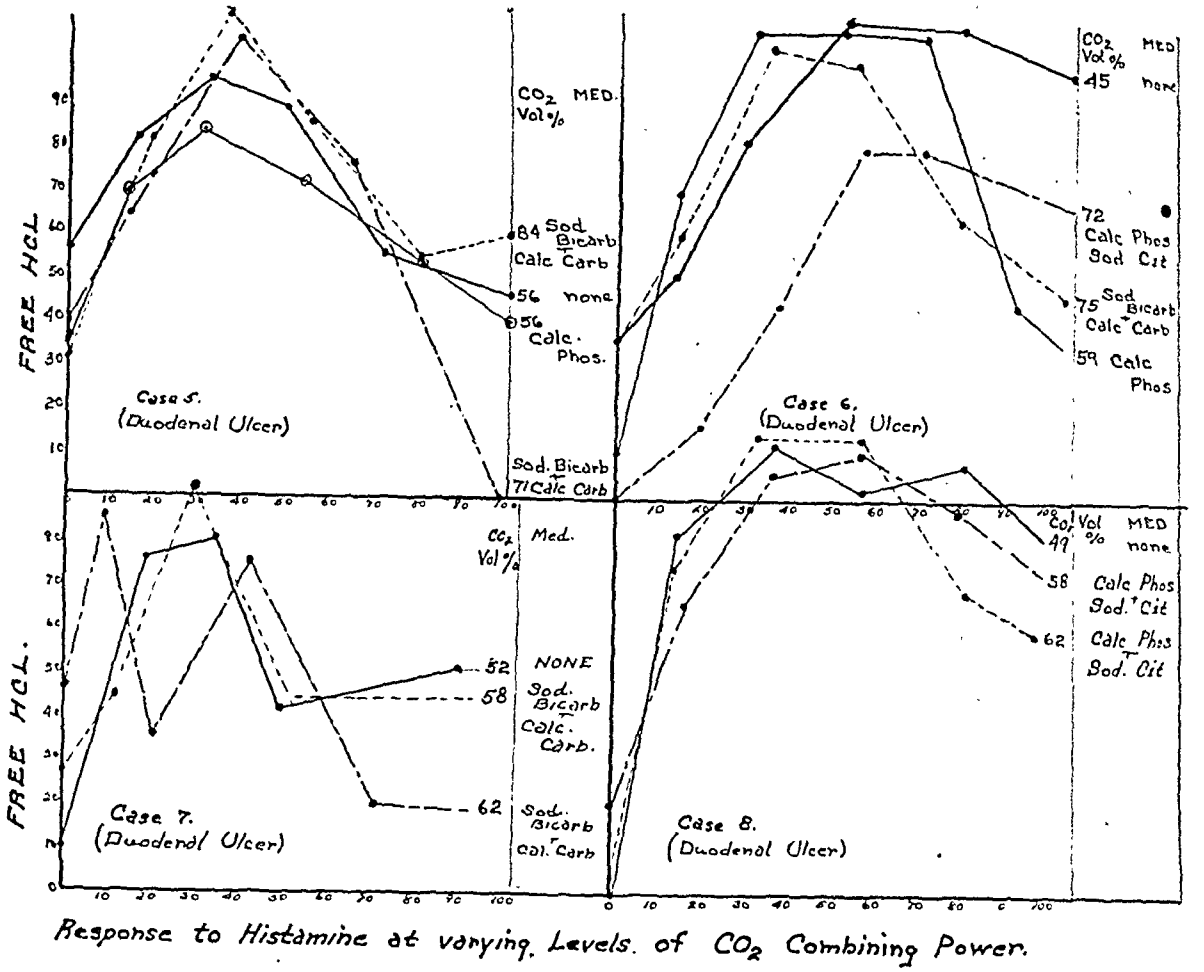

Fig. 4

5. Figure 1, shows the result of sodium bicarbonate ingestion with limited fluids. Although true alkalosis did not develop there was an enormous increase in base which is held combined with protein and organic acids, leaving the sum total of chlorides and bicarbonates practically unchanged. Fluids, therefore, deserve much consideration in the prevention and treatment of alkalosis.

While gastric hypersecretion is apparently one of the basic factors promoting alkalosis, it is possible that there may be a reciprocal action and that changes in the chemistry of the blood influences the activity of the gastric glands. It is occasionally noted clinically that patients taking alkalis have higher acid secretion than before treatment was started. In 1918, Crohn (8) demonstrated that alkali produced an irritative secretory reaction in the stomach. More recent experiments suggest that alkali may also act in an indirect manner to increase gastric acidity.

The gastric secretion of acid has been shown to be augmented by the inhalation of CO_2, (Bakaltschuk (9)) by the intravenous injection of sodium bicarbonate (Szilard (10)) and by pathological conditions causing a rise in plasma CO_2 (Apperly (11)).

In 1932, Browne and Vineberg (12) working with dogs, showed that the total amount of acid secreted could be increased or decreased by artifically raising or lowering the plamsa CO_2 content. Apperly and Crabtree (13) believe that in human subjects certain considerations suggest direct relationship between the concentration of gastric hydrochloric acid and the plasma bicarbonate content. There appears to be an agreement among investigators that the relationship is with the CO_2 content and not with the pH of the plasma.

In this investigation a group of ulcer patients has been studied to determine the reaction of the gastric secretion to various stimuli in the presence of varying levels of plasma CO_2 induced by the use of alkalis.

When the Ewald meal was used as a gastric stimulant, it was found that some cases, at least, did show a somewhat higher acidity curve when the plasma CO_2 was appreciably elevated. (Figure 3).

With histamine as a secretory stimulant there was less difference between the acidity curves produced at varying CO_2 levels. (Figure 4).

An alcohol test meal gave curves which if anything were lower when the CO_2 was elevated. (Figure 5).

However, gastric analyses in which only the concentration of acid is measured, are subject to uncontroll-

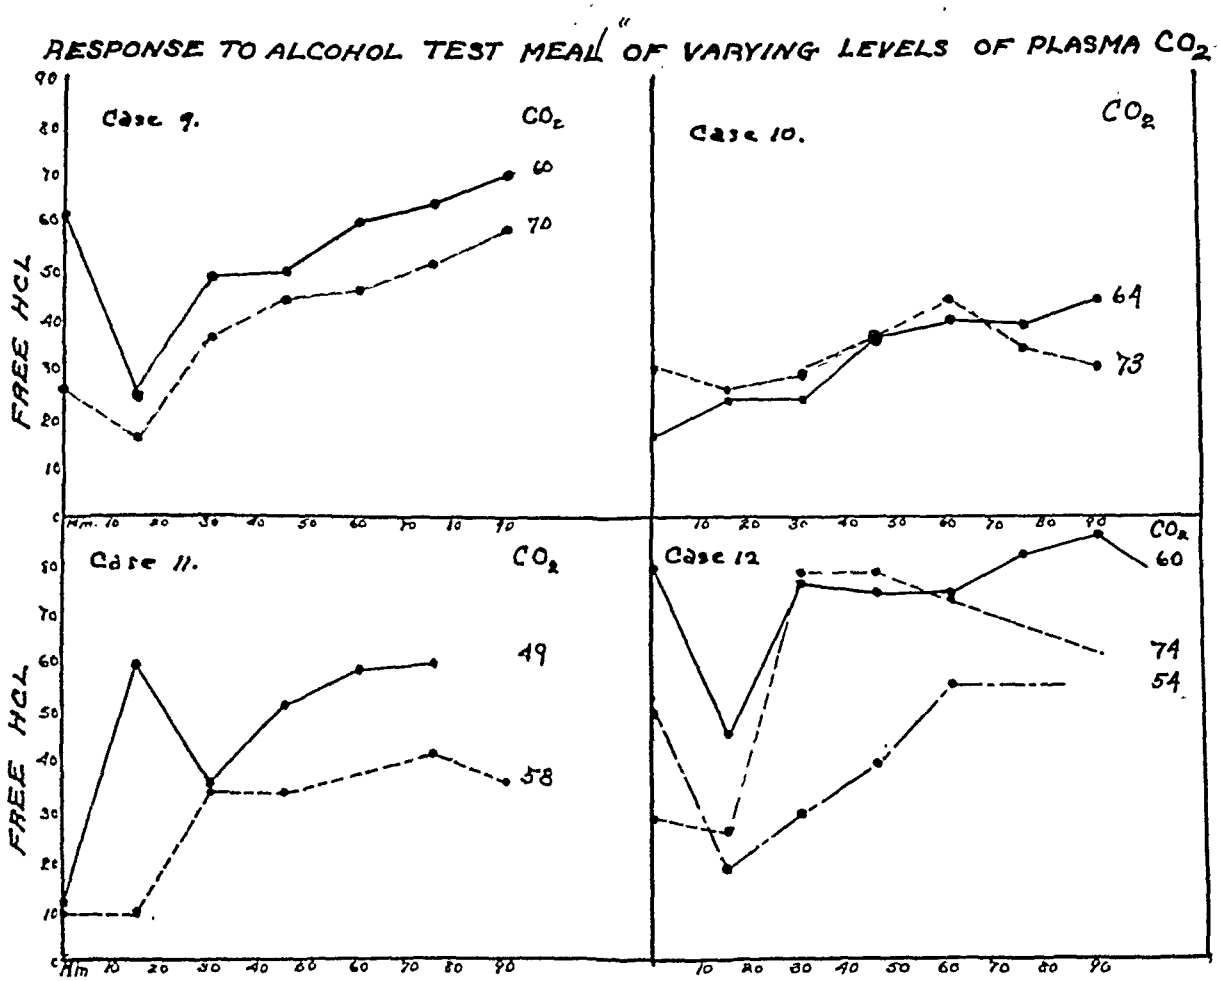

Fig. 5

able variations related chiefly to factors of dilution and emptying of the stomach during the test. It seems more important to determine the total quantity of acid secreted in a given time. This was done in the case of histamine stimulation by aspirating the entire stomach contents every ten to fifteen minutes so that there was comparably little accumulated secretion to be expelled through the pylorus. The product of the volume secreted and the concentration of acid gives the total quantity of acid in a given time. When the alcohol test meal was used, the rate of dilution of an added dye was measured colorimetrically and the volume secreted was calculated according to the method of Bloomfield (14).

The results of the calculations show that in 7 out of 11 cases there is no corresponding increase in acid secretion as the CO_2 is elevated, but that the tendency is definitely in the opposite direction. (Figure 6).

The apparent contradiction to Browne and Vineberg's results may be explained by the fact that their work was an acute experiment with dogs in which the changes in the CO_2 levels were enormously greater than are available in a clinical study.

SUMMARY

In a study of the electrolytes of the blood can be found an explanation for the clinical fact that alkalosis occurs most readily in cases with active ulcers and high gastric secretion; i.e., the secretion and neutralization of excessive quantities of hydrochloric acid is as much a factor in raising the CO_2 as is renal impairment.

Under clinical conditions, there is a direct relationship between the activity of gastric secretion and the degree of change in the plasma CO_2 produced by alkali therapy. On the other hand, there is little evidence that shifts in blood electrolytes, including an elevation in CO_2, appreciably affect gastric secretion except for some tendency to decrease the quantity of hydrochloric acid secreted by the stomach in a unit time.

Laboratory experiments which indicate that gastric secretion is augmented by any increase in blood CO_2, are not confirmed under clinical conditions, at least to a degree which would contra-indicate the use of alkali in the treatment of ulcer.

METHODS

In the study of the blood the total base was determined by the method of Van Slyke, Hiller and Berthelsen (15); the CO_2 content by the method of Van Slyke and Neill (16); the chlorides according to Wil-

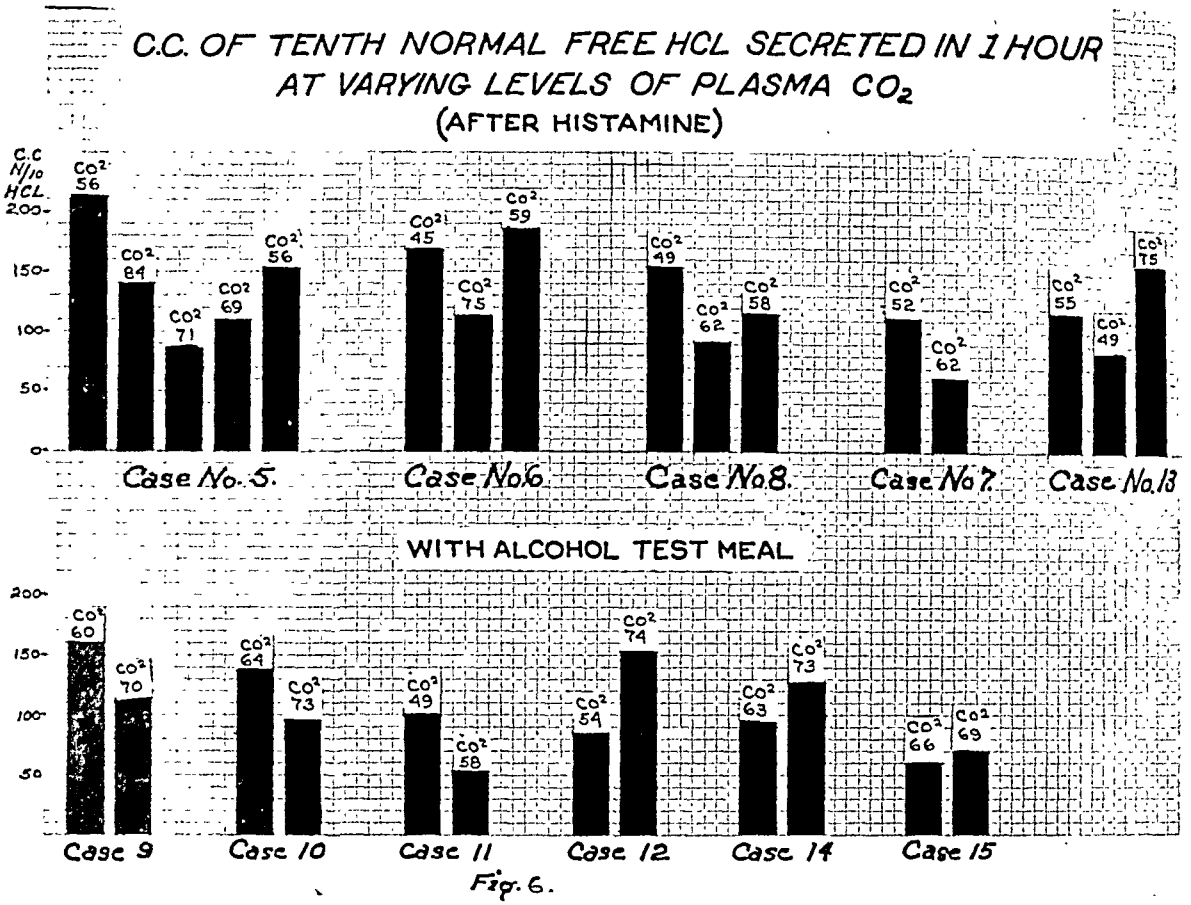

Fig. 6.

son and Ball (17); and the pH of the plasma by the colorimetric method of Cullen (18) with the use of "permanent" color standards. The blood for analysis was drawn from the vein without stasis and with protection from the air by the use of mineral oil. Neutral potassium oxalate was used to prevent clotting and the specimen was centrifuged immediately to obtain plasma for the pH, CO_2 and chloride determinations. Part of the specimen was allowed to clot and the serum was used for the estimation of the total base.

In the study of gastric secretion, the stimulants used were the standard Ewald bread and water meal, subcutaneous histamine in doses of 0.5 to 1.0 mg. depending upon the size of the patient, and 100 c.c. of 7% alcohol. In every case fractional methods were used with an indwelling Rehfuss' tube and the patient lying on his back to promote retention of the gastric contents in the fundus. Patients were instructed not to swallow saliva during the test. Specimens were taken at intervals of from ten to twenty minutes. The tests were carried out eleven to twelve hours after the last powder.

When the Ewald meal was used 10 c.c. specimens were removed for analysis. With histamine the stomach was completely emptied at the end of each test period. The volume of the secretion as well as the acid concentration was recorded in order to calculate the total quantity of free HCl secreted in a measured time. With the alcohol test meal phenolsulphonphthalein was added to the 7% alcohol solution. At the end of each fifteen minute period the entire contents of the stomach were removed, the volume measured and immediately returned to the stomach with the exception that 20 c.c. were withheld for the estimation of free HCl and concentration of dye by colorimetric comparison with the original solution. The method and calculations have been described by Bloomfield and Keefer (14). The total acid secreted in a period of time was calculated as the difference between the quantity of acid introduced into the stomach at the beginning of the period and the quantity of acid present at the end of the period plus the quantity of acid lost by evacuation during the period. The volume of gastric contents evacuated is determined by adding the volume secreted during the period to the volume introduced at the beginning of the period and subtracting the volume found in the stomach at the end of the period.

DISCUSSION

DR. HENRY A. RAFSKY (New York, N. Y.): Upon a previous occasion the fact was emphasized that patients with obstructive peptic ulcers were potential cases of alkalosis; furthermore that they could be successfully treated by comparatively small doses of alkali. This raised the question as to whether hyperchlorhydria and hypersecretion, while valuable as diagnostic aids in peptic ulcer, were equally as valuable as therapeutic guides.

With this in mind, I took a small series of cases of the duodenal ulcers and to one group I gave various antacids and another group hydrochloric acid, minims 25 to 30 t.i.d., a.c., using histamine to determine the acid curve before the treatment was started and before the patients left the hospital. It was interesting to note that there was no material relationship between the secretory and the clinical response, in either group. In some of the patients, to whom antacids were given, there was a downward trend to the curve; the same was noted when hydrochloric acid was administered. In others the acid curves were just as high after the treatment as before the treatment, even though they were symptom free and irrespective of the medication used.

I am not advocating hydrochloric acid as a therapeutic measure. It was only used as a control. These observations indicate that, perhaps, our notions on the relationship of hyperchlorhydria and the use of large doses of alkali are perhaps too fixed and may be subject to change. Some of the charts of these patients are being presented at the Scientific Exhibit, at the gastro-enterological section.

Observations on Gastric Acidity Before and After Development of Carcinoma of the Stomach*

By

MANDRED W. COMFORT, M.D.,† WINFIELD L. BUTSCH, M.D.‡

and

GEORGE B. EUSTERMAN, M.D.§

ROCHESTER, MINNESOTA

WHEN the Ewald meal is used, achlorhydria is detected in about 60 per cent of the cases of cancer of the stomach in which operation is performed, and hypo-acidity characterizes the gastric secretion in a majority of the remaining cases (1)**. For some reason the percentage of anacidity (20) and the mean concentration of free hydrochloric acid (38) found among normal persons of the same sex and age have been respectively increased to 60 per cent and reduced to 26 clinical units among cancerous persons. When does this reduction in gastric acidity take place? Do persons who subsequently develop gastric cancer start life with a low mean secretory capacity, or do they start life with a normal secretory capacity that is partly lost before cancer develops, or does the reduction take place after cancer develops? What is responsible for the loss of secretion? It is our plan to present data of our own and to review those of other observers bearing on these problems.

MATERIAL

Search of our records has disclosed seventy-nine cases in which analysis following a gastric test meal was carried out before and after the development of carcinoma of the stomach. Patients of all ages, from the third to the eighth decades of life, were seen at both the first and the second admissions. At the first admission, the ages of six fell in the third; of sixteen, in the fourth; of nineteen, in the fifth; of thirty, in the sixth; of seven, in the seventh, and of one, in the eighth decade of life. At the second admission, the ages of three fell in the third; of eight, in the fourth; of eighteen, in the fifth; of twenty-five, in the sixth; of twenty-one, in the seventh, and of four in the eighth decade of life. The average ages of the patients at the time of the first test meal, and before the development of cancer, was forty-seven years and at the time of the second admission, and after the development of cancer, fifty-three years.

Twenty-one of the seventy-nine patients were operated on at the time of the first admission. Lesions of the stomach were removed and found to be benign in fourteen cases. Cholecystitis was found in another four, and duodenal ulcer in another two cases. In each of these six cases, as well as in a seventh case, the stomach was examined at the time of operation and was found to be free of organic disease. In these twenty-one cases in which operation was performed a

§Division of Medicine, The Mayo Clinic, Rochester, Minn.

cancer was almost certainly absent at the time of the first admission. In most of the remaining fifty-eight cases, the proof that a cancer did not exist at the time of the first test meal was almost as good. One or more roentgenologic examinations of the stomach were conducted in forty-nine of the fifty-eight cases. In forty-five of the forty-nine cases roentgenologic examinations failed to disclose a lesion of the stomach. In one, the roentgenologic diagnosis was indeterminate; in another, the roentgenologic diagnosis was gastric ulcer, while in two more, the roentgenologic diagnosis was duodenal ulcer. In the last four cases mentioned, the intervals between the first examination and the examination which disclosed cancer were, respectively, seven, three, two, and two years, intervals almost too long for a cancer of any size to exist at the time of the first test meal. In these forty-nine cases in which roentgenologic examination was made, the evidence was definitely against the presence of cancer at the time of the first test meal. In the remaining nine of the fifty-eight cases roentgenologic examination was not carried out, but eighteen, fifteen, eleven, ten, ten, four, three, three, and one years passed after the first test meal before cancer was diagnosed. It is possible that a cancer was already present in the last case, in which an interval of only one year passed between the two examinations, but this patient was in good health, had no gastric complaints, and the test meal was done because the patient, knowing he had had gastric anacidity for years, wanted this checked. In the remaining eight of the nine cases in which a roentgenologic examination was not made, the interval itself eliminates the possibility of a cancer being present at the initial examination. In short, the surgical findings, the roentgenologic examinations, or the time intervening between the first and second examinations make it improbable that a cancer existed at the time of the first examination except in a small percentage of cases and, if present, that it was large enough to affect gastric acidity per se.

METHODS

Modification of the Ewald meal used in determining gastric acidity in this series has been described elsewhere (1). In the presentation of the data culled from these records, the statistical technic of Vanzant, Alvarez, Eusterman, Dunn and Berkson has been followed (6).

GASTRIC ACIDITY BEFORE THE DEVELOPMENT OF CARCINOMA OF THE STOMACH

Of the seventy-nine patients the gastric contents of thirty (38 per cent) were achlorhydric before cancer developed (Table I). Particular attention is called to this figure inasmuch as it will be interesting to remember it at a later time. In the remaining forty-nine or 62 per cent of the cases, the gastric contents contained free acidity of a mean concentration of 27.1 clinical units. In other words, even before cancer had developed the incidence of achlorhydria was greater by 22.1 per cent, and the mean free hydrochloric acid was less by 14.2 units, than that expected for a group of persons of the same sex and age. Either these seventy-nine persons started life with an average gastric acidity below normal or they started life with a normal gastric acidity that was subsequently reduced by some abiotrophic or inflammatory process by the time they had reached the average age of forty-seven years.

GASTRIC ACIDITY AFTER THE DEVELOPMENT OF CARCINOMA OF THE STOMACH

Between the time of the first admission (before the development of cancer) and the time of the second admission (when cancer was diagnosed), an interval of one to eighteen years elapsed (Table 2). Within five years after the first admission forty-seven, or more than half of the patients of this series had developed carcinoma of the stomach. Within six to ten years inclusive, an additional twenty patients had developed cancer. In another group of nine patients, eleven to fifteen years passed before cancer manifested itself clinically, while in the remaining three cases, sixteen to eighteen years rolled by before the disease appeared. The interval averaged six years and by this time the mean age of the patients had increased from forty-seven to fifty-three years.

TABLE II

Intervals in years between the first admission and the development of gastric cancer, cases

Interval, years	Group I	Group II	Group III	Total
1	5	1	9	15

17				
18		1		1
Totals	30	21	28	79
Mean interval	5.4	6.5	5.5	5.8

Definite changes occurred in the secretory activity of the seventy-nine patients in the interval between examinations. The percentage of patients who had achlorhydria had increased from 38 to 64.6 and the number of patients whose gastric contents contained free acid decreased from forty-nine to twenty-eight (Table I). The mean free acidity in the twenty-eight cases was 30.3 units. It is interesting to note that the concentration of acid was higher than that of the

forty-nine persons who had free acid in the stomach six years previously.

The seventy-nine patients can be divided into three groups according to the behavior of the gastric secretory activity in the interval between the first test meal and the second test meal (Table I). Group I includes thirty patients whose gastric contents were anacid at the time of the first test meal and remained so at the time of the second meal. Hurst (7) stated that he had seen five patients who were known to be achlorhydric before carcinoma developed and had found records of at least twenty-two similar cases. Konjetzny (8) stated that Albu, Boas, Kuttner, Porges, Stewart, Zweig and others, as well as Hurst, had observed that cancer developed after the appearance of achlorhydria. Obviously, it is not uncommon for achlorhydria to precede the development of cancer. Group II includes twenty-one patients whose gastric content contained free acid at the time of the first meal but not at the time of the second. Konjetzny has reported a similar case. Group III is composed of twenty-eight patients whose gastric contents contained free acid at the time of the first, and retained it at the time of the second test meal in spite of the development of cancer of the stomach. Hurst (9) reported three similar cases.

In the secretory activity of stomachs of the twenty-one patients of Group II are to be found the changes that have so altered the percentage of anacidity at the time of the second test meal from that found at the time of the first test meal. The mean free hydrochloric acid of these twenty-one patients at the time of the first test meal was 23.9 or 17.4 units less than that expected of a group of normal persons of the same age and sex (Table I). The mean concentration of free hydrochloric acid of the twenty-eight patients of Group III at the time of the first test meal, and who continued to secrete free acid after the development of cancer was 29.4 or only 11.9 units below that expected in a group of normal persons of the same sex and age (Table I). In other words, the secretory activity of the stomachs of the patients of both Groups II and III was subnormal even before the development of cancer. This suggests that some process reducing gastric secretory activity was already at work in these cases of Groups II and III at the time of the first test meal.

Seven of the patients of Group II had undergone gastro-enterostomy for benign gastric ulcer at the time of the first admission. The remaining fourteen patients were not subjected to operative procedures or to operative procedures that reduced gastric acidity. In the seven cases in which gastro-enterostomy was performed, the reduction in gastric acidity may well be attributed to the gastro-enterostomy, although this is not necessarily true, for gastro-enterostomy often fails to reduce gastric acidity to the extent of achlorhydria (10, 11). In at least fourteen cases something other than the surgical procedure reduced the gastric acidity to the point of achlorhydria.

The free acidity in the fourteen cases in which gastro-enterostomy was not performed was 21.7 units or 20 units below the average for normal men and women of the same age at the time of the first test meal. The average secretory activity both of all the patients of Group II and of the fourteen patients of Group II who were not subjected to gastro-enterostomy was less vigorous than that of those in Group III, even before the development of cancer of the stomach. Since free acid was lost from the gastric contents of the patients of Group II but was retained in the gastric contents of the patients of Group III, it seems that the more nearly normal the concentration of free hydrochloric acid, and the more vigorous the secretory activity before the development of cancer, the less likely that it will be absent when cancer develops.

The free acidity of ten patients of Group II was between 1 and 19; of seven, between 20 and 39; of three, between 40 and 59, and of one, between 60 and 79. The free acidity of five patients of Group III was between 1 and 19; of thirteen, between 20 and 39, and of ten, between 40 and 59. In other words, concentrations of free hydrochloric acid from 6 to 60 units were noted in Group II, yet all patients lost their free acid. Con-

TABLE I

Mean age, mean free hydrochloric acid, and percentage of achlorhydria of seventy-nine patients before and after the development of carcinoma of the stomach

	First admission								Mean interval, years	Second admission						
			Achlorhydria			Free acidity				Achlorhydria				Free acidity

Group II—Patients with free acidity at first, and achlorhydria at second admission.
Group III—Patients with free acid at both admissions.

centrations of free acid from 6 to 46 units were noted in Group III, yet all patients retained their free acid. Apparently, higher degrees of free acidity are lost just as well as the lower degrees and lower degrees are retained just as well as the higher degrees when cancer develops. Lower degrees are lost more frequently than higher degrees.

THE LOSS OF GASTRIC ACIDITY A SELECTIVE AFFAIR

The loss of gastric acidity is a selective affair; gastric acidity was lost in all cases of Groups I and II and retained in those of Group III. While the mean free acidity of the patients of Group III was practically the same on the first and second admissions, in four cases the concentration of free acid remained unchanged; in fifteen, it decreased an average of 10 units (extremes 4 and 18 units), and in nine, it increased an average of 20 units (extremes 4 and 60 units). While the variations in Group III, in a general way can be ascribed to the variations in the response to the test meal, it still seems clear that the concentration of free acid is reduced in some and retained in other cases. The process responsible for the reduction of gastric acidity attacks the mucosa in some cases but not in others.

WHEN DOES THE LOSS OF GASTRIC ACIDITY OCCUR?

It is commonly believed that the low gastric secretory activity characteristic of carcinoma of the stomach appears before the development of cancer. Little evidence other than the observation of achlorhydria in a few cases in which cancer developed subsequently has been advanced. We, too, have reported cases in which achlorhydria existed before the development of cancer but we also have shown that the percentage of achlorhydria is above normal and the mean concentration of free acid below normal at an average of six years prior to the diagnosis of cancer (Table I). We also have shown that the secretory activity falls further below normal in the interval between the first examination and the diagnosis of cancer (Table I). The gastric contents of twenty-one patients contained free acid at the time of the first examination but had become achlorhydric at the time the diagnosis of cancer was made. Unfortunately, test meals were not employed in the interval between the two admissions in these cases and, so far as the data go, the development of achlorhydria may have taken place in the interval between the first admission and the development of cancer or after the development of cancer but before the second admission. A depression of gastric acidity occurred also in some of the cases of Group III but not to the point of achlorhydria. In some of these cases test meals were done in the interval between the first admission and the diagnosis of cancer. In these cases the depression of gastric acidity occurred before the development of cancer. The following case is an example:

Case 1. A man fifty years of age registered at the clinic May 17, 1921, giving a history characteristic of ulcer of twelve years' duration. The Ewald meal revealed free acidity of 28 at the end of the first hour. Roentgenologic examination of the stomach disclosed a small ulcer on the lesser curvature. Excision of the ulcer by cautery was carried out and the pathologic diagnosis was benign ulcer. The ulcer measured 0.75 cm. in diameter and was situated high on the lesser curvature, above the incisura.

The patient returned September 20, 1926. Symptoms had recurred one year prior to registration. Fractional analysis after the Ewald meal revealed no free hydrochloric acid at the end of an hour, an hour and fifteen minutes, and an hour and a half, and only 10 units at the end of an hour and forty-five minutes. The roentgenogram again gave evidence of a small ulcer on the lesser curvature, at the angle. The ulcer was excised and a Mayo type of pyloroplastic gastroduodenostomy was performed. The ulcer was situated on the lesser curvature about 2¼ inches (5.5 cm.) above the pylorus. The pathologist reported a simple gastric ulcer.

The patient returned again January 30, 1930. Symptoms had recurred six months previously. Analysis after the Ewald meal revealed free hydrochloric acid with a concentration of 10 clinical units. The roentgenogram gave evidence of an operable carcinoma at the pyloric end of the stomach. Anterior gastro-enterostomy was performed for a perforating carcinoma of the posterior wall just above the pylorus with extension up to the angle. The patient died of carcinoma in February, 1931.

In this case the depression of gastric acidity cannot logically be ascribed to the carcinomatous process that ultimately developed.

We are inclined to believe that the loss of gastric acidity in the twenty-one cases of Group II also occurred before the development of cancer. The cancers of the patients of Group II were, for the most part, too small to affect gastric acidity per se. The general statement that loss of gastric acidity occurs for the most part before cancer develops appears to be a conservative one.

A study of the time intervals between the first and second test meals, and of the gastric acidity of the three groups, develops some interesting points. In the first place, the achlorhydria of cancer may be present at an early age. It was known to be present in two of our cases before the age of thirty years. In the second place, anacidity may exist many years before the development of cancer. It existed one to five years in eighteen cases, six to ten years in nine cases, eleven to fifteen years in two cases, and as long as sixteen years in one case in Group I before the diagnosis of cancer was made (Table II). Even more interesting is the appearance in Group II of achlorhydria in one case within a period of one year, in three cases within a period of two years, in three cases within a period of three years, in three cases within a period of four years, and in two cases within a period of five years preceding the diagnosis of cancer (Table II). The loss occurs at any age and at long and short intervals before the development of cancer. Obviously, the achlorhydria which precedes the development of cancer of the stomach is not an immediate precursor of cancer of the stomach nor is it always attributable to a developmental defect in the mucous membrane of the stomach destined to become ultimately a seat of cancer.

It may well be asked whether a depression of gastric acidity follows also the development of gastric cancer. This question may be answered in the affirmative. Shay and Schloss (12), Robertson (13), Koch (14) and Bockus, Bank and Willard (15) have recorded cases in which a depression of gastric acidity has occurred after the development of cancer. In these cases gastric acidity was actually observed to fall as the

disease progressed. The frequency of reduction in gastric acidity following the development of gastric carcinoma is unknown. On the other hand, gastric acidity may actually rise. In nine cases of Group III free gastric acidity was higher after than before carcinoma developed. Hurst (7) has seen gastric acidity behave in a similar way in a carcinomatous stomach.

WHAT IS RESPONSIBLE FOR THE REDUCTION IN GASTRIC ACIDITY?

Achlorhydria and all degrees of free acidity occur in childhood and young adulthood. Achlorhydria (16, 22) occurs in about 4 or 5 per cent and hypochlorhydria in about 10 per cent of cases. Three major hypotheses have been advanced in explanation of the variations of gastric acidity in childhood and young adulthood. The first hypothesis observes that these variations are constitutional and are present at birth, and that achlorhydria and hypochlorhydria are the results of developmental defects in the secretory mechanism. The second hypothesis assumes that the hypochlorhydria and achlorhydria are attributable to abiotrophic changes in the acid secreting cells that appear after birth. The third hypothesis assumes that achlorhydria and hypochlorhydria are attributable to destruction of the acid secreting cells by an inflammatory process, a gastritis. The advocates of the constitutional hypothesis point to the familial and hereditary nature of achlorhydria or pernicious anemia, shown by the studies of Hurst (23), Wilkinson and Brockbank (24) and Conner (25), as proof that such developmental defects occur. Conner thought it unlikely that the achlorhydria itself is inherited but that the tendency to development of this condition later in life is an inherited factor. Observations of the type reported by Rozendaal and Washburn (26) add weight to such a belief. These authors reported two cases of pernicious anemia in which the concentration of free acid in the gastric contents was 34 and 16 clinical units respectively, nineteen and seventeen years before the development of pernicious anemia. In these two cases at least the anacidity of pernicious anemia was not present at birth and therefore was not the result of a constitutional defect present at birth. The advocates of the hypotheses of constitutional defect and abiotrophy point out that the subnormal secretory states are unassociated with symptoms and for this reason do not represent a disease process. However, the advocates of chronic atrophic gastritis as the cause of subnormal secretory states remind us, on the other hand, that gastritis occurring in the earlier years of life causes reduction of gastric acidity, and that this reduction is symptomless. They believe it is just as reasonable to explain the lower grades of acidity and anacidity on the basis of gastritis as on the basis of developmental defect. The demonstration by Faber (27) and others that changes in the gastric mucosa seen in pernicious anemia exhibit characteristics of a chronic inflammatory process at times without atrophy, and the report of Hurst (28) on the restoration of gastric secretion in pernicious anemia by treatment of gastritis are impressive evidences that chronic gastritis and not a constitutional defect is responsible for changes in gastric secretion in pernicious anemia. Final acceptance of the hypothesis of defect will await the pathologic examination of a number of stomachs removed from infants. At the present time the advocates of an inflammatory origin seem to have a little the best of the argument.

Achlorhydria and all degrees of free acidity likewise occur in middle and old age in normal men and women. Vanzant, Alvarez, Eusterman, Dunn and Berkson (6) using the Ewald meal have demonstrated that the percentages of achlorhydria greatly increase with age in both normal men and women, the percentage of achlorhydria reaching about 26 at the age of seventy years. They have shown likewise that mean free acidity in men is in the neighborhood of 47 units between the ages of twenty and forty years and that thereafter it decreases to a mean of 33.5 units at the age of seventy years; in women the mean free acidity remains remarkably constant at about 33 units at all ages. Polland and Bloomfield (29) have noted the same behavior in gastric acidity when histamine is used as a stimulant. This depression of gastric acidity that occurs with advancing years may be the result of either abiotrophy or an inflammatory process. Alvarez (30) has commented on the fact that the mean acidity of women does not fall off with advancing years. He believes that this makes it unlikely that the decline of gastric acidity is attributable to slow atrophy of the gastric glands, because one would expect age to work the same injury to women as to men. Although there is little direct proof that an abiotrophic process is the cause of the decline of gastric secretion with advancing age, it is an attractive idea. On the other hand, chronic atrophic gastritis is a visible, tangible explanation for the decline. The realization that chronic gastritis and not always a developmental defect plays a rôle in the development of the achlorhydria of pernicious anemia and the recognition that chronic gastritis causes a depression of gastric acidity and even to the point of anacidity in all years of life without producing symptoms, have been the important steps taken toward the acceptance of chronic gastritis as an important cause of achlorhydria. Faber (27) has gone so far as to say, "When one microscopically examines the mucous membrane of the stomach after proper fixation, one always finds in patients with chronic anacidity, very pronounced signs of chronic inflammation and first and foremost, a diffuse gastritis tending to atrophy, a pangastritis."

The subnormal gastric secretory activity present in our seventy-nine cases before the development of carcinoma of the stomach may be attributable to any one of the causes believed responsible for subnormal secretory activity in the general population. The same evidence may be cited in support of, and against, the acceptance of each of them. Until gastric acidity has been followed from childhood to the appearance of cancer, the number of cases of anacidity or hypoacidity possibly attributable to a developmental defect of the gastric glands will be unsettled. It is possible that cancer is more prone to develop in patients with a constitutional defect in the secretory mechanism or in those whose mucous membrane atrophies with the passage of years than in persons with a normal mucous membrane. In this way the high incidence of achlorhydria and of hypochlorhydria in persons destined to develop gastric cancer may be explained. However, certain pathologic evidence may be cited against the acceptance of the hypothesis involving the concepts of either a constitutional defect or of a non-

inflammatory atrophy or abiotrophy, and in favor of the hypothesis of inflammation. In the first place, chronic gastritis seems usually to be associated with the achlorhydria of gastric cancer. Orator (31), using the Ewald meal, found achlorhydria in seven of eight cases of so-called primary cancer and free acid in twelve of fourteen cases of so-called ulcer-cancer. Microscopic examination of the mucous membrane of the stomachs of twenty patients with primary cancer disclosed atrophic gastritis involving the fundus as well as the pyloric region, pangastritis, in nineteen. Microscopic examination of the stomachs of eight patients with ulcer-cancer revealed a well-marked gastritis involving the pyloric region in eight cases but a perfectly normal mucous membrane of the fundus in five, slight gastritis of the fundus in two, and severe gastritis of the fundus in only one of the eight. In other words, diffuse atrophic gastritis involving the mucous membrane of both the antrum and the body was found in cases of cancer with achlorhydria while marked gastritis, involving the mucous membrane of only the antrum, was found in those cases in which free acid was present. Baker (32) has studied the mucous membrane of the fundus in fifty cases of carcinoma of the stomach. In fifteen, or 30 per cent of these cases the presence of free hydrochloric acid was revealed by the Ewald test meal before operation. Of these fifteen patients, Baker found eight to have a normal distribution of acid cells in the fundus and seven to have decreased acid secreting cells. In the remaining thirty-five cases in which free acid was not found in the gastric contents, acid cells were not found in the fundus in twenty-seven cases and only occasional acid cells in eight cases. Baker also examined microscopically the mucosa made available in this series by gastric resection. Resected specimens from nine patients of Group I, from seven patients of Group II, and from ten patients of Group III were sectioned and stained. Care was exercised to take sections at least 5 cm. from the growth. In Group I, the mucous membrane of the upper portion of the antrum or of the lower portion of the body of the stomach gave evidence of marked atrophic gastritis, usually with lymphocytic inflammation, metaplasia, hypertrophy, or atrophy. The acid cells were usually few. It is to be noted that gastritis involved the gastric mucous membrane of the only group of patients whose achlorhydria could possibly be attributable to a defect in the mucous membrane present at birth. In Group II the mucosa of the upper portion of the antrum or the lower portion of the body gave evidence of moderate or marked gastritis, usually with only fair preservation of the acid cells in five of the seven cases. In the remaining two cases, the mucous membrane of the body appeared to be normal. Gastroenterostomy had been performed for gastric ulcer before the development of cancer in these two cases. In Group III the mucosa of the upper portion of the antrum or the lower portion of the body of the stomach gave evidence of slight or moderate gastritis in eight of the cases, while the mucosa of the body was normal in three. Gastritis was marked in the antrum in one case in which it was absent in the body. These pathologic studies of Orator (31) and Baker (32) show that chronic gastritis of marked degree, involving the acid secreting portion of the stomach, is usually present when achlorhydria is present and that it is usually absent when free hydrochloric acid is secreted. They show, further, that the acid secreting cells are absent or reduced in number when achlorhydria exists and are present in good numbers when acid is secreted. Such findings point to chronic gastritis as a cause of the destruction of the acid cells and not to a developmental defect or a degenerative, noninflammatory process. Advocates of the constitutional hypothesis will take the position that a subnormal mucous membrane is more prone to injury and to the development of gastritis than a normal mucous membrane and that the gastritis may not be the cause of the low secretory activity. While it is reasonable to believe that a subnormal gastric mucous membrane is susceptible to injury and to the development of gastritis, it is difficult to discount the effect of such marked inflammatory changes on the secretory activity of the mucous membrane. Pathologic evidence seems to point overwhelmingly to chronic gastritis as an important cause of the depression of gastric acidity in cases in which persons are destined to develop carcinoma of the stomach.

The further decrease in gastric acidity seen in patients of Group II, in the interval between the first and second meals, occurred after they had reached adult life. In these cases at least, a developmental defect present at birth was not responsible. Either abiotrophy of the mucous membrane or an inflammatory process was responsible. Again, the importance of the gastritis as a cause of the depression cannot be discounted.

Progression of degenerative or chronic inflammatory changes already present in the gastric mucosa before the development of gastric cancer explains satisfactorily the further loss of gastric acidity observed by Koch (14), Shay and Schloss (12), Bockus, Bank and Willard (15), and Robertson (13) after the development of gastric cancer. But there is another possible factor in the depression of gastric acidity after the development of cancer; namely, the cancer itself. Certain statistical data point to a relationship between the mean size of the cancer and the secretory activity of the stomachs of patients with gastric cancer. Thus Eusterman and Bueermann found in their study that the percentage of anacidity, which was only 49 per cent in cases of resectable cancer, increased to 77 per cent in the cases in which exploration was carried out but resection was not done and further increased to 93 per cent in the frankly inoperable cases. Comfort and Vanzant studied the relationship between the size of resected cancers and the mean secretory activity. They found that in cases of gastric cancer in which the cancer was 3 cm. or less in diameter, the mean free acidity and the incidence of achlorhydria were practically the same as for a group of normal persons, being 38 units and 17.5 per cent respectively, but that the larger the cancer was, the lower the mean free acidity and the higher the incidence of achlorhydria; the percentage of achlorhydria rose to as high as 90, and the mean free acidity fell as low as 10 clinical units when the lesion was 10 cm. or more in diameter. These statistical studies suggest that the growth of the tumor depresses gastric acidity. However, a study of the relationship between gastric acidity and the size of the cancer in the forty-two cases of this series in which resection was carried out and the size of the tumor reported by

the pathologist, invites another interpretation of the data. The forty-two cases may be divided into three groups: the fourteen patients of Group I had no free hydrochloric acid in the gastric contents at the time of the first admission; the ten patients of Group II had free hydrochloric acid averaging 20 units at the time of the first admission but none at the time of the second; the eighteen patients of Group III had free hydrochloric acid averaging 34.4 units at the time of the first admission, and this concentration had not materially changed at the time of the second. The cancers had attained average sizes of 55.7, 39.8, and 22.7 sq. cm., respectively, in the three groups. In other words, the larger cancers were found in stomachs that were known to be achlorhydric before the development of cancer. This could mean that cancer grows larger before symptoms lead the patient to submit to examination when achlorhydria is known to have been present before the development of cancer than when free hydrochloric acid is known to have been present.

While statistical evidence that the cancer itself has a depressing influence on the secretory activity of the cancerous stomach is inconclusive, it is not unreasonable to believe that this is at times so. It is conceivable that cancer can depress gastric acidity in several ways: 1. By destruction of acid secreting cells in sufficient number to reduce the volume of acid secreted; cancers of the body and fundus of the stomach are not infrequently large enough to destroy an area of gastric mucosa sufficient to reduce the volume of acid secreted. 2. By increasing the amount of neutralizing fluid in the stomach by the exudation of serum from the surface of the tumor; among others, Crohn (33) has mentioned this possibility. 3. Experimental and clinical evidence exists showing that vitamin deficiency may depress gastric secretion. Webster and Armour (34) found in dogs fed on a diet deficient in vitamin B a great impairment of secretory response to sham feeding, to the subcutaneous injection of histamine, and to introduction into the small intestine of food in 5 per cent alcohol, and that complete restoration of gastric secretion occurred within three days after addition of powdered yeast to the diet. Cowgill and Gilman (35) obtained similar results and concluded that "so far as any diminution of gastric secretion occurs during the regimen of lack of vitamin B complex, this is due to the absence of B_1." Odin (36) expressed the belief that deficiency of vitamin B explains the higher incidence of achlorhydria among the population living on a monotonous lacto-cereal diet than among the population living on a mixed diet. Even though Alvarez, Pilcher, Foley, Mayer and Osterberg (37) were unable to produce a change in gastric secretion in two normal persons by feeding a diet deficient in vitamin B, it is possible that a vitamin deficiency may further reduce gastric acidity in the malnourished cancerous patient with a chronic inflammatory change in the mucosa. This is not an impossible explanation in view of the above-cited experimental and clinical data and the actual occurrence in cancerous persons of an avitaminosis such as pellagra.

SUMMARY AND CONCLUSIONS

Gastric secretory activity before and after the development of cancer of the stomach has been studied in seventy-nine cases. The gastric secretory activity of the seventy-nine patients destined to develop cancer of the stomach was below normal before the development of cancer. After an interval of years averaging six, and after each patient had developed cancer of the stomach, the percentage of achlorhydria had increased from 38 to 64.6 per cent, while the mean concentration of free hydrochloric acid in the gastric contents of the remaining twenty-eight patients who retained free acid was little changed. The depression of gastric acidity in patients destined to develop carcinoma of the stomach is a progressive and selective process, appearing early in life and at all ages. The low secretory activity of the stomachs of patients with gastric cancer is present, for the most part, before the development of cancer. The loss of gastric acidity occurred in patients both with high and low concentrations of free acid but more frequently in cases in which the concentration of acid was low before the development of cancer. A further reduction of gastric acidity occurs after the development of cancer. Its frequency and importance are unknown. Theoretically, the low secretory activity of persons destined to develop carcinoma of the stomach may be present at birth (a developmental defect in the secretory mechanism), or it may occur after birth as the result of an abiotrophy of the acid secreting cells or as the result of inflammatory destruction of the gastric mucous membrane. The loss of gastric acidity in adult life excludes a developmental defect as the cause of the loss in a considerable number of cases, while the presence of marked, diffuse atrophic gastritis in almost all cases of achlorhydria and the absence of a marked diffuse atrophic gastritis in almost all cases in which there is free hydrochloric acid in the gastric contents, greatly favor chronic atrophic gastritis as an important cause. In fact, chronic atrophic gastritis appears to be the important cause. Chronic gastritis, as well as the tumor itself by its local and systemic effects, may be responsible for the depression of gastric secretion after the development of gastric cancer.

DISCUSSION

DR. FRANKLIN HOLLANDER (New York, N. Y.): Dr. Comfort's very interesting paper brings to my mind a fundamental question regarding the physiology of hypoacidity, apart from its relation to the cancer problem. In order to account for the low acidities which are associated with carcinoma of the stomach, Dr. Comfort and his associates have suggested several alternative mechanisms. One of these is neutralization by an alkaline fluid from the gastric wall; another is a progressive diminution in the volume of acid secretion which is formed by the parietal cells. Now, there was a time, not so long ago, when we felt it necessary to differentiate between hypersecretion and hyperacidity. Today we no longer feel the need for this differentiation, for we now know that the acidity level at which the secretion is formed in the gastric glands is practically constant and that this constancy persists in spite of other physiological variations of considerable magnitude. As a result, any extensive change in acidity of the gastric contents has come to be considered as due to a corresponding change in the relative volume of parietal secretion which is poured into the gastric cavity. In short, instead of talking about hyper- or hypoacidities we now speak of hyper- or hyposecretion.

More recently, however, with an extension of our knowledge of the chemistry of the gastric juice, we have been confronted with another dichotomy of this kind; namely, where we have an apparent hypoacidity are we dealing with a diminished output of gastric juice, or, are we concerned with an increase in the extent of neutralization (and dilution) of the hydrochloric acid by some alkaline buffer-containing fluid? This fluid may be an actual secretion, a transudate, regurgitated duodenal juice, or something similar.

Now, unlike the earlier dichotomy, this one has not yet been resolved. At the present time very few investigations involving low acidity values are concerned with differentiating between a lowered volume of acid secretion and an increased volume of non-acid fluid. The reason for this situation is simply this: that as yet we have no chemical analytical method which will enable us to distinguish between the two. Thus, although we are fully aware of the problem we are rather at a loss as to how to investigate it. Dr. Comfort's paper presents this same dilemma; it offers these two possible mechanisms in connection with certain clinical manifestations of diminished acidity, but the authors have not coped with the problem which they raise. Sooner or later it must be faced, since it is concerned with a matter of fundamental physiological importance. In this particular case I would venture the suggestion that both factors are operating simultaneously, but that is only a guess.

At the present time at our laboratory in New York we are deeply interested in this very problem. In fact, one of our lines of research is intimately concerned with a method which can be used to measure both the volume of acid secretion and the extent of neutralization and dilution by non-acid secretion. I should like to ask Dr. Comfort whether any such differentiation is being attempted at the Mayo Clinic and whether any such laboratory method is available there at present.

DR. SIDNEY PORTIS (Chicago, Ill.): I should like to ask a question. In the second group of twenty-one cases what was the relationship between operability and achlorhydria?

DR. GEORGE B. EUSTERMAN (Rochester, Minn.): One object of this study was to confirm or refute a somewhat sweeping generalization made several years ago by one of our distinguished British colleagues. On the basis of a few cases coming under his personal observation, apparently supported by a few others reported in the literature, this physician maintained that anacidity in the presence of gastric cancer preceded the onset of the disease, and that those having acid before the development of cancer would always retain it. He further argued that the precursor of the former type was a chronic gastritis, and of the latter a gastric ulcer, in the majority of cases.

Well, our own observations and convictions and the experience of some contemporaries would seriously question such conclusions, even before a critical study was undertaken. While freely open to conviction, I think we have definitely shown that in a certain percentage of the cases the onset and progress of gastric cancer results not only in a lowered concentration and secretion of hydrochloric acid but in an actual cessation or complete neutralization of it. As to the actual cause of such phenomena, this is still a moot point. In this connection I might add that I have also seen the smallest carcinomata actually discovered while examining patients for other conditions which were well within the normal size range of benign ulcer and yet there was a complete absence of hydrochloric acid refractory to histamine stimulation. It is also true that as the growth increases in size the depressing influence on gastric secretion is frequently observed. The factor, or factors, likely responsible for this phenomenon have been discussed.

The well known observations of Konjetzny and others, as well as recent histologic studies of our own resected material (Baker) do confirm the importance of gastritis, not only as a precursor of carcinoma, and which is in agreement with Hurst's observations, but as an important factor in the depression or cessation of gastric secretory function. But on the other hand, to maintain that gastric carcinoma associated with free hydrochloric acid has its origin in an antecedent gastric ulcer seems to us quite difficult of proof, even though it is true of a certain

number, perhaps not exceeding 10 or 15 per cent. Until we can make careful objective studies of individuals destined to have gastric cancer, the problem of precursors, aside from those already known, may go unsolved.

DR. ROBERT ELMAN (St. Louis, Mo.): A number of years ago while studying a series of cases with a test meal composed of 300 c.c. of five-tenths per cent hydrochloric acid, I had occasion to observe a number of patients with proved gastric carcinoma. In each instance there was much more rapid neutralization of this introduced acid than occurs in the normal, which indicates, it seems to me, that perhaps the anacidity in cancer of the stomach may be due to excessive neutralization of acid rather than to true hyposecretion.

DR. HENRY L. BOCKUS (Philadelphia, Pa.): I think this is a tremendously important consideration. I suppose it will be a good many years before anyone will have an opportunity to report a series of cases of this size, of cancer of the stomach that have been previously studied from the gastric secretory standpoint and for that reason alone it is tremendously important, but over and beyond that, it seems to me that it was about time that someone who has a wealth of material refuted the stand of Hurst, because if Dr. Hurst is right, then I suppose most of us sooner or later would assume that gastritis or achlorhydria, or achylia is the cause of cancer.

I can't even altogether agree with Dr. Eusterman in his statement that it has been proved that most cases with cancer of the stomach have a diffuse pangastritis. It has not been proved in many of the cases we have dissected in Philadelphia, not a diffuse pangastritis—a gastritis that is near the lesion, that is very true, but I, for one, do not feel there is enough experimental or pathological data at hand to support the contention that many cases of cancer are engrafted on a previous gastritis.

Another thought of a little interest, is that in our cases we rarely see a true achylia in cancer of the stomach. Many of our cases of cancer are achlorhydric but respond readily to histamine. I take it from Dr. Hurst's writings that he feels that people with constitutional achylia gastrica are predisposed to cancer of the stomach. I know of nothing, clinically or pathologically that bears out that statement, and I think for that reason the paper that Comfort, Butch and Eusterman have presented here is a very important one.

DR. MANDRED W. COMFORT (Rochester, Minn.): The number of cases in this series was too small to allow conclusions to be drawn regarding the relationship between operability and the degree of free acidity. Other work, such as that of the Eusterman and Bueermann, Comfort and Vanzant, show that the operability of the lesion decreases as the percentage of anacidity increases.

The relationship between the situation of the lesion and the degree of free acidity in this series was not studied. Doctor Vanzant and I studied this point statistically in a large number of cases of cancer of the stomach, and were unable to see that the situation of the lesion materially influenced the degree of free acidity.

Doctor Hollander has asked if any attempt has been made to distinguish between low gastric acidity owing to deficient secretion of hydrochloric acid and that owing to increased neutralization. No such distinction has been attempted in these cases. The degree of mean free acidity and the mean volume of gastric content obtained by continuous siphonage from the cancerous stomach after stimulation by histamine are lower than those obtained from the normal stomach. The combination of low volume and low acidity can best be explained by the secretion of a smaller volume of acid gastric juice. It is possible, of course, that the volume of neutralizing fluid is increased but in view of the low volume of mixed gastric content obtained, the increase in the volume of neutralizing and diluting fluid must necessarily be small. It is our belief that inflammation of the gastric mucosa, so frequently found in the cancerous stomach, plays an important causative rôle in the deficiency of the secretion of free hydrochloric acid.

The Psychobiological Approach to Gastro-Intestinal Disorders*

By

KENNETH J. TILLOTSON, M.D., M.Sc.†
WAVERLY, MASSACHUSETTS

SINCE the days of Hippocrates, much has been written in our medical literature about the study of the patient as a whole. [We have been admonished and taught by earnest and sincere clinicians that a diagnosis should not be made until all factors have been carefully considered and evaluated. In physical diagnosis, we are taught to investigate all of the systems carefully before writing a diagnostic summary and that such a summary should contain all of the findings indicating a variation from the normal functions, as well as historical data concerning previous illnesses, especially those of a familial or hereditary nature. In spite of all of this, and if a patient's study contains only this, we find that such a study of the patient is quite incomplete]. However, until quite recently, the study of the patient as a whole has been, as the late Dr. William A. White expressed it, chiefly "lip service." Furthermore it has been definitely shown that when a careful and complete physical examination is made, including all of the laboratory tests that are possible, the summary of such a study often reveals very little in the nature of pathological findings, yet the chief complaints of the patient or the complaint problems of the patient are of a nature to indicate a disturbance of function and that there is, after all, something wrong. Only recently have the psychosomatic aspects and the emotional causes of illness been recognized. These emotional factors may be the underlying cause of indigestion, sour stomach, eructations, pain in the epigastrium, loose bowel movements or constipation, together with headache and feelings of general malaise and discomfort and anxiety with more or less discouragement. The court of final appeals, namely, the X-ray examination, to be sure in many of these patients shows only slight variations from the normal, and usually not sufficient "sui generis" to account for the degree of discomfort of the patients. Yet the patient's symptoms persist and what is to be done? It is not only with this group of patients, where emotional factors or an underlying neurosis is followed by a train of symptoms and complaints closely simulating actual organic pathology of the intestinal tract, that we wish to call attention, but it is the possible rôle of such emotional mechanisms in the etiology of what may later prove to be definite peptic ulcer or ulcerative colitis or other organic conditions of the tract in the emotionally unstable person. Our responsibility as psychiatrists and internists, in relationship to the patients of this type, can be fulfilled only when we consider ourselves physicians and approach every patient with a broad and non-prejudicial point of view. Seeing before us, in each patient a psychobiological study, with the interrelated processes of the psychological, best expressed as emotional factors and responses, exerting their effects on the physiological processes of digestion, assimilation and metabolism, then we must look for the underlying cause of the emotional disturbances. This leads us to a study of the patient's social situation or environment in its broadest sense, an investigation of the psychological factors or a search for the totally integrated personality factors conditioned as they are by heredity or instinctual components, and environmental circumstances or the sociological factors. Such a study and total evaluation in present-day psychiatry or medicine is spoken of as the psychobiological approach and likewise as a genetic-dynamic evaluation of the patient.

Since 1930, when the writer began the psychiatric work in the Out-Patient Department of the Massachusetts General Hospital and formal psychiatric consultation work on the wards psychiatry in itself has changed and developed tremendously in that it is becoming closely integrated into all medical work, not only with us but in many of the leading medical centers of this country.

The late Dr. William A. White recently referred to two great achievements in psychiatry that have taken place during the past 25 years. First, the mental hygiene movement in this country; and second, the development of dynamic psychiatry or the psychoanalytical theories and principles. It would seem to the writer that there is a third of equal significance, and this is the integration of psychiatry into general medicine, not alone in the form of special psychiatric clinics in general medical centers or in the out-patient departments of general hospitals, but in the actual collaboration of psychiatrists with internists and surgeons on the wards.

From the writer's experience, it seems apparent that the greatest value rendered by psychiatrists in the general hospital lies in the opportunity of studying patients at the bedside in the medical wards along

*Read at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7 and 8, 1937.
†Psychiatrist-in-Chief, McLean Hospital, Waverly, Mass., and Psychiatrist to the Massachusetts General Hospital.

with the internists and in some instances with the surgeon, or in the special clinics in the out-patient department, such as the diabetic, the arthritic, the medical, the thyroid, the cardiac, and, what seems most important to us, the gastro-intestinal clinic. Under these conditions, the psychiatrist acts as other consultants and evaluates the psychic and emotional factors in each given patient's study and adds to the completion of the consideration of the total clinical picture and aids in determining which cases should be studied primarily from a psychiatric point of view, there being many cases of course where the immediate medical and surgical problems take precedent beyond any doubt. On the other hand, there are many patients where we have found it was distinctly advantageous, if not necessary, that they should be studied by the internist, the surgeon, and the psychiatrist at the same time or concurrently.

In the gastro-intestinal clinic of the Massachusetts General Hospital, several internists and surgeons, the writer and a psychiatric research fellow constitute the staff. The psychiatrist frequently sits in with the internists or the surgeon during interviews to ascertain the relative importance of emotional factors in a given patient's study. Since the patient's formulation of his or her complaint problems and the patient's own description of symptoms often indicates not only ulcer or anything but ulcer, it indicates also the type of personality we are dealing with as Meyer expresses it the he or the she in the total situation, and many times factors of a social, domestic, economic, or psycho-sexual nature may be readily discerned as the patient's important trouble. Patients should usually be thoroughly examined physically, yet it may be unwise, in the best interests of the patient, especially in certain emotional types, to delve too extensively into special studies or to make special examinations merely to rule out pathological lesions. In many emotionally unstable patients, such procedures add further conflicts to an already overburdened and emotionally, if not mentally ill, patient and tend further to fix the idea of illness in a damaging way, especially where the emotional patterns may be in a formative stage and incapacity is sought as an escape mechanism. The psychobiological approach attempts an investigation and study of patients with gastro-intestinal complaints, proceeding from the "complaint problem" of the patient. The psychic factors are so frequently an outstanding part of the illness of the patient that such considerations of the relative presence or absence of organic pathology is not important in this new and combined study and consideration of gastro-enterological disorders. Then, of course, one not only has to deal with psychic and emotional factors as a primary cause of the disorder but with the psychic disturbances that are secondary to organic disease of the tract. It is on this latter group that I should like to place a special emphasis, since most of the patients seen by the writer in our clinic have or have had definite organic pathology—a definite ulcer or colitis, etc. These patients have been given the customary medical and, in some instances, surgical treatments; nevertheless their clinical progress, in so far as their clinical picture and symptomatology is concerned, still remains unsatisfactory. We have found in many patients that psychic factors, possibly instinctual in origin and manifested as a subtle complication of the personality, in addition to the above, must be dealt with before real clinical improvement can take place.

These patients are from the routine clinical and hospital practice and necessarily have comparatively few contacts with the psychiatrist. Yet the following patients serve to show how important and valuable a psychiatric study can be, even though it is superficial and the hours of psychotherapy are limited. Not only can there be a more complete evaluation of the patient from a psychosomatic standpoint, but the results of psychotherapy of a psychodynamic type, in conjunction with the medical regime of the internist and the surgical procedures and observations, aid materially in dealing more adequately with the patient as a whole, as well as with the specific patient's complaints which are, in most instances, found to be a complicated milieu of organic and physiological, psychic or emotional disturbances rather than such simply defined symptoms as pain, nausea, diarrhea, discomfort, or constipation. There is little need to stress the fact that, in spite of our interest and in spite of the increasingly psychodynamic emphasis in all medicine and research, we psychiatrists have yet little actual concrete knowledge of the mechanisms relating emotions and bodily changes, and we are still handicapped by the limited research methods in this field and the imperfect development of those who are working in a manner similar to ours.

The significance of the conditioned reflex (Pavlov and von Bergmann is well known). Even without a conditioned reflex the site of some previous somatic disease becomes readily the site of an organic neurosis. An hysterical individual, for example, develops swelling of the joints, having previously suffered from a rheumatic arthritis. The body has learned, as it were, the symptom. Furthermore the sense of well being remains decreased in a bodily part that has once been ill. This is the basis for the phenomenon of Hängenbleiben described by Heyer. The pain caused by somatic disease long outlasts the duration of actual organic disease.

This is illustrated by the following case study:

A. S., No. 8027, a married housewife, age 33, has been under care and treatment in the gastro-intestinal clinic for three years. Her symptoms were fairly typical of ulcerative colitis, and, because her symptoms became worse, she was admitted to the house for treatment Oc-

tober, 1936, when an ileostomy was performed and followed by colectomy. Following a normal and satisfactory convalescence from this operation, the patient was discharged from the house in December, 1936, to be followed in the out-patient clinic. She has been seen fairly frequently by the internist and surgeon, and her clinical course, as far as the symptoms of her colitis are concerned, has been entirely satisfactory. She does not, however, consider herself well and complains of nervousness and of queer feelings that are difficult for her to describe. She feels frightened and now still has feelings of discomfort in the abdomen which are not unlike those she had with her colitis. At times there still seems to be the pain that she previously experienced. This patient was seen by the psychiatrist several times before she entered the house for operation. That she is emotionally unstable is undeniable. The present emotional symptoms and residual pain-like experiences represent a conditioned reflex situation and the persistence of the symptoms caused by organic pathology even after the pathological lesions have been removed. This patient is fairly cooperative and simple explanations are grasped and in so far as possible accepted. She must be given, however, a substitute in the way of re-education and diversional interests to take the place of her actual pathological condition which previously preoccupied her. Psychotherapy and an intelligent medical regime will prevent this patient from becoming a helpless neurotic or a drug addict, since sedative drugs have been given all too frequently in the past for this particular type of pain, which persists or outlasts the duration of the actual organic disease. A symptom having its origin in organ symbolism may nevertheless become a conditioned reflex in its own right and then become activated through bodily processes without further psychic causation. Cardio-spasm may develop as a psychogenic organ symbol. Then the psychic cause drops out and the symptom remains as a response to the act of swallowing.

The following case of cardio-spasm illustrates the foregoing statement:

F. P., an American housewife, age 39, has been seen in the gastro-intestinal clinic since 1931. Her chief complaint is pain in the epigastrium, regurgitation of food, and malnutrition. In 1932, it was demonstrated that she had constriction in her esophagus. This was relieved by surgical interference with a cardio-plasty. Subsequently, however, her symptoms recurred, and her cardio-spasm has been relieved by the use of nitroglycerin. She has been quite dependent on nitroglycerin which has relieved the dysphagia, the cardio-spasm, and vomiting. At times, however, she has been able to go several days without her symptoms.

Because of the suspected emotional factors in this case, she was first seen by the psychiatrist in 1931. Her social history reveals that she is the mother of two sons. The older son, 17, is an epileptic, having frequent convulsive seizures. Her younger son of 13 is mentally retarded. Her husband is an electrician and earns a small salary. She is a woman of considerable intelligence and cultural background with a love for "the better things in life." She states quite frankly that she is making the best of life and refers to her husband as a very kind man. She has only part of the necessities and none of the luxuries of life. She has been interested in reading a better than average class of literature and has written poems and sonnets that have been published in magazines and papers and have afforded her a small income. She describes her husband further as a kindly, gentle, unromantic person. This patient's personality can be further characterized as an imaginative, romantic, and obviously unstable individual forced to live in a social atmosphere and at an economic level far below that which she desires. She has extreme apprehension and fear regarding the situation of her oldest son, and she is decidedly on the defensive and excuses the failures of her younger boy. Her sexual life is poorly adjusted, and she gains little satisfaction, although she has a strong desire. Sexual intercourse leaves her usually tense, apprehensive, unsatisfied, and is followed by fantastic dreams, obviously of the wish fulfillment type. Her cardio-spasm and physical symptoms are always intensified following intercourse and likewise following worry or following the epileptic seizures of her oldest boy and are frequent accompaniments of her depressive moods when her social and economic dissatisfaction looms vividly before her. Psychotherapy at times during the past two years has seemed to relieve the patient's symptoms. It was confidently expected by the writer that more intensive psychotherapy would cure this patient's cardio-spasm. In April, 1937, however, this patient's physical condition became actually so acute that it was felt she should have bougies passed. The esophagus was dilated, and the patient was seen at the same time not only by the internist but by the psychiatrist. During this procedure, the patient was emotionally tense and between the interviews had bad dreams, complained of a good deal of pain, and was generally worried. In spite of this however, she was able to eat and discontinued the use of nitroglycerin. During the past two years, this patient's weight has rarely been over 105 pounds. Since April, she has gained 10 pounds in weight, now weighing 115 pounds and is symptom free. It is interesting that she still has all the sensations that she had when she suffered her cardio-spasm, yet she does not vomit, but she seeks relief of these uncomfortable feelings as well as of other emotional symptoms. She will therefore be followed in the clinic.

The following patient, M. P., No. 34286, an American housewife, age 41, was referred from the clinic to the house January 1, 1936, because of symptoms of a severe colitis. X-ray examination and proctoscopy showed a typical ulcerative colitis. She had mucus and blood in her stools, had lost a great deal of weight with severe pain, and was in a highly emotional state. She remained in the house until February 25 and, under a medical regime, her symptoms improved. She has been followed in the clinic by the internists and the psychiatrist. This patient's emotional symptoms were unquestionably occasioned partly by the menopause, together with apprehensive feelings of inadequacy and insecurity, and exaggerated fatiguability, together with vaso-motor disturbances characteristic of the menopause. This patient's whole life was complicated by a husband who drank and a mother-in-law

who was somewhat interfering. A daughter, who was difficult to discipline and who was just arriving at puberty, created further conflicts in the patient's mind. Under a medical regime and with a reasonable amount of psychotherapy, this patient has passed through her menopause and has not had any symptoms of her colitis for nearly a year. She has been able to do her housework and at the present time is enjoying the best health that she has ever experienced in her life.

Case No. 4, N. S., an American housewife, age 36. This patient was first seen in the medical clinic where she was treated for symptoms of cardiac disease. It finally developed that she apparently had a normal heart, but she had symptoms referrable to her gastro-intestinal tract suggestive of an ulcer. She was seen in the gastro-intestinal clinic where a diagnosis of duodenal ulcer was made and confirmed by X-ray examination. In the clinic, she was referred to the psychiatrist who also recognized her extreme emotional instability. After considerable reluctance, she stated that she had been a patient in one of the state hospitals, the record from this hospital showed she was diagnosed as a manic-depressive psychosis of a mixed type, and reports further that she was in a state of euphoria, exaltation, depression, hypersuggestibility, psychomotor excitement, made suicidal and homicidal threats. This patient has been on the usual medical regime in our clinic, but the psychiatric factors seem equally important. Although this patient is free from any gross mental symptoms at the present time, it has been difficult to get this patient to cooperate with her diet and to take periods of rest, although she is perfectly frank in an exploration of her psychogenic background. Some of the important dynamic factors in this patient's life situation have been a disappointment in love and a pregnancy before marriage which resulted in an abortion. She, being a Catholic of the high Anglican faith and having married a man because he was kind enough to have assisted her with her abortion even though she had no love for him, created early in her married life severe conflicts. Although her early life was uneventful, her mother suffered from periodic attacks of manic-depressive psychosis. Her present marital existence, except for her extreme love and accentuated maternal attachment to her only child, a boy of 9, is exceedingly drab and prosaic. She has strong sex drive and receives no satisfaction from sexual relations with her husband. She has been tempted to indulge in extramarital intercourse, and there have been marked emotional upsets as a result of mental conflicts over this problem. She has none of the luxuries in life and, although she is quite an attractive woman, she feels thwarted and compelled to remain at home because of the lack of suitable clothing. Psychotherapy and an effort to secure some employment for this woman so that she has been able to earn money for proper clothing and a better understanding of her sex life on the part of her husband have already helped this patient. We have been able to help her rationalize her situation and to give her some interests in life and some hopes for her future so that her mood swings are less marked and her ulcer symptoms have almost completely disappeared.

Time does not permit of a discussion of the interesting psychiatric factors and the psychological mechanisms and their probable relationship to the clinical symptoms in these cases. It is obvious that disappointments and frustrations have led to emotional conflicts which, in turn, have complicated the normal physiological functions of these patients, with a special reference to disorders of the gastro-intestinal tract. Psychotherapy in these patients has been directed toward better rationalizations and sublimations of these psychological disturbances. That this has been profitable to the patients is undeniable in view of their improved clinical progress.

This paper, therefore, reports an attempt to approach the individual clinical problems with our available methodology and technique. It is hoped that from such a clinical study carried over a sufficient period of time, we may obtain a more complete orientation and understanding in the psycho-somatic field in so far as disorders of the gastro-intestinal tract are concerned. Clinical studies of the above nature can be aided by more comparative physiological and psychiatric studies of the emotions in humans. Experimental studies on animals, as well as on humans, conducted by the usual scientific physiologists, without the background and study of the total personality from a psychobiological point of view, can help us very little toward the solution of the usual patient's problems which involve so high a number of interrelated variables.

Thus the value of a psychiatric study of patients with gastro-enterological disorders may be twofold, first to gain more knowledge of the relationships between emotional disturbances and the actual organic pathological conditions, which will lead us to a better understanding of this group of psychosomatic disorders, and secondly, to give our patients more intelligent and satisfactory treatment on the basis of the logico-experimental evidence gained through such a psychobiological approach. To this extent, the psychiatrist may have valuable suggestions in a considerable number of the patients studied and treated in the gastro-intestinal clinic.

DISCUSSION

DR. ALBERT J. SULLIVAN (New Haven, Conn.): At Yale for the past three years we have followed the example of the Massachusetts General Hospital and we have a psychintrist associated with the Gastro-Intestinal Clinic. The result of this association has been that we have paid more attention to studying the person who has the disease, in contradistinction to the disease that the patient presents.

We are particularly interested up there in the way that patients experience things. Dr. Kahn, of course, who is chief of the Psychiatric Clinic, is noted for his studies in personality.

It is frequently stated that financial and sexual difficulties, for example, can have very little to do with the onset of a peptic ulcer or ulcerative colitis, because, after all, most of us at some time of other have financial worries or sexual difficulties, and very few of us develop ulcerative colitis or a peptic ulcer. Individuals differ in their ways of experiencing things. There are an infinite number of possible combinations of personality types. We know, for example, that under financial worries or sexual difficulties one person may become an alcoholic, another person may commit suicide, a third person may develop a major psychosis, and what we feel, what our studies tend to show, is that certain personality types, given these rather common emotional difficulties, may develop certain specific gastro-intestinal reactions. They may react to these difficulties by the development, or at least the exacerbation of, a peptic ulcer or of ulcerative colitis.

What we hope is that the psychiatrist, by the careful study of a reasonable number of cases of peptic ulcer or ulcerative colitis, by complete psychiatric studies—these, of course, take a great deal of time—will be able to define for us the personality types which tend to develop a specific gastro-intestinal disease and aid us in finding out and anticipating the types of emotional reactions which upset these particular people.

So far we feel that as far as ulcerative colitis and peptic ulcer are concerned, we have definite leads towards both those problems; first, the type of patients who develop the disease, their personality traits; and, secondly, the types of emotional reactions which get them into difficulties.

One could, I suppose, draw a parallel with the allergic individual. After all, passive transfer tests have shown that all of us absorb unaltered protein from the gastro-intestinal tract, but we do not all develop allergy. Of those who are allergic or sensitized, or whatever it is, we have words for it but we still don't understand it—of those who are allergic, some develop asthma, some develop skin disease, some develop hay fever, some develop gastro-intestinal reactions; and I feel that the parallel can hold for certain specific gastro-intestinal diseases, that there are specific personality types that tend to develop specific gastro-intestinal diseases, and that certain emotional reactions, certain emotional problems to which these individuals are sensitive, produce clinical exacerbations.

DR. KENNETH J. TILLOTSON (Waverley, Mass.) (closing the discussion): Mr. President, I wish to thank the discussant. I think there is little danger in trying to delineate special personality types on the basis of our present knowledge in connection with these medical disorders. It is an admirable effort and, of course, everyone recognizes in Dr. Kahn one of the leaders in the study of personality types, particularly of the constitutional psychopathic reactions.

In working with the alcoholic problems, which form one of our researches, we have come to the conclusion—we were speaking of alcohol as secondary, as a defense mechanism, and as secondary to various other situations, and we tried to find out what type of personalities drank, and we came to the conclusion, which may be a bit far-fetched, that real alcoholism is in itself a disease, and the personality of the alcoholic is therefore part of a clinical entity just the same as some other psychoses; to be sure this statement is subject to considerable debate. Our efforts have not been so much of a classificatory nature. We have attempted to find out what the emotional responses produced, and we have been working especially to give the patient more relief through getting a better understanding of the emotional factors in each clinical study, and not going perhaps quite so far as Dr. Sullivan and the group at Yale in the line of studying the personality.

It is an admirable effort and certainly one could not criticize such a scientific point of view as that of Dr. Sullivan and his colleagues.

DEMONSTRATION

DR. V. C. ROWLAND (Cleveland, Ohio): The whole point is that this is a very simple, quarter-inch, collapsible tube introduced through the nose, with a silkworm gut, and it is not irritating to the nose and may stay all week without stirring up much reaction and, being collapsible, it does not permit of any regurgitation. The drip proceeds with regularity, without any change. So far as I know, no one is using the collapsible tube, and it is worth looking at.

The demonstration in the adjoining room by Dr. Woldman consists in the passing of a new collapsible tube used in connection with the aluminum hydroxide drip. The tube is a simple, quarter-inch, collapsible soft rubber tube such as is used as a covering for cigarette drains. A stylet of silkworm gut is used to give it sufficient rigidity to be passed. After lubricating with mineral oil it is more easily passed than the semi-rigid nasal tubes. It is not irritating to the nose and may stay in all week without stirring up much local reaction. Furthermore, being collapsible it acts as a valve and prevents regurgitation due to straining or restlessness on the part of the patient. The aluminum hydroxide drip proceeds with perfect regularity despite variation in intra-gastric pressure. So far as I know, no one is using a collapsible stomach tube, yet it could be used for prolonged intra-gastric feedings of any sort with much more ease and comfort than with the rigid tube.

The aluminum hydroxide drip apparatus is on demonstration in the Scientific Exhibit at the A. M. A. Meeting.

Book Reviews

Dextrose Therapy in Everyday Practice. By E. Martin. New York, Paul B. Hoeber, Inc. and Harper and Brothers, 1937, 451 pp.

THIS is an attractively written and helpful volume reviewing the enormous literature on the use of dextrose in medicine. One does not realize until one looks through this book how useful dextrose is in scores of conditions. It will be a most useful book for the hospital resident who is constantly having to give intravenous and other types of injections containing glucose. There are a number of good illustrations showing the technic of administering these solutions, and there is an excellent index. The book is attractively printed.

W. C. Alvarez, Rochester, Minn.

Clinical Reviews of the Pittsburgh Diagnostic Clinic. Edited by H. M. Margolis. New York, Paul B. Hoeber and Harper and Brothers, 1937, 552 pp.

THIS volume is made up of some forty-eight articles on various phases of internal medicine, written by members of the Pittsburgh Diagnostic Clinic. Many of these articles summarize the experience of the clinic over several years. The volume is interesting and very readable, and will be a useful addition to the library of all those physicians who want to keep up-to-date. A helpful feature at the end of each chapter is a list of from ten to fifty articles suitable for further reading. These titles seem to be well chosen. There are two good indexes. Dr. Margolis is to be congratulated on a difficult job well done.

W. C. Alvarez, Rochester, Minn.

Pathology. By E. B. Krumbaar. New York, Paul B. Hoeber, Inc. and Harper and Brothers, 1937, 206 pp.

THIS is one of the most interesting of a series of excellent small monographs, each on some phase of medical history. Every physician who wishes to be educated must know something of the development of pathology and the theory of disease. It is hard to believe that modern scientific pathology did not come into being until Morgagni published his book in 1761. Only then did a man cast loose entirely from the ancient ideas of "humors" and only then was a book written in which conceptions of pathology were based only on what was found at the autopsy table. The book is well written. There are a number of interesting photographs, and at the end there is a splendid list of what Dr. Krumbaar calls "pathologic milestones." All in all, every student of medical history will want to own a copy of this delightful little volume.

W. C. Alvarez, Rochester, Minn.

Pathophysiology of Hunger Pains. Collected papers from the Medical University Clinic B. By Oline Christensen. Edited by Knud Faber. Series II, Volume 3, 1931.

THIS monograph of 170 pages is based on an extensive study of sixty-six cases. The author concludes that typical hunger pains are associated with vigorous contractions of the empty or nearly empty stomach. He admits, however, that often when the contractions are painful they are not more vigorous than normal.

Furthermore, when, as often happens, the contractions are painful on certain days and at certain hours and are painless on other days and at other hours, the difference cannot usually be accounted for by differences in the depth of the peristaltic waves.

When the pains are relieved by the taking of food, this seems to be due to the fact that the contractions become less forceful. The marked efficiency of an egg-milk mixture in giving relief from pain seems to be associated with the tendency of this particular food to quiet peristalsis.

No relation could be found between the tendency of certain vigorous contractions to produce pain and the degree of acidity of the gastric content at the time. The author suspects that there is a relation between the tendency for contractions to produce pain and the presence of gastritis in the region of the pars pylorica.

W. C. Alvarez, Rochester, Minn.

The International Congresses at Paris and Vichy

By

B. B. VINCENT LYON, M.D.

PHILADELPHIA, PENNSYLVANIA

The International Society of Gastro-Enterology was promoted by Dr. Georges Bróhee of Belgium, in 1934, and the First Congress was held in Brussels in July, 1935, under the Presidency of Dr. Jan Schoemaker of Holland. It was a success. Dr. Franklin A. White of Boston, acted as the "unofficial observer" of the American Gastro-Enterological Association at this first meeting and was one of the American signers of the Constitution of this new International Society.

The Second Congress was held in Paris on September 13, 14 and 15, 1937, in The Faculte de Medecine of the University of Paris, under the Presidency of Professor Pierre Duval, the famous French surgeon, and under the continued Secretary-Generalship of the able Dr. Brohee. In the opinion of the reporter—who was appointed by Dr. Ralph Brown of Chicago, President of the A. G. E. A. to act as its unofficial observer—this Second Congress was again such a success as to warrant much more serious attention and a much larger attendance on the part of members of this Association.

The two subjects discussed were

"The Early Diagnosis of Cancer of the Stomach" and "Acute and Chronic Obstruction of the Small Intestine." There were in attendance about 500 doctors representing 33 countries. To the French and the Germans went the honor of presenting the "major reports" of the first subject. Each speaker was allowed 20 minutes. The Program was as follows:

Rapports francais:

Diagnostic clinique et serologique: MM. le Prof. Paul Carnot et Dr. Caroli. Le radiodiagnostic: M. le Dr. Rene A. Gutmann. Le diagnostic gastroscopique: M. le Dr. Francois Moutier. Le diagnostic gastro-photographique: MM. le Prof. agr. Carin et Dr. Bernay. Le diagnostic chimique: MM. le Prof. Marcel Labbe et Dr. F. Nepveux. Le diagnostic histopathologique: M. le Dr. Ivan Bertrand. Le diagnostic chirurgical: MM. les Drs. Gatellier et Charrier. Conclusions generales des rapports francais: MM. les Prof. Pierre Duval et A. Gosset.

Rapports allemands:

Interne Medizin: Herr Prof. G. Katsch. Radiologie: Herr. Priv. Doz. Robert Prevot. Gastroskopie und gastroskopische Photographie: Herr Prof. N. Henning. Chemische Diagnostik: Herr Prof. Max Buerger. Pathologische Anatomie: Herr Prof. Staemmler. Chirurgie: Herr Prof. Sauerbruch. Conclusions generales des rapports allemands: M. le Prof. G. E. Konjetzny.

Both the French and German presentations were a distinct credit to their respective countries. This reporter was impressed with the grasp each speaker had of his individual topic and the able manner with which he presented his subject matter without using prepared manuscript but talking informally, reinforced at times by an abstract of "hand notes." At the conclusion of the major reports the program listed 53 official discussions of 5 minutes each in which representatives from 19 countries were to take part. Among the doctors from America the following were on the program to discuss the first subject:

R. Schindler, Anthony Bassler, Wm. C. Jacobson, Max Einhorn, Herman I. Goldstein, Roy Upham, Henry Rafsky, Samuel Weiss, H. M. Eberhard, Ben Asher, Reuben Finkelstein, S. W. Johnson, Edw. Kellogg, De Witt Stetten, M. Kraemer, A. L. Levin, D. N. Silverman.

Unfortunately there were a number of absentees. This reporter was given the opportunity of discussing the first subject in the place assigned to Ben Asher of Jersey City. From Great Britain the following doctors discussed the first subject:

Sir Arthur Hurst of London

A. Justras of Montreal

The second subject occupied the third day's Program. The 6 major reports on "Acute and Chronic Obstruction of the Small Intestine" were, in order presented, as follows:

Clinique Medicale: M. le Prof. Heliodoro Mogena (Espagne).

Chirurgie: M. le Prof. Sir D. Wilkie (Ecosse).

Physiopathologie: M. le Dr. Jean Bottin (Belgique).

Radiologie: M. le Dr. Krynski (Pologne).

Anatomo-pathologie: M. le Prof. Cagnetto (Italie).

Biochimie: M. le Prof. Felsen (U. S. A.).

The discussions were to have been participated in by 32 speakers from 14 countries as listed on the Program but again there were a number of absentees. The American discussors present included Max Thorek of Chicago; Max Einhorn, Roy Upham, Henry Rafsky and Anthony Bassler of New York; Hyman Goldstein of Camden and J. A. Ward of Birmingham, Ala.

The 6 official languages were French, German, Spanish, Portugese, Russian and English. To this reporter it appeared that approximately 50-60% of all papers and discussions were presented in French; 20-25% in German and the balance divided among the

A PHARMACEUTICAL ACHIEVEMENT

Aspirin, in an *Effervescent, Alkaline* Tablet

Aspir-Vess

More Palatable, Better Tolerated, More Effective

You will at once appreciate the convenience, palatability and therapeutic advantages of securing the combined effect of aspirin and alkali buffer salts in the medium of a sparkling, effervescent solution.

Aspir-Vess makes this possible by reason of a unique chemical process developed by specialists in the manufacture of effervescent tablet medication.

Clinical experience has proved most favorable to the use of Aspir-Vess in such conditions as the common cold, influenza, acute and muscular rheumatism, neuralgia, headache and pain generally.

EACH TABLET OF ASPIR-VESS CONTAINS:

Aspirin	5 gr.	Magnesium Sulphate (dried)	1 gr.
Calcium Di-Hydrogen Phosphate	2 gr.	Sodium Bicarbonate	31 gr.
Potassium Bicarbonate	1 gr.	Citric Acid	19 gr.

Supplied in convenient glass tubes of 25 tablets

WRITE FOR SAMPLES AND LITERATURE

EFFERVESCENT PRODUCTS, Inc.

ELKHART INDIANA

other 4 official languages. The Americans and the British were at a distinct disadvantage because of their linguistic deficiencies.

The Programs were run off with unusual precision and celerity, in view of the large number of papers and discussions. If a speaker was not present or not ready when his name was called the Chairman passed him over and proceeded to the next speaker with complete impartiality. There was no discussion from the floor.

Compared to American Medical Meetings of national importance, the Commercial Exhibits at the Paris Conference were very meager, were not well "ballyhooed" and were not well attended—save one. Comments were made by both the American and British delegates on the relatively large number of French exhibitors dealing in formidable looking apparatus for colonic irrigation. It seems to be more popular on the Continent of Europe than elsewhere. In fact you could, if you chose, have your colon "laundered" while you waited. The most popular exhibit was one displaying and dispensing a special brand of champagne—a very excellent champagne. But no one abused this hospitality.

After the Monday afternoon session was concluded a reception was held at the Hôtel de Ville where the Mayor of Paris and other dignitaries made the customary speeches of welcome and the customary group photographs were taken. Among other entertainments, the banquet on Wednesday night held at the Hôtel Lutetia on the Left Bank, was most impressive, dignified and formal, and Paris lived up to its reputation for food and wine. Pierre Duval was toastmaster and called upon representatives from a number of countries for short speeches. For the most part these were well prepared and delivered. Sir Arthur Hurst spoke for Great Britain and Dr. Anthony Bassler in his capacity as President of the U. S. membership represented the United States. This dinner was attended by more than 700, including guests. This concluded the Second Congress of the International Society of Gastro-Enterology.

On September 14, 15 and 16 another International Conference was held at Vichy under the Presidency of Professor Maurice Loeper, the famous French internist, and the able Secretary-Generalship of Docteur J. Aimard. At this Congress over 900 doctors from 60 countries, as well as their wives and members of their family were guests of the French Government, which owns the Vichy Spa, famous for its waters and baths. Most excellent hotel accommodation, as well as lavish entertainment, was provided. A special train to Vichy and back to Paris carried a large number of delegates and guests.

"Insufficiencies of the Liver" was the only subject discussed. To the uninitiated it may seem amazing that 23 major papers and 135 discussions could be devoted to this one topic. This is a testimonial to the great margin of reserve and the great power of reparation that the liver possesses. Many other organs would not have survived so much attention.

The first afternoon was devoted to the formality of Registration, followed by a special concert at the Salle du Theatre du Grand Casino, and a reception by the Mayor of Vichy and representatives of the Government where welcoming speeches and the customary photographs were made. One dined at one's hotel and at 10 o'clock a Soiree de Bienvenue was held in the Salons du Grand Casino with dancing and an elaborate supper.

Save for an hour's motor bus ride at noon of the 17th, giving the delegates and guests a too brief view of beautiful

Intestinal Toxemia

Modern eating habits often lead to the loss of normal selectivity of the intestinal mucosa with consequent absorption of protein substance not prepared for use in the body. The liver becomes overtaxed and protein sensitization—sometimes called intestinal toxemia or autointoxication—results.

Along with symptomatic treatment for constipation, diarrhea, and other symptoms which invariably accompany such a condition, the use of Soricin has been found to be of definite value. Soricin (sodium ricinoleate) possesses marked detoxifying properties and relieves the symptoms of toxic absorption.

The suggested use of Soricin as an intestinal detoxifying agent is based on extensive clinical studies. The value of this compound has been demonstrated in the treatment of intestinal toxemia, non-ulcerative colitis, allergic diarrhea, and "irritable colon."

Soricin is available in two dosage forms:

Soricin Capsules (Enteric Coated):

10 grain size:
boxes of 20 and 100 capsules each

5 grain size:
boxes of 40 and 100 capsules each

Soricin Tablets (Enteric Coated):

5 grain size: bottles of 100 tablets

The Wm. S. Merrell Company
CINCINNATI, U. S. A.

Vichy, its bathing pavilions and its bottling works, all of Friday and in addition Saturday morning was devoted to the 23 major reports and Saturday afternoon was devoted to the 135 five minute discussions listed on the Program. To facilitate official handling of the latter, the discussions were subdivided into three divisions: Biology, Medicine and Therapeutics. Each was held in a separate hall with adequate seating arrangement and under responsible Chairmanship, and the delegates and members wandered in and out to listen to such speakers as they might wish to hear.

The Program of the major reports of 20 minutes each was as follows:

Biologie

L'exploration fonctionnelle de l'insuffisance hepatique, par K. Glaessner (Vienne).

L'insuffisance hepatique pigmentaire, par M. R. Castex et A. Lopez Garcia (Buenos Aires).

La fonction soufree du foie, par Leon Binet (Paris).

La peau et le foie, par E. Urbach (Vienne).

Le foie et les glandes endocrines, par C. I. Parhon (Bucarest).

Liver insufficiency in malaria, par N. Hamilton Fairley (Londres).

Medicine

Les gros foies de l'enfance, par R. Debre, E. Gilbrin et G. Semelaigne (Paris).

Les oedemes des hepatiques:

Etude clinique. Facteurs extra-hepatiques de production, par J. Olmer (Marsaille).

Etude chimique des oedemes hepatiques, par A. Lemaire, A. Varay (Paris).

Les relations du foie et de la nutrition avec considerations speciales du systeme nerveux:

Physiologie experimentale, par A. Lathan Crandall, Jr., M.D., Andrew C. Ivy, M.D. (Chicago).

Pathologie clinique du foie, par W. Norman Elton, M.D. (Reading).

Maladies et desordres cliniques, par Anthony Bassler, M.D. (New York).

Bibliographie avec references, speciales sur la degenerescence hepatolenticulaire progressive, les effets des toxines, l'hemachromatose, les lipoides, etc., par Hyman I. Goldstein, M.D. (Camden).

Syndromes hepatiques neurogenes et neuro-endocriniens, par N. Pende (Rome) et M. Bufano (Sassari).

Les insuffisances circulatoires du foie, par M. Villaret, L. Justin-Besancon, R. Cachera et R. Fauvert (Paris).

Therapeutique

L'insuffisance cellulaire du foie et ses indications therapeutiques, par R. de Grailly (Bordeaux).

La medication hepatique dans les accidents d'intolerance, par M. Brule et J. Cottet (Paris).

Le pronostic de la crise operatoire par l'examen des fonctions hepatiques, par Pierre Duval, J. Gatellier, J.-C Roux et R. Goiffon (Paris).

L'insuffisance hepatique pre et postoperatoire et son traitement preventif et curatif, par B. O. Pribram (Berlin).

Le regime alimentaire dans la reparation du foie malade, par F. Gallart-Mones (Barcelone).

La therapeutique hydrominerale de l'insuffisance hepatique, par M. Piery et M. Milhaud (Lyon).

These reports, in whatever language of presentation, were abstracted in the other five official languages and paper-bound in a "Transactions" which was put in the possession of every delegate and member on his registration. Of the 23 major reports, eighteen were delivered in French, three in English. Again this reporter is enthusiastic regarding the presentation by our Continental Confreres. The major reports

170 VARICK STREET NEW YORK, N. Y.

Golden Gate Bridge *Insert: Safety net during construction*

'Copavin'

(CODEINE AND PAPAVERINE, LILLY)

● Secondary infection in a common cold often leads to sinusitis, bronchitis, tracheitis, or otitis media. The importance of preventing invasion of the respiratory tract by pneumococci, streptococci, and staphylococci is a well-established fact. Precautions against secondary infection may at times be as vitally important as was the safety net during construction of the Golden Gate Bridge.

'Copavin' will frequently bring to a termination the acute coryza and other early findings in head colds. Secondary infection does not have an opportunity to develop. The patient is made comfortable and is able to "carry on."

ELI LILLY AND COMPANY

Principal Offices and Laboratories, Indianapolis, Indiana, U. S. A.

of the American representatives, by comparison, were less able and less dignified. Drs. Crandall, Ivy and Elton were not present.

Among the approximately twenty Americans attending the Paris Conference this reporter noted the following members of the A. G. E. A.: Einhorn, Freeman, Felsen, Rafsky and Lyon. Of the 28 registered members at the Vichy Congress, the following fourteen were not in attendance: G. H. Whipple of Rochester (N. Y.); Ivy and Crandall of Chicago; A. A. Aaron of Buffalo; W. G. Morgan of Washington; Elton of Reading; Bishop and Stetten of New York; Rehfuss, Swalm, Eberhard and Mary Spears of Philadelphia; Silverman of New Orleans; F. A. White of Boston. Those present included Einhorn, Bassler, Upham, Twiss, Weiss, Rafsky, Lutz, Jacobson and Felsen of New York; Goldstein of Camden; Thorek of Chicago; Ward of Birmingham (Ala.); Sexton of Washington; Lyon of Philadelphia.

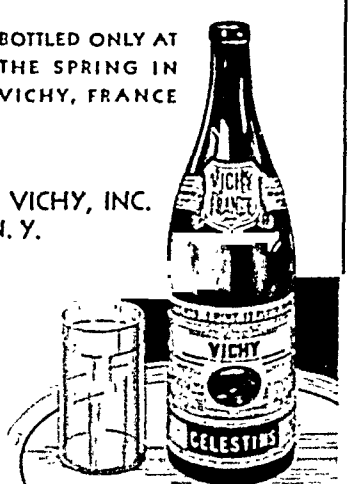
The most frequent question asked this reporter by delegates or members from other countries at both Congresses was "Why are there so few of the better known men in gastro-enterology in the United States in attendance? Where is so and so?" This reporter was unable to reply except to say that he hoped we would make a better showing in London in 1940.

On Friday night there was given in the opera house of the Grand Casino, one act from 3 operas, and two ballets, with leading roles taken by members of the casts of the Paris and Boulogne Opera Companies. On Saturday night an elaborate dinner was faultlessly served to over 1800 persons. Prof. Loeper, the toastmaster, called upon delegates from a number of countries for short speeches. Dr. Bassler again represented the United States.

This reporter believes that these International Meetings are very well worth while, promoting international amity as well as serving the excellent purpose of bringing together outstanding men from all over the world who are interested in a common topic. He believes that in the future those similarly interested in the U. S. A. should take a larger cognizance and a more active participation in future meetings.

The Third Congress of the International Society of Gastro-enterology was awarded to England. It will be held in London in 1940 under the Presidency of Sir Arthur Hurst.

Gastro-Intestinal Toxemias



BECAUSE of its antacid properties, Vichy Celestins has been found useful for gastro-intestinal toxemias, particularly those of the fermentative type. In disturbances due to overeating, faulty diet or alcoholism, Vichy Celestins also has a marked corrective influence.

A valuable FREE booklet on the Therapeutic Value of Vichy, with medical bibliography, will be sent to any physician on request.

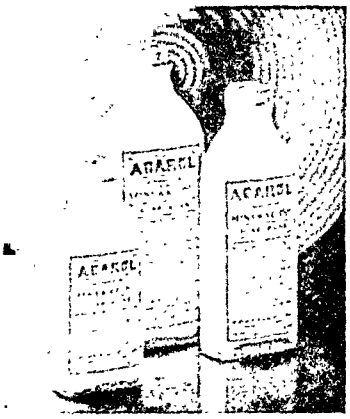
Abstracts

KOEPCKE, G. M.

Vitamins and Infections of the Eye, Nose, Throat and Sinuses. Lancet, Oct., 1937.

Four considerations now operate to foster the use of vitamins in otolaryngological practice, thinks G. M. Koepcke, M.D., Minneapolis. They are: (1) sounder, better work by investigators, (2) the visual photometer for vitamin A deficiency, (3) urinalysis and the capillary fragility test for vitamin C, and (4) to a lesser degree, the heart rate test for vitamin B.



Vitamin deficiencies, Koepcke holds,

In the DARK

At night, it is said, all cats are gray. To the physician unfamiliar with the situation all mineral oil emulsions look alike. But let the spotlight of searching observation shine on Agarol, and it stands alone.

No other mineral oil emulsion excels Agarol in efficacy. No other product approaches it in palatability and freedom from oiliness. The painstaking effort and care that go into making Agarol—the ingredients of exceptional quality that enter into its composition, stamp it, indeed, a unique product.

AGAROL is available in 6, 10 and 16 ounce bottles. The average adult dose is one tablespoonful.

To the physician who has tried mineral oil emulsions in the treatment of constipation—who has experienced disappointments of uncertain quality—who is now ready to try the sound logic and common sense of the principle that has brought distinction to Agarol—we extend this cordial invitation: "TRY AGAROL."

• *Write on your letterhead for descriptive literature and a liberal trial supply of Agarol. You will find it a short cut to a satisfying experience.*

WILLIAM R. WARNER & COMPANY, INC., 113 West 18th Street, New York City

are now all but established as causative factors in respiratory infections, while infections of the nose, throat and sinuses, must be considered in the light of avitaminoses. Though vitamins must not be regarded as "cure-alls"; nevertheless, they form a useful and necessary adjunct to other treatments and preventive measures. Bircher-Benner, for instance, declares that neither prophylaxis nor therapeutics will be wholly successful if there is a vitamin deficiency.

Lowered resistance is probably due to avitaminosis A and C. Avitaminosis A substitutes stratified keratinizing epithelium for normal epithelium in the respiratory tract; and Mackie believes infections of the eyes, tonsils, sinuses, buccal and lingual mucosa, and the skin, are due to avitaminosis A. Glands of internal secretion, particularly, seem dependent on vitamin A.

Tislowitz has treated diphtheria circulatory weakness with the adrenal cortical extract.

Treatment: The nutritional type of corneal ulcers respond very well to vitamin therapy. There is pain, scratching and soreness of the eye; small punctuate areas of ulceration are seen near the limbus. These coalesce after a few days, and corneal destruction progresses rapidly. Balanced combinations of vitamins reinforced by additional vitamins A and B stimulate healing and ulceration ceases.

Congenital cataract likewise yields to vitamin treatment if it is well fortified with vitamins A and C.

The convalescent period following severe acute inflammation is shortened if vitamin therapy is used; while herpes zoster ophthalmia should be treated with vitamin B_1.

If a patient complains of sensitivity to light, Koepcke recommends administration of vitamin A for several weeks, saying that he, himself, is usually able to estimate the amount required from his own clinical observations.

In sphenopalatine neurosis, the extreme pain and discomfort are speedily eased by administration of vitamin B_1.

Acute sinusitis, Koepcke advises, responds well to vitamin A plus combined concentrates; but the vitamins merely augment the routine treatment. The period needed to establish immunity to the predominating organism in the infection is much shortened, allowing quicker surgical intervention with less danger of extension of infection. The healing period is "surprisingly short." The vitamin A and concentrate must be given in large doses.

In general, Koepcke concludes, vitamins may be regarded as food for the endocrines, as good preoperative strengtheners of systemic resistance, and excellent curative agents in the conditions cited above. Surgical intervention is, of course, resorted to where indicated.

KRUSE, FRED H.

The Complications of Peptic Ulcer and Their Treatment. J. A. M. A., Vol. 109, pp. 869-874, Sept. 11, 1937.

The complications of peptic ulcer are intimately related and a brief consideration of their nature and treatment is of value. The most common ones are intractability, hemorrhage, alkalosis, obstruction, hypersecretion and perforation.

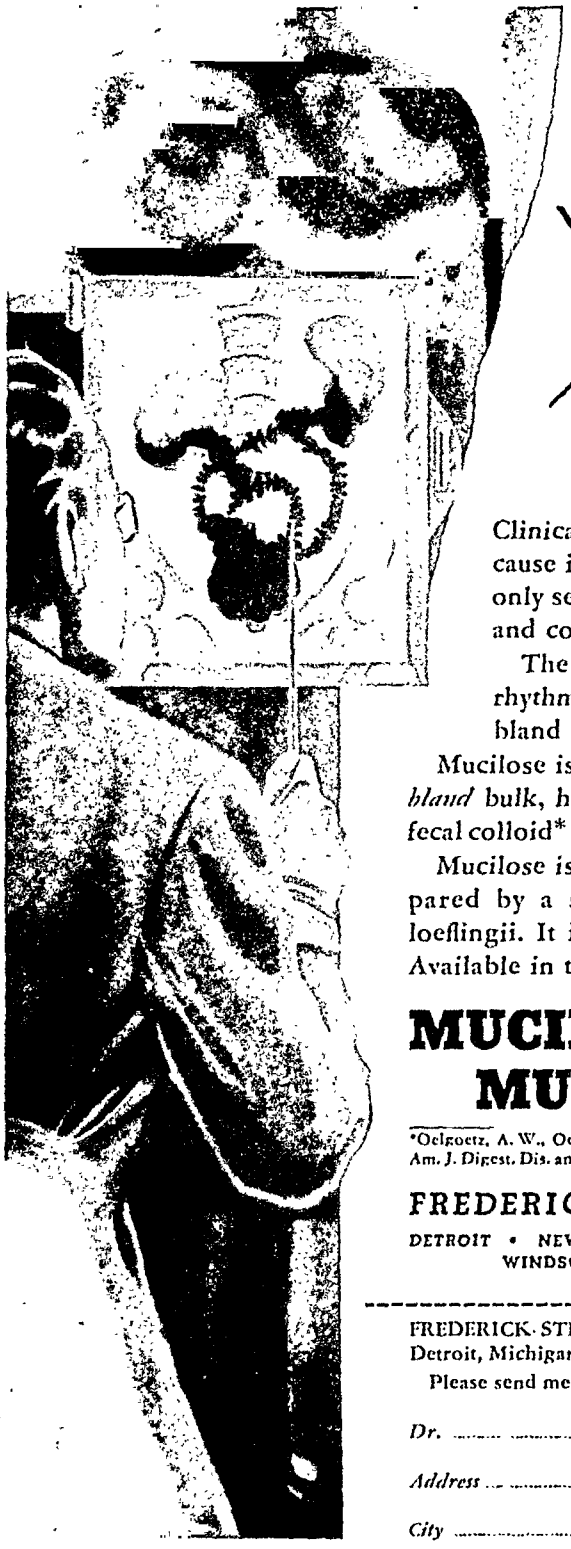
Intractable ulcers are those which do not respond to medical treatment. If, after foci of infection have been removed and nervous manifestations have been overcome, the ulcer does not respond, surgical intervention is the treatment required.

A bleeding ulcer usually is recognized by the appearance of gross hema-

TRI-CALSATE

THE BUFFERED NEUTRAL ANTACID

For rapid relief in the treatment of hyperchlorhydria and peptic ulcer without harmful systemic effects. Tri-Calsate causes no rebound in acidity, no alkalization of stomach contents. The buffering effect of its end salts protects against a harmful alkalosis, thus eliminating a major disadvantage of the alkaline antacids.



Non-toxic, non-irritating; palatable and economical. Available on prescription at your pharmacy or direct in 4-oz. and 18-oz. bottles.

Avoid the Vicious Circle of Alkali Neutralization

Dr. .....

Address .....

City ..... *State* .....

temesis, or melena, or both. It is accompanied by the usual symptoms of severe blood loss. The treatment in the early stages is medical. It should consist of rest in bed with enough morphine to keep the patient quiet. Fluids should be given intravenously, subcutaneously and per rectum. The patient should be starved for at least 48 hours. The author believes that gastric lavage is beneficial when there is evidence of remnants of food or blood. The blood pressure, hemoglobin and red blood count should be carefully watched. Small transfusions are often of value. The patient should be alkalinized. If the patient does not respond to this treatment, surgical intervention will be necessary.

Alkalosis is due to obstruction, vomiting, renal disease, hemorrhage, low salt intake, excessive perspiration, hepatic disease and excessive doses of alkalies. It is characterized by anorexia, depression, distaste for food, irritability, headache, vertigo, timitus, nausea, vomiting, aching joints, pruritus, apathy, drowsiness and coma. Laboratory examination reveals a high nonprotein nitrogen, urea nitrogen, CO_2 of plasma and serum sulfate, while the blood chlorides and the sulfate clearance are normal. The urine will show albumin and casts, and the phenolsulphonphthalein test will be low.

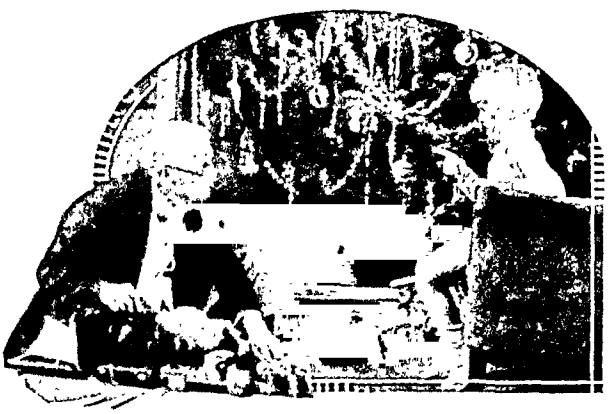
The author's treatment is as follows:

1. Discontinue alkalis.
2. Give N. saline by hypodermoclysis and ten per cent dextrose intravenously.
3. No food or fluid is given by mouth.
4. Stomach lavage.
5. Ammonium chloride 300 c.c. of two per cent solution rectally or ten to twelve gms. by mouth.
6. Feed in three or four days.
7. Use of only neutral or insoluble alkalis in the presence of even a slight degree of renal disease.

Obstruction may be due to pylorospasm, edema and inflammation of the pylorus, or pyloric fibrosis and hypertrophy. It is characterized by increased pain, vomiting, dilatation, distress and emaciation. The treatment is a return to the first part of the ulcer regime. If this is not effective, surgical intervention will be necessary.

Hypersecretion usually accompanies obstruction and should be managed accordingly.

Perforated peptic ulcers may be divided into acute, subacute, and chronic. The acute form is characterized in the first stage by severe abdominal pain, followed by immobility, vomiting, subnormal temperature and shock. In the second stage all the symptoms and signs decrease somewhat in severity, but the abdominal tenderness and rigidity remain. The third stage is that of generalized peritonitis with its concomitant findings. The subacute type is similar to the acute type except that the symptoms are much less severe. The chronic type is usually only recognizable as an ulcer which does not respond to medical treatment.



Francis D. Murphy, Milwaukee.

ANDREWS, FRED L. AND WALKER, THOMAS F.

Intestinal Obstruction Due to Ingestion of Dried Peach. J. A. M. A., Vol. 109, pp. 431-432, Aug. 7, 1937.

Green Light...RED LIGHT

FOOT on the brake, off the brake. Green light, red light, green light. Millions of cars on the roads requiring continuous watchfulness. Pedestrians leaping out of nowhere. You, as a physician, know how hard and nerve-racking a day's driving can be. Headaches are frequent—and often chronic.

Have you ever given Bromo-Seltzer a real trial as an analgesic? It has established itself as an effective pain conquerer. Its rapidity of action is a feature which merits your consideration. In scientific, synergistic proportions, Bromo-Seltzer ingredients are blended—for analgesia, sedation and gentle stimulation of mental activity. Citrates provide carbonic effervescence and combat hyperacidity.

Turn the green light on Bromo-Seltzer. You can prescribe it, with confidence, to your patients for relief of pain.

Samples and literature cheerfully furnished.

EMERSON DRUG COMPANY

BALTIMORE MARYLAND

eaten sardines at noon the day before, also the dried half of a peach which had slipped down her throat. The pain began in the upper abdomen and gradually became more severe. It was not relieved by enemata, either at home or in the hospital. The vomiting gradually became worse, projectile and fecal in character. The temperature was 99° Fahrenheit, the pulse 136, and the leucocyte count, 2,500. At operation, there was found to be a sausage shaped mass obstructing the small intestine. This proved to be a half of a peach which had swollen sufficiently to cause a complete obstruction. The convalescence was uneventful until the fourth day when she coughed and felt something snap. The wound was reopened and part of the incision in the intestine was found open. Bile and fecal material were found in the peritoneal cavity. This opening was resutured and rubber drains were inserted. The patient died the next morning.

Francis D. Murphy, Milwaukee.

THOMPSON, JOHN C.

The Hemopoietic Response Following Oral Administration of Desiccated Duodenal Mucosa. Ann. Int. Med., Vol. 11 (O. S., Vol. XVI), July, 1937.

The author reports that gastrectomy does not promptly produce a primary anemia but in dogs, following an experimental stricture of the small intestine, in man following lateral anastamosis, in chronic intestinal obstruction and in sprue there is produced a blood picture resembling pernicious anemia.

In the summary of seven cases treated with small oral doses of desiccated duodenal mucosa of swine, the author states that as good or better results were obtained than with larger doses of desiccated gastric mucosa as reported by others.

Whereas W. B. Castle obtained his results with desiccated gastric mucosa, the author produced results with desiccated duodenal mucosa of swine. Therefore, Dr. Thompson maintains that the hemopoietic principle is produced in both the stomach and small intestine of swine, and believes that it is reasonable to deduce that the same condition exists in the human.

B. B. Vincent Lyon and
Clifford H. Arnold, Philadelphia.

WAKERLIN, G. E.

The Hemopoietic Liver Principle. Ann. Int. Med., Vol. 11 (O. S., Vol. XVI), July, 1937.

This paper reviews the history of the various blood building liver products, leading up to the hemopoietic principle, and discusses the tests which prove the presence of this principle.

The stomach and the duodenum contribute materially in the formation of the so-called "intrinsic factor" which combines with the so-called "extrinsic factor" of the dietary, to form a third substance which is formed or stored in the liver. Dried stomach and duodenum extractions contain, not the hemopoietic liver principle, but the intrinsic and extrinsic factors.

The intrinsic factor has been found in the gastric mucosa. Only a mild type of anemia follows complete gastrectomy in experimental animals. Deficient vitamin B_1 diet produced macrocytic anemia in monkeys. Gastro-colic fistulae cases in the human; and constriction of the small intestine in dogs generally cause a macrocytic hyperchronic anemia. Destructive liver conditions, reducing the liver cells and thereby the storage capacity of the liver, show a deficiency in the hemopoietic principle, and these cases improve on oral administration of the hemopoietic liver principle.

B. B. Vincent Lyon and
Clifford H. Arnold, Philadelphia.

Bisiodide

Bisiodide is brought to the attention of Gastro - enterologists because it probably is the most easily administered of all effective oral anti-syphilitic drugs. It is tolerated by the most sensitive stomachs.

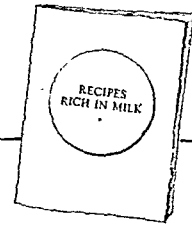
On absorption it exerts a bodywide curative effect on syphilis by producing and maintaining a concentration of bismuth and iodine in the tissues equal in degree, and more constant in duration than is given by injection.

Complete literature is available on request.

IN THE ORAL TREATMENT OF SYPHILIS

SALB LABORATORIES, INC.
22 UNION TRUST BLDG. INDIANAPOLIS, INDIANA.

90% better milk?



Yes, in that the processing of Pet Milk eliminates 90% of the original curd tension of the whole cow's milk from which it is made, thereby making it more digestible.

This elimination enhances its nutritive and therapeutic value in the treatment of digestive disorders. Nutrients are embodied in small curds of low tension, curds in which the nutritive substances are not only more readily available for utilization, but which are less likely to have an irritating effect during the process of digestion.

Other qualities which make Irradiated Pet Milk superior to ordinary milk are: Sterility, precluding the possibility of milk-borne infection; altered whey proteins, less likely to cause allergic disturbance; complemental vitamin D, created by irradiation to facilitate utilization of calcium and phosphorus; lower cost generally than any other form of milk.

In therapeutic procedure consider the advantages of Irradiated Pet Milk over both ordinary milk and the usual milk and cream mixture.

Samples and literature will be sent on request.

PET MILK COMPANY, 1446L ARCADE BUILDING, ST. LOUIS, MO.

HEALING
Roentgenologically
Demonstrable in 7 to 10 Days in
PEPTIC ULCER

When administered through the Creamalin Automatic Drip Control, Creamalin produces roentgenologically demonstrable healing of gastric or duodenal ulcer in 7 to 10 days. Many cases are reported in the literature, in which Creamalin achieved these results after all other modes of therapy had failed.

★

Under drip administration of Creamalin, *all pain and discomfort* disappear within a few minutes and are held in complete abeyance.

★

Creamalin is a distinctive colloidal cream of aluminum hydroxide, prepared by a process distinctly its own. It fixes by physicomolecular affinity 12 times its volume of N/10 HCl in less than 30 minutes, maintaining a constant state of anacidity within the stomach. It cannot lead to alkalosis or to alteration in blood pH, does not produce secondary rise in HCl secretion. • • • Creamalin is of proved value in gastric and duodenal ulcer, in jejunal ulcer, in hyperacidity without ulcer, and in the management of actively bleeding ulcer. It is equally effective by mouth, producing demonstrable healing in 3 to 6 weeks.

Reprints of published reports together with literature and sample, on request.

THE SUCCESSFUL
ULCER TREATMENT

MEANS, J. H., HERTZ, S. AND LERMAN J. *Nutritional Factors in Graves' Disease. Ann. Int. Med., 11:429-436, Sept., 1937.*

The authors as a result of observation and study of some 35 cases conclude that malnutrition is an important factor in precipitating thyrotoxicosis. In 14 of the cases the prethyrotoxic weight loss was occasioned by reduction cures and in the remainder it was due to other factors leading to diet restriction such as, treatment of ulcer, ulcerative colitis, diabetes, and diseases leading to malnutrition.

A distinction is made between general malnutrition due to total negative calory balance and malnutrition due to shortage of specific dietary elements such as vitamins or minerals.

They discuss certain manifestations in Graves' disease which are apparently related to the more specific types of malnutrition. Among these are myasthenia, skeletal decalcification with increased calcium and phosphorus excretion and evidences of iron shortage with smooth tongue, nail changes, and achlorhydria.

They have shown that addition of adequate amounts of vitamin B_1 to the diet in thyrotoxicosis, though not affecting the basal metabolic rate, does cause a marked improvement in appetite and consequent gain in weight. They use it routinely in preparation of such cases for surgery. They also suggest the possible etiological relationship between vitamin B_1 shortage and cardiac insufficiency of thyrotoxic patients. Night-blindness was a prominent symptom in one case of Graves' disease that followed the use of a grossly inadequate diet. It cleared up with the use of an adequate diet.

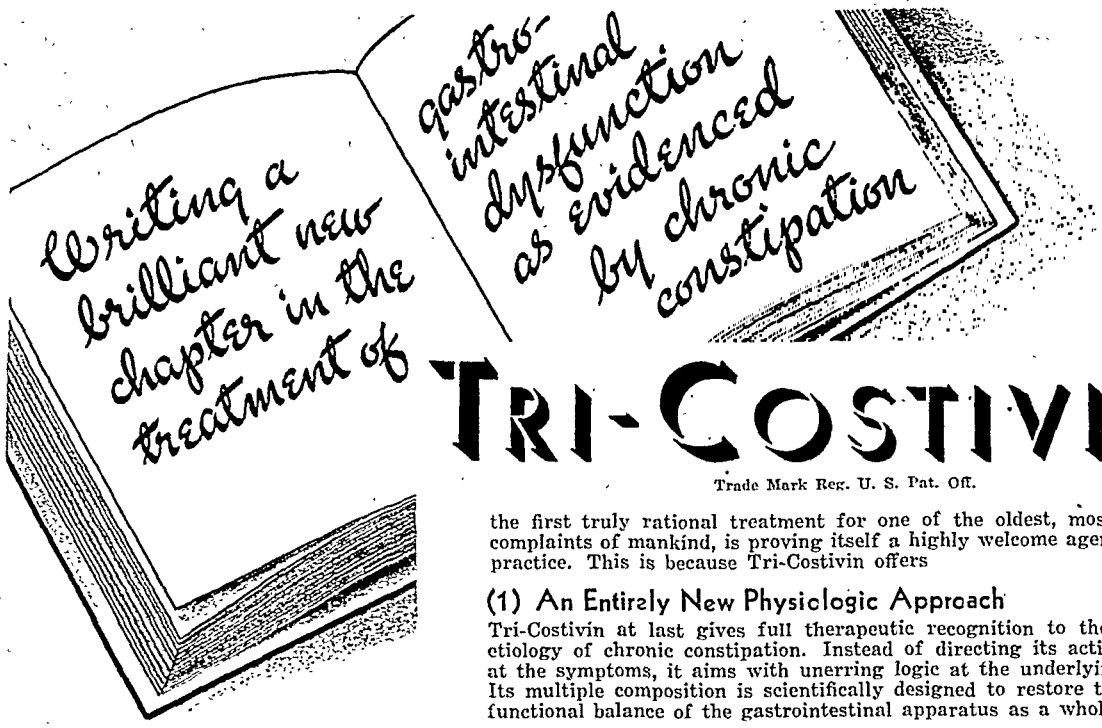
The authors stress the need for proper attention to the nutritional deficiencies in preparing patients for surgery, and cite a case illustrating this point.

In conclusion they sound a note of warning against too vigorous reduction cures as thyrotoxicosis may be induced thereby. In the matter of diet they suggest the use of vitamin B_1 in preparing thyrotoxic patients for surgery because of its beneficial effects upon the appetite and possible beneficial action upon cardiac function. Excessive protein is considered undesirable because of its specific dynamic action. Carbohydrate in large amounts is insurance against depletion of the glycogen stores of the liver and thus safeguards that organ. Fat may be given as the patient desires.

Malnourished thyrotoxic patients as well as those with psychosis, or cardiac insufficiency are considered poor operative risks. They advise, in addition to the routine pre-operative preparation, therapeutic measures adjusted to the individual's needs.

Hanes M. Fowler, Fort Wayne.

ROBINSON, C. S., CUNNINGHAM, R. S., BLALOCK, A., GRAY, M. E. AND ROGERS, B. C. *Chylous Effusions Produced by Ligation of the Superior Vena Cava: Chemical and Cytologic Studies. Arch. Path., 24:3-501, Sept., 1937.*



The authors review the meager literature on chylothorax and analyze the references to one hundred cases in man in which the diagnosis seems to be correct. In these cases but meager data on the cellular content of the fluid and on the changes in the cell picture in the blood stream is found.

Chylothorax was produced in twenty-eight of forty-seven animals (dogs and cats) in each of which the superior vena cava was ligated. In eleven animals fluid was obtained from the pleural cavities which was not chylous in character, and in eight animals no fluid developed. Studies were made of the cellular content of the milky fluid and the circulating blood and the chemical constituents of the fluid. They found that the fluids were very rich in lymphocytes and also contained a considerable number of neutrophils. They averaged 20,000 cells, of which about 2,000 cells were neutrophils and about 17,500 cells were lymphocytes.

In the circulating blood of the animals the total number of lymphocytes and the total number of eosinophiles dropped markedly following ligation; the former due probably to the obstruction of lymphatic drainage, but no explanation was found for the drop in the circulating eosinophiles.

The milky fluids obtained were true cholous effusions, the opacity of which was due to free fat. The lipids estimated as "neutral fat" comprised about 80 per cent of the total lipids. The quantities of cholesterol were small but formed a constant fraction of the total lipid. The esterified cholesterol did not vary uniformly with the neutral fat. The total nitrogen values probably included nitrogen from the nonlipid compounds, but the aminonitrogen was due mostly to true lipids and tended to vary with the neutral fat. The phosphatide fraction contained substances which were neither lecithin nor cephalin and these varied with the neutral fat. The phosphorus and the aminonitrogen constants seemed to rise and fall together.

N. W. Jones, Portland

TRI-COSTIVIN

Trade Mark Reg. U. S. Pat. Off.

the first truly rational treatment for one of the oldest, most common complaints of mankind, is proving itself a highly welcome agent in daily practice. This is because Tri-Costivin offers

(1) An Entirely New Physiologic Approach

Tri-Costivin at last gives full therapeutic recognition to the multiple etiology of chronic constipation. Instead of directing its action merely at the symptoms, it aims with unerring logic at the underlying causes. Its multiple composition is scientifically designed to restore the normal functional balance of the gastrointestinal apparatus as a whole.

(2) A New Pharmacologic Triumph

Research by a group of internationally famous collaborators revealed the need for eight therapeutic factors for the *physiologic* treatment of intestinal stasis. The combination of these ingredients in a palatable, easy-to-take granule represents a significant scientific achievement. Tri-Costivin supplies these factors without the admixture of irritant laxatives or cathartics of any kind.

(3) A New Record of Clinical Success

Tri-Costivin has been employed in groups of cases of the most stubborn type. In many instances, bowel movement had previously depended for years on the daily employment of cathartics. Under Tri-Costivin therapy alone, eliminative function has been almost invariably restored to normal after a short period of administration.

The details of investigative work and protocols of clinical investigation on this important new therapy are available in comprehensive book form. A copy, together with a clinical sample of Tri-Costivin, will be gladly mailed to the physician on request.

For sale on prescription in plain containers of 266 gm. with cellophane slip label — which the pharmacist is instructed to replace with a prescription label.

PROFESSIONAL LABORATORIES, INC
155 EAST 44th STREET NEW YORK, N. Y.

In Tri-Costivin are combined the following ingredients for an effective simultaneous therapy:

Vitamin B_1 Concentrate (650 Chase-Sherman Units Per Daily Dose)

Vitamin B_2(G) Concentrate (125 Sherman Borquin Units Per Daily Dose)
For promotion of appetite, increasing hydrochloric acid secretion and tonicity of stomach, maintenance of acid base equilibrium and normal assimilation.

Lacto-Banana Concentrate
For the conversion of bacterial flora in the intestines and replacement of putrefactive bacteria by the friendly type.

Trilactic (Trade Mark) with Calcium Lactate
To energize and sustain bacterial conversion. A new, efficient medium in eliminating putrefaction of the colon.

Gall-bladder Tissue Extract (Hormone Cholezysmon)
For intensifying the action of the pancreatic enzymes.

Bile Extract
To increase the contractile action of the gall-bladder.

Duodenum Gland Extract (Hormone Cholecystokinin)
To stimulate gall-bladder function.

Agar-Karaya Gum
To increase stool to ample size and soft consistency and to provide a soft gelatinous bulk to correct intestinal stasis.

(Copyright, 1937, by Professional Laboratories, Inc.)

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

PREVENT DIGESTION OF THE PROTECTING CLOT!

Amphojel

WYETH'S ALUMINA GEL

● In gastric and duodenal ulcer, the protecting clot over the ulcerated area often represents the thin margin between safe healing and dangerous hemorrhage. The maintenance of this clot through proper control of gastric acidity is therefore of utmost importance.

Amphojel, Wyeth's Alumina Gel, reduces gastric acidity to physiologic neutrality and prevents interference with the body's protective forces. Whether administered orally or by the "drip" method Amphojel will not produce alkalosis, acid rebound or threat of kidney damage.

Available in 12-ounce bottles

JOHN WYETH AND BROTHER
INCORPORATED

Ulcer Recurrences Attributed to Upper Respiratory Tract Infection: A Possible Illustration of the Shwartzman Phenomenon*

By

BURRILL B. CROHN, M.D.

and

GREGORY SHWARTZMAN, M.D.

NEW YORK, NEW YORK

VARIOUS factors contribute to frequent recurrences of ulcer activity after periods of remission or apparent cure. Among the most important of these elements, writers generally recognize (1) dietary indiscretion, (2) overactivity, physical or phychic, leading to fatigue or exhaustion, (3) abuse of alcohol, (4) nicotinism, particularly the misuse of cigarettes, (5) seasonal incidence, and (6) probably closely affiliated with the former, upper respiratory, pharyngeal, accessory sinus and other forms of so-called focal infections.

The relative frequency or comparative importance of these several factors has not been statistically computed, insofar as the accepted dictums or the authorized text-books or publications on gastro-enterology are concerned; but that they all play a rôle individually or on occasions is doubted only by the unorthodox. The significance of the abuse of smoking (cigarettes) may perhaps still be in the province of debate, but to the role of infection in predisposing to or actually causing ulcer recurrences, there seem to be no dissenters. Particularly potent in such a causative relationship are infections of the upper respiratory and nasal passages, a fact which is attested by most of the writers of standard works. Rehfuss (1) accepts focal infection in this rôle without hesitation, quoting freely from the experimental work of Rosenow (2), as confirmed by Haden and Bohan (3). Hurst and Stewart (4) warn against sudden exposure and changes of temperature and advise a rapid resumption of active ulcer therapy when a cold threatens to awaken gastric symptoms. Eusterman and Balfour (5) quote not only fully the relationship between focal infections (particularly of the teeth and tonsils) and peptic ulcer, but refer to studies of Rosenow in which experimental ulcer in animals can be reproduced by utilizing bacteria recovered from cases of bleeding ulcer in man.

That duodenal ulcer was particularly susceptible to reactivation in the fall and winter months was attested by Moynihan (6) in his earliest clinical descriptions of that disease, though Hutter (7) has been able to find no variations of climatology, humidity, altitude or temperature fluctuations to account for the phenomenon. Christiansen (8) notes an even distribution of ulcer recurrences with hemorrhage throughout the months of the year, though most Scandinavian authors find between 35 per cent and 46 per cent of hemorrhage occurring during the fall months of September and December. Emery and Monroe (9) in evaluating the relative importance of the various factors which cause ulcer recurrences enumerate them as follows:

Of 1279 cases, ulcer activity was reawakened in 334 by fatigue; in 258 by emotion, in 167 by infection (colds and grippe rather than frank pneumonia) and in 37 by dietary indiscretions.

Personally, we feel that these figures of Emery and Monroe understate the frequency with which infective agencies cause a lighting up of a healed ulceration, particularly in years such as the present one (1937) in which bulletins of the Public Health Services publish an annual incidence and a greater severity of grippe, tonsilitis, and upper respiratory infections.

While unable to quote actual figures we have always been convinced of the malign influence of tonsillar infections, acute naso-pharyngitis, grippe, influenza, pleurisy and even pneumonia, bronchial and lobar, in activating ulcer recurrences. It has always seemed a hopeless cause to preserve an apparently healed ulcer case in the presence of a susceptibility to recurrent head colds or chronic sinusitis. Not infrequently a tonsillectomy or a tooth extraction may be followed by an ulcer recurrence. "In a case of gastric ulcer which had been under observation for about two years, and which had shown a disappearance of a penetrating niche with subsidence of all clinical symptoms, there developed a lobar pneumonia. During the convalescence hematemesis and melaena occurred with a renewal of the symptoms" (10) and with a reappearance of the niche.

During the present year of 1937, particularly during the months of February and March, the grippe was unusually prevalent and unusually severe. During that time, and shortly thereafter, a number of cases of hematemesis and melaena of a severe grade were admitted to the hospital for urgent treatment of that complication of ulcer. At one time, within a period of ten days, seven actively bleeding ulcers were seen at the height of the grippe epidemic. In another large city institution as many as eleven ulcer hemorrhages were admitted during the same period.*

The causal relationship between grippe and ulcer hemorrhage became an alarming fact, to such an extent that all latent ulcer cases were warned to avoid coughs and colds lest ulcer recurrence with hemorrhage occur. That this advice was timely was succinctly shown in the case of a young man who, in his third week of Sippy treatment, when free of all digestive complaints, developed a severe head cold. He was

*From the Medical Services and the Laboratories of The Mount Sinai Hospital, New York City, N. Y.

Read at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7 and 8, 1937.

*Personal communication of Dr. Mostkowitz, of the Staff of the Queens General Hospital, Jamaica, L. I.

immediately warned to take to his bed, disregard the cold, avoid aspirin or other irritating medications or drinks, and to return to the first week of strict Sippy diet with the resumption of his alkaline medication. In spite of this warning and its strict obedience, a gross gastric hemorrhage resulted within 21 hours, necessitating urgent hospitalization.

The relationship between bacterial infection and ulcer hemorrhage was further suggested by an interesting set of facts. The patient, a physician and an accurate observer, reported that in 1926 he had had a series of prophylactic injections of typhoid vaccine. In May, 1936, ten years later, he was given the first of another series of typhoid inoculations. By a mistake in dosage he was given, in the first injection, a triple overdose. Within 24 hours he vomited a gross amount of blood, noted hematuria and petechial hemorrhages over his lower extremities. Coincidentally he developed postprandial distress and night pains. An X-ray carefully read showed an irregular defect of the duodenal bulb. On the occasion of a subsequent hemorrhage in February, 1937, and because of continuous digestive pain and distress, operation was considered indicated. A partial gastrectomy revealed a penetrating duodenal ulcer.

The explanation of the possible causal relationship between bacterial infection and ulcer recurrences with hemorrhage leads to several interesting hypotheses. In the cases of upper respiratory infections with active bacterial invasions, a direct esophageal approach to the stomach through infectious saliva and swallowed secretory discharges must be considered; or an indirect hematogenous route may well be imagined and given credence. This explanation would only apply if we were to regard the ulcer in the peptic mucosa as an active infective focus or site of potential infection, a view which is not generally held.

The case of the physician in which the injection of a dead bacterial vaccine was the apparent factor in activating a peptic ulcer seems to offer a clue to a more satisfactory hypothesis; namely, the phenomenon of local skin reactivity to bacterial filtrates.

Before attempting this correlation the following basic experiments concerning the phenomenon should be recalled:

The phenomenon is elicited by combination of two injections of bacterial filtrates, i.e., preparatory injection into a tissue and provocative injection into the blood stream. The interval of time necessary ranges between 8 to 120 hours, optimum being 24 hours. No specific relationships exist between the preparatory and provocative injections. Bacterial products producing the phenomenon for themselves produce it for each other. The bacterial factors producing the phenomenon, however, are specifically neutralized by immune sera. It is interesting, therefore, that the phenomenon is both non-specific and specific, antigenically specific substances of a great variety producing the same type of injury in the animal tissue by means of the same mechanism (11).

While most of the work on the phenomenon was done thus far with bacterial filtrates, substantial evidence exists that infections are also capable of eliciting the state of reactivity of the phenomenon. The phenomenon was produced at sites infected with streptococcus hemolyticus (Shwartzman (11)), B. anthrax (Gratia and Linz (12)), vaccinia virus (Gratia and Linz (13) and Koplik (14)), B.C.G., pseudotuberculosis of guinea pigs (P. Bordet (15)) and Debonera, Tzortzakis and Falchetti (16)), virulent tubercle bacilli (P. Bordet (17), Freund (18) and Shwartzman (11)), pneumococcus (Michelazzi (19)), B. influenza and B. Bordet-Gengou (Witebsky and Salm (20)), etc.

Thus, at certain stages of infection with the foregoing bacteria and viruses, tissues assume a state of reactivity of the phenomenon under discussion. While this state of reactivity exists, bacterial factors introduced into the general circulation produce lesions characteristic of the phenomenon in the reactive sites. As already mentioned, no specific relationships exist between the provocative factors and those responsible for the local state of reactivity. The lesions obtained bear certain characteristic features in the gross and histologically. They are predominantly hemorrhagic and apparently due to marked capillary fragility similar to hemorrhagic diathesis. The profuse capillary bleeding is associated with severe necrosis, thrombosis and considerable inflammation. It is justifiable, therefore ,to assume that a similar mechanism of production of injury may exist in animal and human pathology of spontaneous diseases associated with hemorrhagic manifestations.

The opinion has been already voiced that purpuric manifestations of acute infectious diseases produced by bacteria and viruses may be due to the mechanism illustrated by the phenomenon of local tissue reactivity (small pox, measles, typhoid fever, meningococcus meningitis, etc.). Previous observations of various authors bring supporting evidence to the assumptions of this sort. Thus, Ikeda (21) in reporting a series of 131 cases of purpuric small pox noted that nearly all the cases had streptococcus bacteremia and that streptococcus could be cultured with regularity from hemorrhagic pox but that the non-hemorrhagic ones were always sterile. According to Koplik (14), in experimental vaccinia infections, a spontaneous transformation of a mild lesion into a hemorrhagic one may be due to a superimposed bacterial infection.

In direct relation to this topic also stand the observations of Ichikawa (22), who reported that intravenous administration of typhoid vaccine into typhoid fever patients brings about a critical drop in temperature not infrequently associated with bleedings in the intestines, lungs, nose and hemorrhage in the skin.

The clinical observations already discussed suggest that a mechanism as described in the foregoing may also, at least in part, be responsible for exacerbations, perforations and bleedings in gastric ulcers. Whatever the primary etiologic factor of gastric ulcer may be, secondary bacterial invaders are commonly found in the bed of gastric ulcers. These bacterial invaders may be, then, responsible for a lasting state of reactivity in the tissues of the gastric ulcer. Once this state of reactivity exists viruses and bacteria-producing infections in organs distant from the gastric ulcer may be able to produce injury in the ulcer by way of the general circulation. The lesion obtained by means of this mechanism should, as already mentioned, consist of necrosis and hemorrhage, i.e., precisely of the type found in bleeding and perforated gastric ulcers. Assumption of this sort is further supported by the fact that the phenomenon of local

tissue reactivity was successfully produced also in the gastric mucosa by Karsner, Ecker and Jackson (23).

DISCUSSION

DR. ALBERT F. R. ANDRESEN (Brooklyn, N. Y.): This paper and the previous discussions have brought to mind the many times that Fenton Turck appeared before this Society and demonstrated the production of gastric ulcer as a result of the sloughing out of areas of focal necrosis in the stomach mucosa following the injection into animals of his cytost or cell toxin, an extract of dead tissue of the animal or another animal of the same species. I have long felt that the obvious connection between focal infection and peptic ulcer could best be explained on the basis of the absorption of cytost from the focus, rather than by direct infection, as suggested by Rosenow. I feel that the phenomena demonstrated in the present paper could be explained just as well on the basis of the development of a new ulcer at or near the site of the previous ulcer as on the theory of reactivation or sensitization of a previous ulcer. Lewis Gregory Cole has demonstrated conclusively that each attack of ulcer symptoms represents the development of a new ulcer. We are coming constantly nearer to the solution of the ulcer problem.

DR. ASHER WINKELSTEIN (New York, N. Y.): The ideas of Dr. Crohn and Dr. Shwartzman are of great importance, particularly in relation to the question of the erosive gastritis which interests us so much in the ulcer problem.

I should like to cite very briefly three cases that I saw recently. One was a man who had been treated after five years of ulcer symptoms, quite thoroughly, and lost his symptoms for several months. Then he had eight teeth extracted. Twenty-four hours later he had a severe gastric hemorrhage and a marked recurrence of ulcer symptoms. Partial gastrectomy was performed. In addition to old scars, three fresh ulcers and a severe gastroduodenitis were found in the specimen.

The second case was that of a man with a chronic ulcer who had been without symptoms for two years. He then had a severe grippe. On the fourth day, a hemorrhage occurred from the stomach and rigidity appeared in the upper abdomen.

The third case was a man with penetrating duodenal ulcer, with some pyloric obstruction. He was transferred to the surgical service, and, as he was about to be operated upon, he developed a facial erysipelas. With sunlight therapy he recovered and also lost his ulcer symptoms. His operation was cancelled. It is now several months since his discharge and he is perfectly well.

The problem that arises first is whether this activation of ulcer symptoms isn't really the direct effect of toxins or organisms on the mucosa rather than a Shwartzman phenomenon. Knud Faber has shown that during influenza you frequently get a severe gastritis and duodenitis.

The second question comes up as to whether it really is the phenomenon. I think it is in most instances. The phenomenon explains the activation of the symptoms probably by lighting up the associated gastritis rather than the ulcer itself.

Another point comes up as to whether an intercurrent infection may not improve the ulcerative gastritis and the ulcer by provoking an increased immunity. This may have been the case in the patient with the erysipalas. Also, the phenomenon may in itself promote healing (Shwartzman). man).

DR. BURRILL B. CROHN (New York, N. Y.) (closing the discussion): Dr. Shwartzman pointed out that in the mechanism of the phenomenon, necrosis takes place before inflammation; this may explain one point, namely, the incidence of hemorrhage as an initiatory symptom in recurrence of ulcer.

Studies in Mucous Membrane Hypersensitiveness

III. The Allergic Reaction of the Passively Sensitized Rectal Mucous Membrane*

By

IRVING GRAY, M.D.

and

MATTHEW WALZER, M.D.

BROOKLYN, NEW YORK

IN previous investigations (1, 2) the allergic reactions of the passively locally sensitized ophthalmic and nasal mucous membranes were studied. The present communication deals with the allergic reaction as it occurs in the rectal mucous membrane which has been passively sensitized. This site was chosen for study because it represents the only accessible portion of the gastro-intestinal mucous membrane. It is, however, quite characteristic in structure and fairly representative of the lining of the entire intestinal tract.

* Read at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7 and 8, 1937.
From the Division of Applied Immunology, Jewish Hospital of Brooklyn.

TECHNIC

The technic employed in this study is similar to that used in the investigations on the eye and nose. It is a modification of the immunologic procedure employed by the authors in their studies on the absorption of unaltered protein (3). It consists of sensitizing the rectal mucous membrane to peanut protein by the local injection of a human serum containing reagin antibodies for peanut. Twenty-four to forty-eight hours later, the peanut antigen is ingested on a fasting stomach. Within a few minutes an inflammatory reaction usually develops at the sensitized sites in the rectum. As pointed out in previous communications (4), this signifies the presence of the unaltered peanut protein in the circulation and represents the allergic reaction of the sensitized mucous membrane to specific excitation by the circulating peanut antigen.

A—Passive Local Sensitization of the Rectal Mucous Membrane.

1. Sensitizing Serum: Peanut was selected as the antigen to be investigated solely because a serum which was particularly suitable for the study of this antigen happened to be available. It was obtained from a patient who manifested a very marked positive reaction to a skin test with peanut antigen and who developed immediate severe constitutional symptoms following the ingestion of this food. His serum showed a very high titer for reagin antibodies to peanut and was used in a dilution of 1 to 10 for sensitizing purposes.

2. Site of Sensitization: The rectal mucous membrane was sensitized at a distance of 2, 4 or 6 cm. from the anus. In some of the cases, the mucous membrane of an internal hemorrhoid was the site of sensitization. In every subject the skin on the forearm was also injected with the serum for purposes of control and comparison.

3. Technic of Sensitization: All forms of nuts were excluded from the subject's diet for a period of twenty-four hours previous to the sensitizing injection. The rectal mucous membrane was visualized with the aid of a rectal speculum. About 0.05 c.c. of the sensitizing serum was introduced into the mucous membrane on either the posterior or anterior wall of the gut. A 27 gauge needle was employed for the purpose and the procedure was seldom followed by any bleeding or subjective symptoms.

B—Administration of the Protein Meal.

One or two days after sensitization the patient reported without breakfast and was given the peanut meal. This was administered orally in most instances and consisted of 10 grams of raw ground peanuts in 30 c.c. of water to which was added 1 gram of sugar and 0.05 c.c. of oil of cloves. In a small series of cases, the meal was introduced into the rectum or was directly applied on an applicator to the sensitized rectal site.

THE REACTION FOLLOWING ORAL ADMINISTRATION OF THE ANTIGEN

Following the administration of the peanut meal reactions developed at the sensitized cutaneous and mucous membrane sites. In most instances the reaction of the mucous membrane preceded that of the skin by several minutes. The reaction on the skin, as has been described in previous communications (5), consisted primarily of erythema and wheal formation and was usually preceded and accompanied by marked pruritis. The reaction at the sensitized sites in the rectum consisted of edema and hyperemia. The subjective symptoms associated with its development varied with its location. Generally speaking, the nearer the sensitized site was to the anus, the more pronounced were the subjective symptoms caused by the allergic reactions.

The onset of the local allergic reactions was usually heralded by the appearance of symptoms such as pruritis, burning, a sense of fullness, and a desire to empty the bowel. On proctoscopic examination, the development of an edema involving the sensitized site was the first objective finding. The edematous mucous membrane was at first paler than the contiguous mucosa. Within five minutes after its onset, the edema had reached its peak. Several minutes after the appearance of the edema, a hyperemia started to develop. This gradually grew in intensity for about ten minutes, the mucous membrane at the sensitized area becoming deeply congested. The inflammatory process was confined to the neighborhood of the sensitized site which acquired a much deeper color than that of the normal mucous membrane. Associated with these changes there was an increase in mucous secretion over the affected area. The reaction reached its peak about fifteen or twenty minutes after its onset and then gradually began to subside. All traces of it were usually lost in about an hour. Several examinations of the mucous secretion produced by the allergic reactions failed to show the presence of any eosinophiles. Attempts to aspirate fluid from the edematous area were unsuccessful.

On six subjects an internal hemorrhoid was the site of sensitization (Table I, Cases 1-6, inclusive). In two-thirds of these cases, the mucous membrane reaction preceded that on the skin by two or three minutes. Pruritis accompanied the reaction in five cases. A sense of fullness in the rectum and a desire to empty the bowel were present in two patients. Only one complained of a burning sensation in the rectum. Objectively, the reactions all showed characteristic edema and hyperemia.

In ten subjects, the mucous membrane of the rectum was sensitized 2 cm. from the anus (Table I, Cases 7-16, inclusive). In all but one, the allergic reaction in the rectum preceded that of the skin by several minutes. The subjective symptoms differed from those of the previous group in that pruritis was less commonly noted. A sense of rectal fullness was reported by seven of the group. Desire to empty the bowel was experienced by six patients and three complained of burning in the rectum. Objectively edema and hyperemia were present in all ten subjects.

In eight cases, the rectal mucous membrane was sensitized at a site 4 cm. from the anus (Table I, Cases 17-24, inclusive). Five of these patients complained of varying degrees of fullness in the rectum and two complained of burning. Pruritis was present in only one patient. The subjective symptoms in this group were less pronounced than those reported by the preceding groups, in whom the allergic reactions were closer to the anus.

In fourteen subjects, the rectal mucous membrane was sensitized 6 cm. from the anus (Table I, Cases 25-38, inclusive). The subjective symptoms in this group were relatively few. Pruritis was present in two cases and two others complained of fullness in the rectum. Rectal burning and a desire to empty the bowel was not reported by any of this group. The objective findings at the 6 cm. level were more difficult to observe through the proctoscope than in the preceding groups. In all respects, however, they are the same as those already described.

In the twenty-two cases in which the local reaction occurred at the 4 and 6 cm. levels, the average reaction time of the mucous membrane was about the

same as that of the skin. In the preceding groups, where the sensitized sites were nearer the anus, the mucous membrane reaction usually preceded that at the cutaneous site by several minutes. It is not improbable that the difficulty in detecting the exact time of the onset of those reactions which occurred higher up in the rectum is responsible for the apparent delay in reactions at these levels.

RECTAL ADMINISTRATION OF THE PEANUT ANTIGEN

In eight subjects, the antigen was introduced into the rectum (See Table II). In three instances, the full protein meal was given. In five subjects a cotton swab saturated with several cubic centimeters of the peanut meal was locally applied to the sensitized mucous membrane site. In three of these cases, this

TABLE I

Summary of results following oral administration of antigen

swab was left in situ; in the remaining two it was withdrawn.

In the three cases in which the entire meal was administered by rectum the reaction seemed to develop in the same manner as noted after oral administration of the antigen. However, in subjects 14 and 15, who had been tested on separate occasions by both methods of antigen administration, the reaction time was shorter by several minutes with the rectal than with the oral technic (See Table II).

TABLE II

Summary of results following rectal administration of antigen

Amount of Antigen	Case No.	Diagnosis	Site of Sensitization Distance from Anus in cm.	Reaction Time in Minutes		Subjective Symptoms			
				Skin	Rectal	Pruritis	Fullness	Desire to empty bowel	Burning

Cotton swab	44	Colitis	4	14	10				

*Readings in parenthesis represent results following oral administration of antigen in same patient.

In the five subjects in whom a minimal amount of the peanut meal was applied on a cotton swab solely to the sensitized site, the allergic reactions which developed were similar in character to those noted when the full meal was administered either by rectum or given by mouth. These reactions, however, did not reach their maximum until after the skin reaction had appeared.

DISCUSSION

In previous investigations (1, 2) it has been shown that the external mucous membranes in normal humans, such as those of the eyes and nose may be passively and locally sensitized by the injection of human reagin-bearing sera. In the present communication the writers have demonstrated that the rectal mucous membrane may be similarly sensitized. The fact that reagins can be fixed in the mucous membrane of the gastro-intestinal tract as well as in those of the ophthalmic and respiratory organs, suggests the universality of reagin fixation in human mucous membranes.

In the ophthalmic and nasal studies, the allergic reactions were usually elicited by the external or direct application of the related offending antigens to the sensitized mucous membranes. In the present study, however, they were produced by the oral administration of the antigen as well as by its local application. The ingested antigen reached the sensitized site by way of the circulation. This, no doubt, is the manner in which antigenic stimulation of allergic mucous membranes occurs in many forms of food hypersensitiveness.

The cardinal and constant characteristics of the allergic reactions in the passively sensitized mucous membrane of the rectum are essentially the same as those which were observed in the allergic reactions of other mucous membranes. They consist of edema, erythema and increased mucous secretion. The allergic reaction of the passively sensitized rectal mucous membrane is short-lived and disappears within an hour. A strong reaction usually neutralized the fixed antibodies so that, on subsequent feeding of the antigen, no further local reactions occur. Occasionally, however, a second mild reaction may be obtained upon restimulation of the site.

The allergic reaction of the rectal mucous membrane was associated with symptoms which varied with the individual and with the site of sensitization. They included such complaints as pruritis, rectal fullness, desire to empty the bowel, and burning. The closer the inflammatory reaction of the mucous membrane was to the anus the more severe were the complaints. Usually the subjective symptoms preceded the appearance of the local reaction. Pruritis was present in most of the patients in whom the reaction occurred on a sensitized internal hemorrhoid. Fullness and desire to empty the bowel was a more common complaint when the reaction occurred at a distance of 2 or 4 cm. from the anus. When reaction was at the 6 cm. level, the paucity of subjective symptoms was quite noticeable.

The local application of the antigen to the sensitized sites in the rectum revealed some findings which illustrate the possible mechanisms which may be involved in gastro-intestinal allergy in humans. It was noted that, on the rectal administration of the antigen, the edema at the sensitized site began to develop slowly. This reaction preceded the lighting up of the control site on the skin by as much as six minutes. With the appearance and development of the cutaneous reaction, the edema and erythema at the rectal site became more intense and rapidly reached its height. This sequence of events was the same when the entire meal was introduced in the rectum and when only a small amount

of it was applied on an applicator to the sensitized site. It suggested the probability that the amount of antigen in contact with the mucous membrane was not necessarily more important in determining the intensity of the reaction, than the amount that reached the sensitized site by way of the circulation. The fact that the local reaction did not reach its maximum until there were evidences of a general systemic dissemination of the antigen emphasizes the importance of this factor in the mechanism of food allergy symptoms in humans. It is quite evident, therefore, that in considering the mechanisms by which food or drugs may cause allergic manifestations, there are three possibilities to be considered: first, that symptoms may result from the direct intimate contact of the offending allergen with the sensitized mucous membrane; secondly, that the reaction of the sensitive mucous membrane may be the result of stimulation from an antigen which had been absorbed into the circulation from another part of the gastro-intestinal tract; and thirdly, that both mechanisms may be jointly involved. The fact that an antigen may cause disturbances of sensitive mucous membranes, locally and at a distance, within the period of a few minutes, may explain some of the bizarre and unusual clinical pictures which sometimes occur in food allergy.

CONCLUSIONS

1. The rectal mucous membrane can be passively and locally sensitized with human reagin-bearing sera.
2. The allergic reaction can be induced by either the oral or the rectal administration of the antigen.
3. The allergic reaction consists of edema, hyperemia, and increased mucous secretion.
4. Subjective symptoms, such as pruritis, burning, a sense of fullness, and a desire to empty the bowel, are commonly associated with the allergic reaction and vary with its location.
5. The allergic reaction in the sensitized mucous membrane of the gastro-intestinal tract may be induced by antigen which is in direct contact with it or by absorbed antigen which reaches it via the circulation or by both.

DISCUSSION

DR. ALBERT F. R. ANDRESEN (Brooklyn, N. Y.): This beautiful and very important presentation has demonstrated to us the nature of the reactions that take place in the gastro-intestinal tract in allergy. I think it is one of the most beautiful demonstrations that I have ever seen. It shows us that the reactions in the gastro-intestinal tract may be due not only to local contact with the food to which a patient has been sensitized, but that they are probably more frequently due to absorbed food antigen in the circulating blood. The rapidity with which absorption has taken place is one of the remarkable things demonstrated. Within twelve or fifteen minutes after ingestion, the reaction was noted at the rectum.

Some clinicians have doubted that pruritus ani could be due to food allergy, because the irritation occurred so soon after the food was taken, but we have been shown that direct absorption of the food protein, unchanged, takes place with great rapidity.

The rectal symptoms usually attributed to allergy, pruritus ani, and even actual ulceration, can easily be understood when we conceive of repeated insults to a rectal mucous membrane permanently sensitized, and we can easily understand how even severe conditions like ulcerative colitis are so frequently caused by a food allergy. On the other hand, bacterial allergy might be the explanation for similar phenomena occurring in the stomach as were shown by Dr. Crohn and Dr. Shwartzman in a previous paper today.

This paper is another very important contribution to the subject of food allergy and helps us to understand better what is going on in a sensitized individual.

I compliment the authors on what they have done.

DR. T. T. MACKIE (New York, N. Y.): I should like to echo Dr. Andresen in congratulating Dr. Gray and Dr. Walzer on the work which they have presented here this morning. We have had a good many reports in recent years in the clinical literature indicating the validity of so-called food allergy in the intestinal tract. This paper which has been presented this morning is one of a group of studies which Dr. Walzer and his associates have carried out, which present the first objective experimental evidence demonstrating the validity of the allergic mechanism in the intestine.

To be sure, it is passive sensitization, which is not the mechanism which would be involved in the production of symptoms in the human being. As yet no one has succeeded in producing active sensitization. It would appear, however, that this is merely a matter of time and of devising a satisfactory technic. This study and the others which fall in the same group, constitute definite proof that the intestinal tract, including the stomach and areas below, to the rectum, may properly be spoken of as a shock organ.

The implications of this work, I think, are very great, and again I should like to congratulate the authors.

DR. ARTHUR J. ATKINSON (Chicago, Ill.): I should like to substantiate Dr. Gray's observations. We have produced a similar phenomenon and acute ulcers in dogs in an exteriorized segment of the colon, by actively sensitizing dogs to various foreign proteins, by injecting these foreign proteins intravenously and subsequently injecting the same protein in an exteriorized segment of the colon.

In some of the dogs ulcers developed, but we could not make these ulcers chronic. They would heal in spite of subsequent injections. All the dogs did not show ulcerations although they did show the same type of phenomena that Dr. Gray had pointed out.

This work was done after Dr. Ivy had produced ulcers of this type in the stomachs of dogs by active sensitization.

DR. A. C. IVY (Chicago, Ill.): Mr. Chairman, there is one question which I have in mind which I should like to put to Dr. Gray and see whether he can answer it. It is: I obtained the impression that the sensitization he observed did not last very long, and desensitization resulted. That is exactly what we observed in the allergic ulcers we produced a number of years ago in the pyloric mucosa, and in the duodenal mucosa. Continued administration of the antigen produced desensitization. Now, if allergy plays an important role in the human being in the production of pruritus ani and of ulcers in the colon and stomach, I wonder why some sort of desensitization process does not occur and lead to the spontaneous relief of the condition.

DR. B. M. BERNSTEIN (Brooklyn, N. Y.): From the

point of view of desensitization, there are two cases I should like to report. One is that of a doctor, who had an ulcer for a number of years and suddenly found he had hay fever. During the time he was getting pollen injections, he had no pains of any kind. He then found that every time he had an upper respiratory infection, if he didn't take any pollen, he had pains; if he took pollen, he had no pains.

Another man only recently came into the office with recurrence of severe ulcer symptoms. For a number of years he had had recurrences only during the time he had upper respiratory infections. I was giving him nonspecific therapy. During the course of injections he had a severe upper respiratory infection and yet in spite of that, had no recurrence of symptoms.

I think these two cases show the desensitization phenomenon. We combine the Shwartzman phenomenon and the allergic factor at the same time.

DR. IRVING GRAY (Brooklyn, N. Y.) (closing the discussion): I wish to thank Drs. Andresen, Mackie, Atkinson, Ivy and Bernstein for their discussion of our presentation.

In our studies we have shown that the mucous membrane of the gastro-intestinal tract can be passively and locally sensitized. We have had the opportunity of presenting to you the phenomena associated with the local allergic reaction in the mucous membrane of the rectum, colon and ileum. While the clinical symptoms of gastro-intestinal allergy have been recognized we believe that this is the first time as stated by Dr. Andresen that edema and hyperemia of the human gastro-intestinal mucous membrane has been experimentally produced and demonstrated.

Dr. Mackie has been interested in the subject of active sensitization. This field of investigation in immunology has attracted the attention of many investigators but to date little has been accomplished. The work that Dr. Atkinson has cited in experimental studies on the colon of dogs is interesting but we have had no experience in this type of investigation.

Dr. Ivy has raised the question of desensitization. This subject has been widely studied by the allergists and I believe that it is the accepted opinion today that treatment directed toward specific hypersensitiveness as it occurs in hay fever or food hypersensitiveness may bring about improvement or cessation of objective symptoms by some alteration in the shock tissue. The fact remains that on the study of the blood serum after such successful treatment, the reagin antibody content remains essentially the same.

In our present communication we have called attention to the fact that after passive sensitization of the mucous membrane, administration of the antigen is followed by an allergic reaction which usually neutralized all the antibody at the site of the injection. It is pertinent at this time to point out that the reagin antibody is fixed in the tissues at the site of local injection and is not absorbed.

The allergic reaction which we have described in this presentation, as previously demonstrated by Dr. M. Walzer, is due to the absorption of the whole unaltered protein into the circulation and its reaction at the local site of sensitization. The recent experimental work on dogs by Alexander, Shirley and Allen conclusively proves that unaltered protein is absorbed into the general circulation by way of the lymphatics emptying into the thoracic duct. Those studies are important because they show that whole protein reaches the general circulation in not insignificant amounts without passing through the liver. The allergic reaction as described in our communication is brought about by the reaction in the passively sensitized tissues between the injected antibody and the related protein which has been ingested and absorbed in an unaltered state. Alterations in X-ray patterns of the stomach and colon following the administration of barium to which had been added the specific excitant in allergic individuals has been recently reported by Fries and Zismore of the Walzer clinic in their studies in allergic children.

We are hopeful that from all these various studies further progress in the field of gastro-intestinal allergy will be made.

Secondary Effects of Radiation Upon the Rectum Following the Treatment of Extrarectal Pelvic Lesions*

By

L. K. FERGUSON, M.D., F.A.C.S.†
PHILADELPHIA, PENNSYLVANIA

GREAT advances have been made in the treatment of malignancy of the uterus, prostate and bladder by the use of radium and cross fire roentgen-ray therapy. The action of these therapeutic agents, however, cannot always be confined to the organ involved in the malignant process. It is not surprising, therefore, that the irradiation should affect the rectum. The proximity and fixation of this structure in the pelvis has resulted not infrequently in secondary effects, which may be mistaken for an extension or recurrence of the malignancy, and in symptoms which may make the cure seem worse than the disease.

Buie and Malmgren (1), in 1930, reported a study of 65 patients after irradiation therapy in the pelvis. They described the lesions and the symptoms and outlined treatment by rectal irrigations and instillations. Jones (2) in 1932, again mentioned the rectal and bladder complications encountered in the treatment of carcinoma of the cervix. He spoke of two types of rectal complications, the early, characterized by frequency of defecation and tenesmus, and the late, which was often mistaken for a recurrence of the malignancy. In the later type, severe pain, tenesmus, and blood and mucus in the stools were prominent symptoms. He pointed out that digital examination was extremely painful, and that on proctoscopic inspection, ulcers, scars and telangiectases were noted in the rectum at the level of the cervix. Later, Jones and Collins (3, 4), reported 6 cases of stricture of the sigmoid and 1 of the small intestine after irradiation therapy of carcinoma of the uterus.

In 1935, Newell and Crossen (5) reported 5 cases

*Read at the Annual Meeting of American Gastro-Enterological Association, Atlantic City, June 7 and 8, 1937.

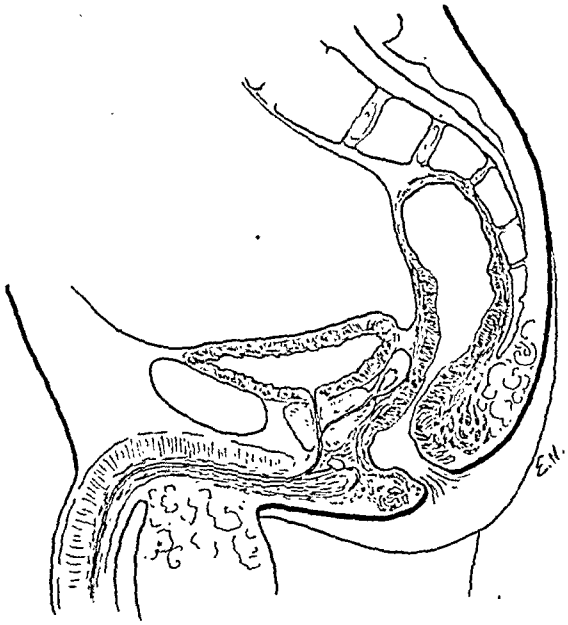

Fig. 1. Diagrammatic drawing showing the site of rectal stenosis following cross fire roentgen therapy for carcinoma of the prostate and bladder.

of rectal stricture after radium and roentgen irradiation for carcinoma of the cervix. The strictures appeared as long as 2 years after therapy and were all easily treated by dilatation. They state that they "have come to expect considerable rectal irritation in the effective irradiation treatment of carcinoma of the cervix, the rectal mucosa apparently being more susceptible to the effect than the bladder mucosa. Ordinarily the rectal irritation subsides after 2-3 weeks. In some instances, however, the rectal irritation progresses to ulceration and infiltration with subsequent stricture formation." Other authors have also mentioned the rectal disturbances associated with irradiation therapy for uterine cancer (6, 7).

David and Lauer (8), in 1932, reported a case of rectal stricture following irradiation treatment of carcinoma of the prostate and David (9) later reported on burns of the rectum following radium applications for carcinoma of the rectum and prostate. Bothe (10) mentioned variable bowel symptoms ranging from mild to severe diarrhea following roentgen therapy in cases of bladder tumors.

It is the purpose of this paper to describe the types of irradiation reaction observed in the rectum, to emphasize that they are not due to a recurrence or an extension of the malignancy, to detail their clinical course and to suggest methods of treatment.

IRRADIATION REACTION IN THE RECTUM FOLLOWING ROENTGEN IRRADIATION FOR CARCINOMA OF THE PROSTATE AND BLADDER

Two patients were observed following intense irradiation, one for carcinoma of the bladder and the other for carcinoma of the prostate. In both cases, several series of cross fire roentgen-ray treatment were given through multiple ports, both anteriorly and posteriorly. In both patients there developed a browny edema of the skin with pigmentation, and during the period of treatment there were intermittent attacks of diarrhea. The patient with bladder carcinoma began to develop intense tenesmus with the passage of blood and mucus about 6 months after his first treatment. When first seen 9 months later he had practically no control of his bowel movements. Similar symptoms appeared in the other patient, except that incontinence did not occur. Both were troubled by painful, almost prostrating spasms of the colon at the time of bowel movements, especially following bouts of temporary fecal impaction, at which times rectal bleeding and irritation became more marked.

The findings on examination were somewhat alike in both cases. Beginning about 5 cm. from the anal orifice, the rectum was narrowed to a diameter of about 1 cm. (Fig. 1). The introduction of the finger into the rectum, even with the utmost gentleness, was painful. The rectal wall felt uniformly thick and indurated but not woodeny hard. The stenosis was due to a contraction of the entire rectal wall. In the patient with the most severe symptoms, there was at first noted a longitudinal ulceration with a gray indolent base. The ulcer healed slowly during the period of several months' observation, and with its healing the marked tenesmus and fecal incontinence became less prominent. The mucosa of the other patient was pale and thin. This patient died of uremia due to a carci-

Fig. 2. Specimen following roentgen treatment for carcinoma of the prostate. Note the localized area of stenosis and thickening of the rectal wall in the lower rectum. Case 2.

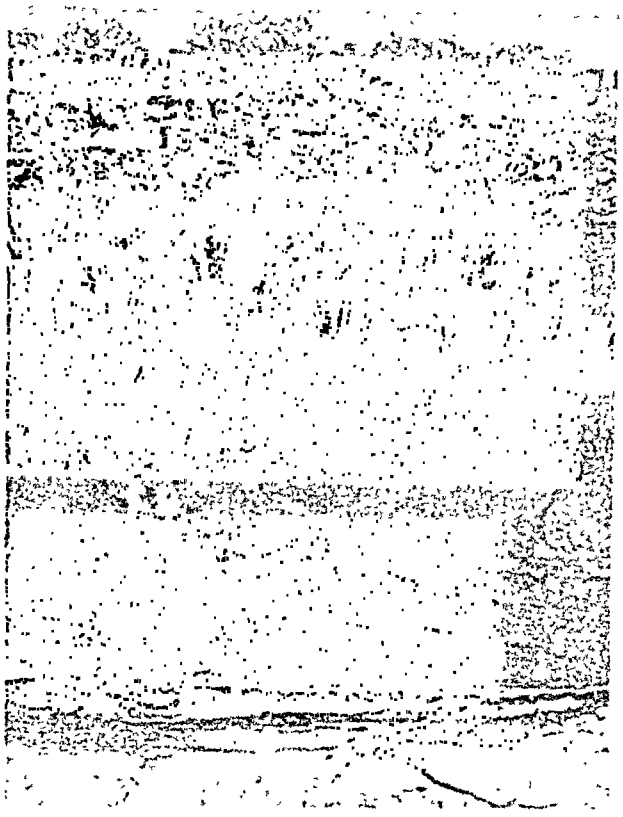

Fig. 3. Cross section of the rectum through the area of rectal stenosis, showing marked atrophy of the rectal mucosa with a slight degree of fibrosis in the sub-mucosa and muscularis. The chief thickness of the bowel wall and the probable cause of the stenosis is marked degeneration with swelling and edema in the muscular coats, especially the circular muscle. Case 2.

nomatous obstruction of the ureters. He was found to have a stenosis of the rectum about 5cm. long due to a marked thickening of the rectal wall involving its entire circumference; the rectum was not involved in the carcinomatous process. Sections of the gut at the stenotic area showed a marked atrophy of the mucosa and a relatively slight amount of fibrosis. The thickness of the rectal wall was largely due to a marked degeneration of the inner circular muscle with swelling of the muscle fibers and edema. The outer longitudinal layer showed definite hypertrophy (Figs. 2, 3, 4).

The symptoms of these patients can be easily understood when the lesion is once recognized. The ampulla of the rectum is practically obliterated by the rectal stenosis, making frequency of movements. The irritability of the rectum produces marked spasm of the bowel with excessive mucus secretion. Bleeding is due to the trauma of the stool passage through the stenotic area and over the intensely hyperemic and thickened bowel wall.

The treatment of these patients is difficult. In both cases colostomy was suggested as a method of relieving the distressing symptoms. Because of local recurrence this was refused. Improvement in the symptoms was obtained by the careful regulation of the diet, with the administration of mineral oil, bismuth subcarbonate and charcoal.

Case I. F. C. A., male, 64 years. In March, 1935, the patient developed hematuria. On cystoscopic examination, a papillomatous carcinoma of the bladder was found. He was given a series of roentgen ray treatments from April 4 to May 13, 1935, the dosage of which was not known to us.

Roentgen Irradiation: First series, begun June 8, 1935, when the patient was transferred to the University Hospital: 165 Kv, 15 Ma, with a thorneus filter equivalent to 2 mm. Cu. at 50 cm. T.S. distance. About 200 r were given through five 15 x 15 cm. portals, two iliac, two gluteal and one perineal. The patient received about 2000 r x 4, plus 1000 r into the perineum in 46 days.

Second series, begun October 8, 1935: the same physical factors were used. The patient received 2000 r x 5 in 60 days through portals as outlined above. In addition, two 8 x 10 cm. portals below the gluteal portals received 2000 r x 2 in 12 days. The last treatment was given on December 31, 1935.

October, 1935: The patient began to have urgency and frequency of bowel movements. In the spring of 1936, his rectal symptoms became much worse, with frequency of movements containing blood and mucus.

July 8, 1936: the remaining bladder tumor was removed by electrocoagulation.

September, 1936: patient examined for the first time; he had practically complete incontinence and constant urgency. The bowel wall was found to be thick and hyperemic. Along the lateral and anterior wall on the right side, there was a long narrow ulceration which had a grayish indolent base. Bleeding occurred on slightest trauma. The proctoscope could be advanced for about 10 cm. from the external orifice.

November, 1936: patient very much improved. On occasions he developed fecal impaction with marked spasm. The lumen was contracted to about 1 cm. at a point beginning about 6 cm. from the external orifice. The ulcera-

Fig. 4. Section from the rectum about two inches above the area of stenosis. The bowel wall is of normal thickness for comparison with Fig. 3. Case 2.

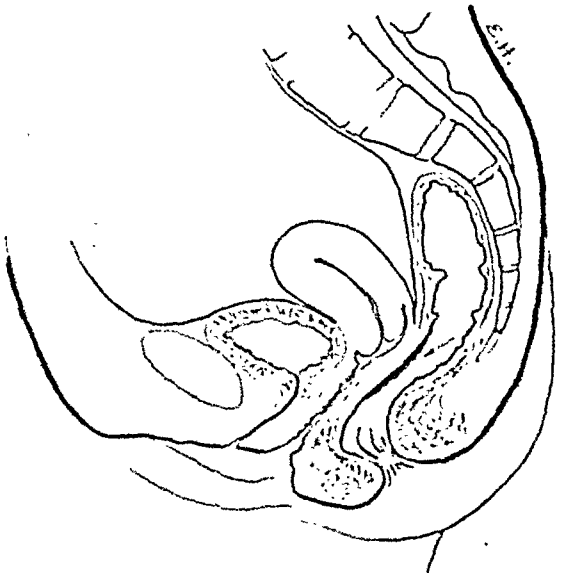

Fig. 5. Diagrammatic drawing to show site of localized proctitis following radium and roentgen irradiation for carcinoma of the cervix.

tion appeared to be covered with granulation tissue. The mucosa was red and thick and bled easily on slight trauma.

April, 1937: patient was having 8-10 bowel movements daily; and there was considerable blood and mucus in the stools, especially if the fecal material was formed. The bowel movements were associated with prostrating spasms of abdominal and pelvic pain. Examination showed definite annular stricture about 1 cm. in diameter and about 2 cm. long in the lower rectum. Colectomy was recommended but refused because of bladder recurrence.

Case II. M. J. M., male, 69 years. *Carcinoma of the prostate.*

Roentgen Therapy: First series, begun August 20, 1934: high voltage radiation, 165 Kv, 15 Ma, filters 0.5 cm. Cu. plus 2 mm. Al, 50 cm. T.S. distance. The radiation was directed through 4 portals measuring 15 x 15 cm., two iliac and two gluteal; 165 r were given per day. The patient received about 1650 r to each skin portal in 30 days.

Second series, begun December 21, 1934: the same physical factors were employed except that 2 mm. Cu. were used instead of 0.5 mm. About 2000 r were delivered in each of four portals in 33 days.

Third series, begun May 13, 1935: the same physical factors except a thoraeous filter equivalent was used instead of the 2 mm. Cu. The patient received 1500 r through a sacral portal and 2250 r through a peroneal portal in 11 days.

October 22, 1935: prostatic resection.

Fourth series, begun December 26, 1935: high voltage radiation using 200 Kv; all other factors as above. The patient was treated through one suprapubic and two gluteal portals, 2000 r being delivered through each portal in 21 days.

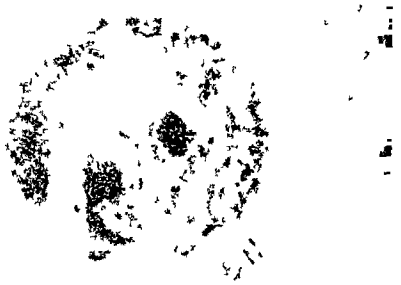
August 19, 1936: patient complained of marked tenesmus and rectal bleeding with bouts of constipation and extreme pelvic pain. On examination, the lower rectum was found to be contracted to a diameter of about 1 cm. The bowel wall was thick and indurated, the mucosa smooth and hyperemic. Capillary bleeding occurred on the slightest trauma.

April, 1937: gradual improvement with regulation of the diet. Still had recurrent attacks of fecal impaction with symptoms of intestinal obstruction. The mucosa was pale: the bowel constriction was still present.

April, 1937: death from pyonephrosis with complete block of the ureters by carcinoma. The rectum showed a definite area of stenosis about 5 cm. long; the lumen was contracted to about 1 cm. There was no involvement of the rectum by the carcinoma. The stenosis was due to a marked thickening and contracture of the bowel wall which was found on microscopic section to be due to a degeneration and edema of the inner circular muscle and a definite hypertrophy of the outer longitudinal muscle. The mucosa was atrophic; there was relatively little fibrosis in the bowel wall.

REACTIONS IN THE RECTUM FOLLOWING RADIUM AND ROENTGEN IRRADIATION FOR MALIGNANCY OF THE CERVIX AND UTERUS

Six patients have been observed with rectal lesions following radiation therapy for malignancy of the cervix and uterus. The usual treatment was the implantation of radium in the cervical canal and against the cervix and in a colpostat around the cervix, followed by cross fire roentgen irradiation through multiple ports, both anteriorly and posteriorly, in one to three series. Most of these patients developed temporary rectal irritation which subsided a few weeks after therapy. In five of the six cases there is no evidence of recurrence of the carcinoma.



The symptoms of the secondary irradiation reaction were similar in all cases, and appeared from 3 months to 2 years after the radium treatment. Diarrhea, rectal bleeding, rectal pain and tenesmus were the usual symptoms. The diarrhea was not of the usual type, but was characterized by one soft or formed movement in the morning followed by several liquid evacuations containing little fecal matter. There were often 8 to 10 stools per day. Bleeding from the rectum was the most alarming symptom to the patients. It appeared not only at the time of stool but there often followed, an hour or two later, an evacuation consisting largely of blood clots.

The findings on examination were of two types. The first type is characterized by a localized area of in-

Fig. 6. Biopsy from area of acute proctitis, Case 5. Note marked mucous degeneration of the rectal glands, round cell infiltration with hyperemia and edema of the tissue of the rectal wall.

tense hyperemia and swelling of the anterior rectal wall about 6-7 cm. long, corresponding to the position of the cervix (Figs. 5, 6). The rectal mucosa appears normal both above and below the area. Bleeding which was produced by the slightest trauma appeared to be a diffuse capillary hemorrhage and is so profuse as to obscure the field of examination and to produce clots in the rectal lumen.

Figs. 7 and 8. Ulceration of the rectal mucosa following radium and roentgen irradiation therapy for carcinoma of the cervix, Case 7. Note shallow ulcers with indurated base, 6 months after last roentgen treatment and 1 year after radium applications. Fig. 8: 3 months later; ulcers healed with scar formation and telangiectasis.

When observed over a period of 6-8 months, the swelling and hyperemia gradually decreases, and the rectal irritability gradually subsides. There is an exacerbation of the symptoms if the patient becomes constipated or strains at stool.

The second type of irradiation reaction is characterized in the same way by a localization of the rectal lesion to the anterior wall underneath the cervix. The mucous membrane is thin, pale, smooth and atrophic. It is marked by shallow ulcerations, the bases of which are dull gray in color, having much the appearance of a pseudomembrane (Figs. 7, 8). There is no heaping up of tissue at the edge of the ulcer. Dotted over the unwrinkled mucosa are numerous telangectatic vessels which seemed to lie almost on the surface of the bowel mucosa. From these vessels bleeding occurs in considerable amounts on the slightest trauma.

Two patients with radium ulcerations have been observed over a period of months. In both cases the ulcers have healed, in one patient in a period of 3 months, in the other in 10 months. Fibrous scars dotted with telangiectases have remained.

The treatment in these cases was designed to reduce to a minimum all irritation to the rectum. As experience was gained it was found that the irritability of the rectum gradually decreased and only bleeding remained as a prominent symptom. The use of a smooth diet with bismuth subcarbonate and powdered charcoal by mouth were found to be helpful. Mineral oil was given in quantities sufficient to keep the movements soft. Astringent and cleansing enemas were employed but were discontinued when it was found that the above course of therapy was successful.

Case III. E. H., female, 42 years. Carcinoma of the cervix, cervicofundal type. Supravaginal hysterectomy was performed March 12, 1936.

Radium Irradiation: March 30, 1936: 100 mg. radium in cervix with 1 mm. platinum and 2 mm. rubber for 24 hours. 100 mg. radium with 2 mm. platinum and 1 cm. rubber in colpostat intravaginally for 24 hours.

Roentgen Irradiation: High voltage radiation, 200 Kv, 15 Ma, 0.5 mm. Cu. and 2 mm. Al, 50 cm. T.S. distance employed. Radiation directed through 15 x 15 cm. portals, two iliac and two gluteal. The patient received about 300 r daily through 1 portal each day. About 1600 r was delivered in each of four portals in a period of 29 days ending on July 7, 1936.

During the X-ray treatments the patient began to have some rectal irritation and in July her stools became smaller in caliber. In September, she complained of frequent stools, 7-8 daily, often containing fresh blood or clots. On examination, there was an area of edema and hyperemia of the anterior rectal wall underneath the cervix. Oozing occurred from this area on the slightest trauma. There were no other rectal lesions.

November, 1936: patient complained of intense griping abdominal pains with 6 movements daily. Rectal bleeding less.

April, 1937: patient becoming weaker due to metastasis to the lungs. Bowel symptoms somewhat improved. A recto-vaginal fistula has developed.

Case IV. H. B. W., female, 52 years. Sarcoma of the cervix. Biopsy January 5, 1935.

Radium Irradiation: 100 mg. with 2 mm. platinum and 1 cm. rubber in the vagina in a colpostat for 21 hours.

Roentgen Therapy: First series, January 11 to February 8, 1935: high voltage radiation, 165 Kv, 15 Ma, 0.5 mm. Cu. plus 2 mm. Al. Four 15 x 15 cm. portals, two anterior and two posterior pelvic. 200 r per day; total of 1600 r in each of 4 portals.

Second series, April 8 to 20, 1935: same physical factors and 200 r per day; total of 1600 r in one anterior portal and 1600 r in each of two gluteal portals.

Third series, November 2 to 29, 1935: same physical

factors except a thoraeus filter equivalent to 2 mm. Cu. was used instead of the 0.5 mm. of Cu. 200 r per day; 2000 r to each of two iliac and two gluteal portals.

Fourth series, May 2 to 29, 1936: same physical factors except that 200 Kv. were used. 300 r given daily; 2000 r in each of two iliac and two gluteal portals.

Following the last series of X-rays the patient had rather marked cystitis with dysuria. This gradually cleared up.

October, 1936: patient first noted rectal bleeding which became more profuse. She often passed clots after her bowel movement. There was marked rectal tenesmus.

January, 1936: rectal symptoms as above. Examination showed a localized area of hyperemia and swelling in the anterior rectal wall underneath the cervix. Diffuse bleeding occurred from this area. There were no other proctoscopic findings. Diet regulation plus the use of mineral oil, bismuth subcarbonate and charcoal was the treatment recommended.

May, 1937: patient saw bleeding on irregular occasions. No clots noted. On examination, the area of hyperemia and edema was much less definite, although still easily demonstrated. Bleeding was easily induced by slight trauma.

Case V. J. S., female, 41 years. Dilatation and curettage with a diagnosis of functional uterine bleeding, January 12, 1935. Tissue obtained was diagnosed as "questionable malignancy."

Radium: 50 mg. with 1 mm. platinum and 2 mm. rubber inserted into the uterine cavity for 6 hours.

February 7, 1935: biopsy of the cervix.

Radium: 100 mg. with 1 mm. platinum and 2 mm. rubber at the cervix. 100 mm. radium with 2 mm. platinum and 1 cm. rubber in colpostat in the vagina for 24 hours.

Roentgen Irradiation: First series, begun March 13, 1935: high voltage radiation, 165 Kv, 15 Ma, 0.5 mm. Cu. plus 2 mm. Al, 50 cm. T.S. distance employed. Radiation directed through one 20 x 20 cm. anterior portal and two 15 x 15 cm. gluteal portals, treating one portal with 200 r daily. Total of 1600 r were delivered in each of the three portals in 22 days.

Second series, begun June 17, 1935: same physical factors as above. 200 r given daily, using one anterior and one posterior pelvic portal; 1600 r given to each portal in 18 days.

February, 1936: patient began to have rectal pain and bleeding. On examination, there was found a marked thickness of the rectovaginal septum. The rectum contained fresh blood and clots. On inspection of the rectal wall, there was marked hyperemia and swelling of the mucosa with diffuse oozing. Biopsy specimen removed from this area was reported as inflammatory tissue. There was no evidence of carcinoma. This patient continued to bleed from the bowel and was finally admitted to the medical ward for treatment of her secondary anemia.

October 26, 1936: an exploratory laparotomy was performed and no lesion of the large bowel was found to account for the bleeding.

March, 1937: patient still had occasional bleeding from the bowel. On inspection, the bleeding was seen to come from a localized area of the anterior rectal wall underneath the cervix. The hyperemia was less marked than noted before.

Case VI. L. P., female, 55 years. Carcinoma of the body of the uterus extending into the left broad ligament.

Roentgen Therapy, summer of 1932: 6 treatments, amount unknown.

Radium: September, 1932: 2400 mg. hours r into the uterus. March, 1933: 1200 mg. hours r into the uterus. July, 1934: 2400 mg. hours r into the uterus with 1 mm. platinum and 1 mm. rubber.

Roentgen Therapy: July 20, 1934: high voltage radiation, 165 Kv, 15 Ma, 0.5 mm. Cu. plus 2 mm. Al Filtration, 50 cm. T.S. distance employed. Through two iliac and two gluteal 15 x 15 cm. portals, 150 r were given daily until 1600 r was delivered in each of four portals during 27 days.

January, 1936: patient began to note bleeding from the bowel, usually not associated with the bowel movements which she had habitually in the morning but in the afternoon when the movement would consist of clots of blood with little or no feces. She was troubled frequently with abdominal distention.

April, 1936: proctoscopic examination showed the bowel wall thickened and the mucosa hyperemic along the sacral curve of the rectum about 10 cm. above the external orifice. The lumen was contracted to about half the normal diameter and bleeding occurred on slight trauma. Barium enema showed a lack of haustral markings indicating an irritable colon. The patient was advised as to regulation of diet and given charcoal, bismuth subcarbonate and a mild cathartic.

October, 1936: the patient had had very slight bleeding from the bowel occasionally. The lumen was much increased; hyperemia was less.

April, 1937: slight bleeding noted once or twice a month. No other symptoms; proctoscopic picture showed little change.

Case VII. J. R., female, 42 years. Carcinoma of the cervix involving the posterior lip.

Radium, May 16, 1935: 100 mg. radium filtered with 1 mm. platinum and 2 mm. rubber held with a stitch against the posterior lip of the cervix. 100 mg. radium filtered with 2 mm. platinum and 1 cm. rubber in colpostat in the vagina. Irradiation applied for 24 hours.

Roentgen Irradiation: First series, begun June 19, 1935: high voltage radiation, 165 Kv, 15 Ma, 0.5 mm. Cu. plus 2 mm. Al, 50 cm. T.S. distance employed. The patient was treated through two iliac and two gluteal 15 x 15 cm. portals. 200 r were given daily; a total of 1800 r was delivered in each of four portals during 35 days.

Second series, begun November 4, 1935: same physical factors using thoraeus filter instead of 0.5 mm. Cu. Same portals treated until 2000 r x 4 were delivered in 43 days.

April, 1936: the patient developed marked diarrhea with 10-12 movements daily.

May, 1936: the diarrhea was associated with marked bleeding and passage of clots.

June, 1936: diarrhea and bleeding continued with increasing tenesmus and soreness and burning in the rectum after movements. On examination, in the anterior rectal wall underneath the cervix the mucosa was pale and thin and was dotted with several small sharply defined ulcers. Telangiectatic vessels were seen on the surface of the mucosa. The rectum elsewhere appeared normal except for a slight paleness of the mucosa. Barium enema showed irritability of the colon, especially of the rectum and sigmoid. A smooth diet was prescribed for the patient, and mineral oil, bismuth, subcarbonate and charcoal were given.

August, 1936: patient had only occasional slight bleeding. She noticed considerable tenesmus if she ate fruits and other rough foods. The ulcers of the bowel wall now practically healed with definite linear scars. Telangiectatic vessels were numerous.

November, 1936: patient noted only a few drops of blood with bowel movements occasionally. She had no symptoms if she remained on a smooth diet. The ulcers entirely healed but the scars were still visible. Telangiectasis was marked.

Case VIII. A. U., female, 60 years. Epithelioma of cervix involving cervix, posterior vaginal wall and both parametria.

Radium, January 20, 1933: 50 mg. radium with 1 mm. platinum and 1 mm. rubber sutured across the cervix. 100 mg. radium with 2 mm. platinum and 1 cm. rubber in

colpostat in vagina on each side of the cervix. Irradiation for 21 hours.

Roentgen Therapy: First series, begun December 18, 1933: high voltage radiation, 165 Kv, 15 Ma, 0.5 mm. Cu. plus 2 mm. Al, 50 cm. T.S. distance employed. The patient was treated through two iliac and two gluteal 15 x 15 cm. portals. About 150 r were given daily until 1800 r were delivered in each portal during 30 days.

Second series, begun March 10, 1934: same physical factors. One 20 x 20 cm. anterior portal and two 15 x 15 cm. gluteal portals employed; 1600 r were given in each portal during 28 days.

January, 1935: patient began to have 8-10 movements daily, with marked tenesmus. There was some bleeding from the bowel but the patient was more troubled by the passage of clots some hours after a normal bowel movement.

April, 1935: the same symptoms continued. On examination, the lumen of the bowel was filled with dark blood and clots. The bleeding appeared to come from a localized area on the anterior rectal wall. In this area the mucosa was thin and atrophic. There were several small shallow ulcerations. Barium enema showed nothing except slight irritability of the lower bowel. The patient was instructed as to regulation of the diet and given mineral oil, bismuth subcarbonate and charcoal.

August, 1935: the bleeding had continued but was much less than before. The rectal irritability had disappeared. The ulcers were healing and multiple telangiectatic vessels were seen in the thin mucosa.

February, 1936: bleeding only on rare occasions when the patient was constipated. The ulcers were entirely healed. Telangiectatic vessels were more marked in the mucosa.

May, 1937: patient still noted an occasional show of blood if rough foods were eaten. No other symptoms: the bowel ulcerations were completely healed.

DISCUSSION AND SUMMARY

From a study of these cases, several points of interest to the gastro-enterologist and the proctologist may be noted.

1. Irradiation therapy for malignancy of pelvic organs may produce marked secondary effects in the rectum.

2. The rectal lesions produced by intensive cross fire roentgen irradiation are characterized by a progressive constriction of the bowel lumen. The reaction appears to involve all of the layers of the rectal wall. The mucosa may show the intense hyperemia and ulceration of an acute proctitis or may later become thin and atrophic. The symptomatology is due to a combination of marked irritability and stenosis of the rectum, producing tenesmus and frequency of movements, mucus and blood in the stools, spasms of rectal and abdominal pain and bouts of fecal impaction above the rectal stricture.

3. The rectal lesions found after radium and roentgen treatment of malignancy of the cervix are probably largely due to the radium irradiation. The lesion is confined to a well-defined area of the anterior rectal wall beneath the cervix, and varies from an intense hyperemia of the mucosa, with swelling of the rectal wall, to a marked mucosal atrophy, with ulcerations and telangiectases. The symptoms of the acute phase of the irradiation reaction are those of an intense proctitis with frequency of movements, tenesmus, burning pain in the rectum and profuse bleeding during and after movements. As the reaction subsides, the symptoms decrease until occasional bleeding from trauma to telangiectatic vessels is the only remaining complaint.

4. The symptoms of the secondary irradiation in the rectum may not appear for 3-18 months after the last irradiation treatment.

5. The irradiation reaction tends to subside spontaneously if irradiation therapy is discontinued.

6. The treatment of most benefit is one in which trauma to the area of reaction is prevented by insuring soft and non-irritating fecal discharges. In patients with a rectal stenosis, rectal dilatation or colostomy should be considered.

7. It is important to remember the possibility of these reactions. The diagnosis can readily be made on the basis of the history and the proctoscopic findings.

8. The irradiation reaction should not be mistaken for an extension or recurrence of the malignant process.

I wish to thank Drs. Floyd E. Keene, Eugene P. Pendergrass, T. Grier Miller and Albert E. Bothe for the privilege of seeing and reporting their cases.

DISCUSSION

DR. JEROME M. LYNCH (New York, N. Y.): This very interesting paper of Dr. Ferguson's illustrates something, the fact that I think the patients who are having surgical irradiation should be told what they may expect.

I know of two very prominent medical men who recently told me their mothers had had cervical irradiation and they were sure, from the suffering they underwent, they would have preferred surgery even though it wasn't as curative as radiation.

Radiation appears to be the accepted method of treating cervical carcinomata. The percentages of five-year cures are larger than with surgical extirpation, we are told; however, there is another side to the picture. Experts admit that distressing and painful sequelae frequently occur in neighboring organs. It is with these mishaps that we are forced to cope.

Let us, therefore, consider their origin. Some are due to faulty technic or overdosage but most are the inevitable result of a radium barrage sufficiently powerful to destroy the growth. That is to say, the radiologist has fully considered the damage to neighboring viscera which must result from an adequate radiation of the tumor and has felt that its destruction more than compensates for their impairment. Throughout the world search for the happy medium continues but progress is distressingly slow.

The effects of radiation are the same throughout the body. Smaller doses stimulate and larger ones destroy. Certain cells are more radiosensitive than others; that is, more easily stimulated or destroyed. It is on this basis that the treatment of carcinoma by radiation rests. The more embryological or undifferentiated a cell is, the more

radiosensitive. Hence, in Utopia it will be possible to deliver a barrage sufficient to destroy malignant cells without even stimulating physiology, but here we must accept stimulation of normal tissues in varying degrees.

The immediate result of stimulating tissue is to produce an active hyperemia. In the rectum this may disclose itself by symptoms varying from a feeling of fullness in the ampulla to an actual extravasation of blood. Hemorrhoids, if present, may evince symptoms, and thromboses are frequent, but this is transient and rarely necessitates treatment.

The second state occurs when the stimulation is removed. The pendulum swings the other way. Hypoemia supervenes. The vessels exhibit endarteritis, which appears to be progressive throughout the life of the patient. The resultant poor blood supply causes the tissues to undergo fibrous degeneration. This may continue to stricture formation, and I think very often does.

These structures were the first signs to call our attention to the sequelae of cervical radiation upon the lower bowel. We regret to say that we have had to perform abdominal colostomies upon several patients for this condition, that is, stricture, and Dr. Ferguson spoke of dilatation. That is a very dangerous procedure because, as you know, the bowel always ruptures in the long axis of the gut and you never can tell when you are overdilating, and a colectomy is inevitable, after all, and might as well be done in the first place.

As surgeons of the lower bowel, it is not our province to discuss the treatment of cervical cancer, but our duty to point to the all too frequent reaction of cervical radiation on the rectum. I have on several occasions had to remove the rectum, though we knew it wasn't recurrence of the carcinoma but was done to relieve the pain, and it did that, and we have had to do this also after radiation in rectal cancer.

DR. JAMES T. PILCHER (Brooklyn, N. Y.): You will appreciate the fact that Dr. Ferguson has again given us the pleasure of listening to a very practical presentation of a very difficult subject.

I have had several instances of this complication occur and they are certainly most troublesome in their treatment, and I think if nothing else is brought to our attention by this very excellent presentation, it is the universal use and indiscriminate application of radium, which is so easily purchased from commercial laboratories and employed and utilized by men who know absolutely nothing about the complications and sequelae that may follow its improper application, without a proper attempt to guard against the direct ray on the anterior wall of the rectum.

I agree both with Dr. Ferguson and Dr. Lynch relative to the subsequent treatment in that primarily one should perform a colostomy. Do not wait. You have got to perform it anyhow eventually, and in many of these cases where the lesion has proceeded to a condition of sclerosis, you will have to remove the rectum, which is the only way that this intolerable distress can be controlled.

DR. ROBERT ELMAN (St. Louis, Mo.): I wish to report on one patient who several months after pelvic radiation developed manifestations of acute intestinal obstruction with marked abdominal distention and inability to pass stool. Characteristic rectal changes were observed but there was also definite occlusion due to the inflammatory process; however, with conservative non-operative therapy, continuous gastric suction, nothing by mouth, and enemas, the acute obstruction subsided and, in accordance with the experience of Dr. Ferguson, the acute inflammatory lesion subsided.

DR. V. C. ROWLAND (Cleveland, Ohio): I should like to ask if the speaker has had any cases of gas bacillus infection that seemed to have gained entrance through the irradiated uterus.

I had an autopsied case in which edema developed over the pubes and hypogastrium one year after apparent cure of carcinoma of the uterus by radium. This edema was present about two weeks when X-ray treatments were given on the suspicion of recurrence of carcinoma. There was a rapid generalization of the gas bacillus infection and at autopsy cultures were positive and typical gas cavities in the brain and elsewhere were demonstrated. There was severe proctitis with edematous swelling throughout the pelvis but absolutely no evidence histologically of carcinoma. The pathological opinion at the time was that the local lesions had provided an antrium of infection to the gas bacillus.

DR. J. ARNOLD BARGEN (Rochester, Minn.): I think Dr. Ferguson should be congratulated for bringing this important subject to our attention and that the Committee and Council should be congratulated for offering him the prize for this well presented paper.

Fortunately, these lesions are not common but they often present a very distressing situation.

At the clinic, we occasionally see patients who present such a characteristic picture that we have been designating the disease as "factitial" proctitis and colitis. When we speak of a factitial lesion, we are thinking of a lesion which occurred after irradiation therapy.

The important points about the diagnosis is the situation of the lesion and its very characteristic appearance. Telangiectasia about the lesion is very striking. Differentiation of this lesion and other conditions, particularly neoplasms, is important. The diffuse involvement brings up the consideration of other hyperplastic lesions.

I have seen these lesions remain the same for several years; then they gradually cleared up and left a peculiar tissue-paper-like stellate scar. The lesions appeared on the anterior wall of the rectum, opposite the point where the radium had been applied.

We have also seen a less advanced lesion, following roentgenologic treatment.

Every once in a while, following deep roentgen therapy, patients have diarrhea which is difficult to control. It is probably a phase of the same type of difficulty as the factitial proctitis. In some cases there may be no visible lesions at all, but an intractable diarrhea may persist for weeks and sometimes for months. Symptomatic treatment will usually suffice.

DR. L. K. FERGUSON (Philadelphia, Pa.) (closing the discussion): I want to thank Drs. Lynch, Bargen, Pilcher, Elman and Rowland, for their discussion of this paper.

With regard to the dilatation which Dr. Lynch mentioned and did not feel was justifiable, I can only say that I have had no experience with dilatation of these strictures. Newell and Crosson stated that in five of their cases they were able to overcome the rectal obstruction by dilatation without the necessity for colostomy. As a matter of fact, in the cases I have seen with stricture, colostomy was indicated in both cases but on account of recurrence, it was not insisted upon. One case has already died, and the other, I think, is going to die.

As far as gas bacillus infection is concerned, I have never seen any cases in which the ulcers have been infected by gas bacillus.

Deficiency States Associated with Gastro-Intestinal Disease*

By

DWIGHT L. WILBUR, M.D.

and

ALBERT M. SNELL, M.D.†

ROCHESTER, MINNESOTA

IN spite of the widespread publicity given to vitamins and deficiency diseases in both the medical and lay press it is not apparent that such clearly recognizable forms of deficiency as beriberi, pellagra, scurvy and xerophthalmia are encountered now with greater frequency than in the past. Even as a result of the economic hardships recently suffered by large sections of the population there has not been a material increase in the incidence of full-blown vitamin deficiency states, at least in the north central portion of this country. However, extensive researches resulting in increased knowledge of the chemical and physiologic activities of some of the vitamins have provided laboratory methods of study which, along with clinical observations, have permitted recognition of early and preclinical states of partial deficiency with increasing frequency.

Such studies have indicated clearly that an abnormal diet is not the only factor responsible for the development of a deficiency disease in an otherwise healthy individual. Other significant predisposing factors include an increased requirement for vitamins during periods of rapid growth and increased metabolism, in pregnancy, or in infectious and toxic states; and altered metabolism with respect to a particular vitamin. It is the purpose of this paper to consider another factor, namely, the relation of impaired or altered gastro-intestinal function to the development of deficiency syndromes. So far as our experience at the clinic is concerned, gastro-intestinal disease is the condition most commonly present as an etiologic factor and one which may be operative without respect to the adequacy of the diet.

Since the gastro-intestinal tract is primarily concerned with the digestion and absorption of food, and therefore with the general nutritive state of the individual, it seems quite obvious that a close relationship should exist between alterations in gastro-intestinal function and the occurrence of a deficiency state. In fact, the relationship may be a reciprocal one, for abnormalities in gastro-intestinal structure and function may be the outstanding feature of a deficiency state, not only in the experimental animal, but also in man. For some years there have been reports, such as that of Eusterman and O'Leary, in which pellagra was reported to be associated with and apparently secondary to lesions involving the gastro-intestinal organs. Three years ago Strauss aroused much interest among those especially concerned with gastro-intestinal and nutritional problems by calling attention to the rôle of the gastro-intestinal tract in the conditioning of deficiency diseases and by collecting a variety of illustrative cases from the literature.

Analysis of the means by which alterations in gastro-intestinal function may set the stage for the development of deficiency states reveals a rather large number of mechanisms which differ widely in character. This obviously is to be expected because of the large variety of conditions which may significantly influence gastro-intestinal function and thus lead eventually to an insufficiency or deficiency of an essential substance which the tissues under normal conditions obtain from food. We have attempted a classification of the alterations in digestive function which may predispose to the development of deficiency states, and we will cite cases illustrating some of the various mechanisms involved (Table I).

In presenting a classification it should be emphasized that in some cases it is difficult to evaluate clearly the various etiologic factors involved and to establish definitely the rôle which the gastro-intestinal tract plays in the development of the deficiency state. In some instances the condition may depend only in part, or perhaps not at all, on the associated gastro-intestinal abnormality, the relationship being entirely coincidental. Experience indicates that, fundamentally, the most significant rôles of the gastro-intestinal tract in predisposing to or conditioning deficiency disease have to do with an inadequate intake of food, loss of essential secretions or of food itself, a lack or decreased production of essential endogenous substances, inadequate intestinal absorption and, perhaps, impaired metabolic activity of certain of the digestive organs.

INADEQUATE INTAKE OF FOOD

An inadequate intake of food is usually taken to be the most common cause of a deficiency state. Beriberi, scurvy, pellagra and xerophthalmia, which have occurred so frequently in the past and which are still observed in the Orient but not commonly in this country, are clear-cut examples of the results which follow a long continued inadequate diet.

Economic difficulties, eccentricities, faddism, ignorance, and chronic alcoholism.—These are in this country the commonest causes of an inadequate diet, and clinicians should be on the lookout for deficiency diseases, particularly among patients who may be handicapped in one of these ways. Excellent examples of these conditions are: the multiple neuritis of chronic alcoholics; the occurrence of nutritional abnormalities due to self-managed, weight-reduction diets, which are inadequate in many respects and followed because of fads and ignorance of nutritional requirements; and beriberi following eccentricities of diet, such as occurred in a case we recently observed and in the one reported by Kepler.

Diseases with anorexia, dysphagia, dyspepsia, and pain.—Attention should also be called to those patients

*Read at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7-8, 1937.

†Division of Medicine, The Mayo Clinic.

who, because of some gastro-intestinal complaint, have voluntarily adopted an eccentric diet. Any disease which leads to anorexia, dysphagia, dyspepsia, or pain (particularly when in the abdomen), *may result in a* deficiency disease caused by an inadequate intake of food. This is well illustrated by the following case:

Case 1. Benign esophageal stricture, from ingestion of lye, followed by pellagra (inadequate intake of food). A woman, aged thirty-three years, four months previously had drunk concentrated lye with suicidal intent. She was thereafter able to swallow only small quantities of liquids because of the development of an esophageal stricture. She was markedly emaciated and had lost 44 pounds (20 kg.). The lesions on her hands and face were characteristic of pellagra. During the course of the disease, diarrhea and dementia developed and a fatal bronchopneumonia ensued. Postmortem examination revealed marked cicatricial narrowing of the esophagus.

TABLE 1

Deficiency states associated with various types of gastro-intestinal lesions

Type of Lesion	Deficiency State	Cases
Esophageal stricture (lye)	Pellagra	1
Gastric carcinoma	Pellagra	4
Gastric ulcer	Pellagra	1
Gastric ulcer	Osteoporosis and nutritional edema	1
Gastric syphilis	Pellagra	1
Malfunctioning gastro-enterostomy	Pellagra	1
Malfunctioning gastro-enterostomy	Pellagra and neuritis	1
Bicornal stomach	Macrocytic anemia	1
Duodenal ulcer with obstruction	Pellagra	3
Obstruction of second portion of duodenum	Pellagra	1
Occlusion of duodenum (with ulcerative colitis)	Pellagra and beriberi	1
Cirrhosis of liver (and fibrosis of pancreas)	Pellagra	1
Biliary fistula	Pellagra	1
Extensive metastasis in liver (?); carcinoma; source?	Pellagra	1
Obstructive jaundice	Multiple neuritis	1
Carcinoma of pancreas (with duodenal obstruction)	Pellagra	1
Carcinoma of pancreas	Sprue	1
Calculous pancreatitis	Sprue	1
Acute pancreatitis (with duodenal ulcer and obstruction)	Beriberi	1
Diffuse chronic pancreatitis	Sprue and pellagra	1
Malfunctioning ileac stoma	Pellagra	1
Malfunctioning jejunal stoma (inadequate feeding)	Pellagra	1
Chronic ulcerative colitis	Pellagra	4
Chronic ulcerative colitis	Pellagra and vitamin A deficiency	1
Chronic ulcerative colitis	Pellagra and neuritis	1
Carcinoma of sigmoid	Pellagra	1
Carcinoma of descending colon (with fistula into small bowel)	Pellagra	1
Associated colitis (gastro-enterostomy for duodenal ulcer)	Pellagra	1
Polyposis	Nutritional edema	1

So far as we are able to determine, this is the only clear-cut vitamin deficiency disease due to an esophageal lesion which has been reported in the literature.

Therapeutic dietary inadequacy.—Of much importance from the practical standpoint is the possibility that a diet prescribed by a physician in the treatment of a gastro-intestinal or other disease may be inadequate in essential substances. The frequency with which limited diets are prescribed because of allergic conditions, and such chronic diseases as peptic ulcer, ulcerative colitis, nephritis, and cardiac disease, make possible the development of deficiency states among individuals affected with these diseases who continue on such diets over long periods of time. We have recently observed a case in which pellagra developed following a year's adherence to an elimination diet in an attempt to relieve hay fever and asthma. The occurrence of scurvy among patients receiving dietary treatment for duodenal ulcer, while something of a rarity, is another example of this type of dietary inadequacy. The following case illustrates very effectively the necessity for care in dietary management, particularly for those patients who for various reasons must follow a restricted diet:

Case 2. Bleeding leiomyoma of the stomach; jejunostomy for feeding followed by pellagra. A woman, aged forty-six, had a bleeding leiomyoma of the stomach which could not be removed surgically. Jejunostomy was performed for purposes of feeding and, after three months on jejunal feedings, there developed stomatitis, diarrhea, and characteristic early pellagrous lesions of the hands. On the addition of brewer's yeast, meat and meat juice to the jejunal feedings, the patient gained 15 pounds (6.8 kg.) in six weeks and the oral and cutaneous lesions disappeared.

LOSS OF ESSENTIAL SECRETIONS OR OF FOOD

The second type of gastro-intestinal disturbance which may lead to deficiency disease is loss of essential secretions or of food even though the diet given is adequate in respect to vitamins. Such loss may occur as a result of vomiting, diarrhea, or because of the presence of an external fistula. The peripheral neuritis which accompanies the vomiting of pregnancy, or which may sometimes develop postoperatively, is at least in part the result of loss of food by emesis and a reduced intake of food. An inadequate supply of, or an increased demand for vitamin B_1, such as may occur in pregnancy, may be contributing factors also:

Case 3. Vomiting of pregnancy with polyneuritis* (loss of essential secretions and food). A woman, aged twenty-six, was three months pregnant at the time of admission to the clinic. She had vomited almost daily for ten weeks and had lost about 50 pounds (22.7 kg.). She originally weighed 200 pounds (90.7 kg.). She was drowsy and confused and had visual hallucinations. Examination revealed a mild peripheral neuritis, nystagmus, limitation in ocular rotation and retinal hemorrhages. Ten days later, following an adequate intake of food, vitamin B_1, liver extract and yeast, all of these symptoms had practically disappeared.

Loss of essential substances or food may also occur as a result of diarrhea. Although the characteristic

*Previously reported by Randall and Wagener.

dehydration incidental to loss of fluid and electrolytes during episodes of diarrhea, recently studied by Wakefield and his associates (16), is well known, actual deficiency syndromes are considerably less familiar. Keefer has described a macrocytic anemia, resembling pernicious anemia, in chronic bacillary dysentery, and Boyce and Padget have reported cases in which pellagra was associated with the diarrhea of rectal disease. The rapid changes in the electrolyte content of the blood, which may occur following the establishment of a pancreatic, gastric, or duodenal fistula with loss of these secretions, are actually part of a deficiency state. Similar conditions may also result from loss of food and secretions from an intestinal fistula, as is illustrated in the following case:

Case 4. External ileal fistula with pellagra (loss of feces). A woman, aged twenty-six, came to the clinic with a fistula of the small intestine of nine months' duration which had developed following drainage of an abdominal abscess. The diet had been adequate, at least during the preceding four months. She had lost 37 pounds (16.8 kg.) from an original weight of 115 pounds (52.1 kg.). Lesions characteristic of pellagra were present on her hands. It was estimated that at least half of the intestinal content had been lost through the fistula.

LACK OR DECREASED PRODUCTION OF ESSENTIAL ENDOGENOUS SUBSTANCES

Just as loss of essential dietary substances or food may lead to the development of a deficiency disease, so also may a lack or decreased production of essential endogenous substances produce a similar effect. The importance of this feature in the etiologic consideration of a particular case is, however, much more difficult to evaluate than are some of the factors previously discussed. Nevertheless, the essential rôle of the stomach, liver, pancreas, and small intestine in maintaining a state of normal nutrition has already been established.

Stomach.—A lack or decreased production of the intrinsic factor of Castle by the gastric mucosa may lead to the development of pernicious anemia, now classed by many as a deficiency disease. The following case illustrates very graphically the effect of the apparent lack of this intrinsic factor following resection of the stomach:

Case 5. Gastric resection followed by macrocytic anemia* (lack of intrinsic hematopoietic factor). A woman, aged forty-eight, on admission to the clinic had gastric carcinoma, achlorhydria, and macrocytic hypochromic anemia. Hemoglobin was 50 per cent and erythrocytes numbered 3,600,000 per cubic millimeter of blood. Eleven months after gastric resection the patient returned complaining of stomatitis. At this time the hemoglobin was 54 per cent and erythrocytes numbered 2,600,000 per cubic millimeter. Smears of the blood revealed marked macrocytosis with normochromasia and a right shift of the neutrophils. There was prompt improvement of the blood picture following the administration of liver extract parenterally.

Lack of secretion of hydrochloric acid frequently results in hypochromic or nutritional anemia due to a deficiency in the absorption of iron. There is experimental evidence to suggest that lack of hydrochloric acid may interfere considerably with the absorption of vitamins B, C, and G (B_2) and, as a result of this, or because of excessive destruction of the vitamin, achlorhydria may be a significant predisposing factor in the development of a deficiency state.

Liver.—The influence which the liver may play under these circumstances is best illustrated by those conditions in which there is a loss of bile through a biliary fistula or when bile fails to reach the duodenum in adequate quantities because of congenital atresia or other obstruction to the common duct. Aldrich has recently reported observations of eleven infants in whom the bile duct was found at postmortem to be congenitally atretic. Despite an adequate diet and although clinical evidence of vitamin A deficiency was lacking, the livers of six of the eleven showed microscopic changes similar to those described in vitamin A deficiency by Widdicombe and Howe. We have observed a case of pellagra in association with an external biliary fistula, and McVicar, in 1925, reported a case of peripheral pruritis in which long-continued obstruction of the jaundiced duct to stones in the common duct proved to be the only significant predisposing factor. Recent interest in disturbances in coagulation of the blood of patients with jaundice has been directed toward the possibility of reduction in prothrombin content of the blood as a result of deficiency of certain factors, namely, vitamins C and K. Failure of bile to enter the duodenum may be a possible etiologic factor in such a deficiency, since vitamin K, which is fat soluble, and also vitamin C, may depend in part at least on the presence of bile for absorption.

Pancreas.—The failure of pancreatic juice to enter the duodenum must be an important factor in predisposing to a deficiency state, as is illustrated by the cases we have observed in which pancreatic atrophy, lithiasis, or carcinoma were present:

Case 6. Pancreatic lithiasis with pancreatic insufficiency simulating sprue* (lack of essential constituent; inadequate absorption of fat). A man, aged sixty-five years, complained of diarrhea of four years' duration. His stools were frequent, voluminous and greasy; he was cachectic, and had diabetes mellitus. He had lost 60 pounds (27.2 kg.). His tongue was reddened and its appearance was characteristic of that seen in sprue. Examination of the blood revealed the hemoglobin to be normal; the serum protein was reduced (5.1 gm. per 100 c.c.). Roentgenograms of the stomach, intestines, and colon were negative; that of the pancreas showed multiple areas of calcification. Examination of the duodenal content on two occasions failed to reveal any pancreatic ferments whatever. The fat content of the stool was 21.8 per cent by weight. Careful dietary and medical management did not check the diarrhea or loss of weight, but the patient finally improved remarkably on pancreatic extract. His tongue resumed its normal appearance and most of the lost weight was regained.

Small intestine.—Failure of the small intestine to secrete juice containing adequate amounts of enzymes may be a contributing factor in predisposing to a deficiency disease. In such a case as Case 8 it seems quite likely that the diffuse inflammatory and atrophic change in the stomach and small intestine leading to lack of secretion of certain enzymes may have been a

*Previously reported by Heck and Walters.

*In referring to sprue in this paper, we have reference to a clinical syndrome characterized by stomatitis, fatty stools, emaciation, and disturbances in the metabolism of calcium, with hypocalcemia, osteoporosis, and at times there is also tetany. Hypoproteinemia and edema and frequently macrocytic hypochromic anemia may also be present. This syndrome we have seen in connection with extensive atrophy of the intestinal mucosa, pancreatic insufficiency from carcinoma and atrophy, enterocolic fistula, and in association with tuberculosis of the lymph nodes.

significant factor, along with failure of absorption, in producing the clinical picture of sprue and pellagra.

INADEQUATE INTESTINAL ABSORPTION

The importance of bile, hydrochloric acid, and pancreatic juice in facilitating intestinal absorption and the rôle which the absence of these substances may play in the development of deficiency states has already been emphasized. However, of perhaps equal importance are those changes which may involve the intestine directly and interfere with absorption. Obstruction, atrophy, or other mucosal disease, or short circuiting between loops of intestine or the stomach and colon, are specific changes which may significantly interfere with absorption.

Obstructing lesions.—Many clinicians have observed cases in which obstructing lesions in the stomach or duodenum have led to the development of secondary pellagra. Two of our patients with malfunctioning gastro-enteric anastomoses had pellagra, and one in addition had peripheral neuritis. In three cases of duodenal ulcer with obstruction and in one of cicatricial obstruction of the second portion of the duodenum pellagra was present, whereas in another case duodenal ulcer with obstruction led to the development of a clinical picture of beriberi. In these cases probably other factors, such as reduced intake of food and vomiting, may have hastened the development of the deficiency state, but inadequate absorption as a result of the obstructing lesion and interference with the normal passage of the gastro-intestinal contents were also potent factors.

Case 7. Duodenal ulcer with obstruction and pellagra (inadequate absorption). A man, aged sixty-four, came to the clinic because of attacks of abdominal pain of four or five years' duration. For six months this pain had been associated with periodic vomiting of retained food. There was a characteristic gauntlet-type of pellagrous lesion of the hands and wrists, increasing mental depression and an unexplained diarrhea. Roentgenologic studies revealed duodenal ulcer with obstruction, a finding which was confirmed at operation.

In this connection it is interesting to note that Faber and Meulengracht have reported cases of intestinal stricture with pernicious anemia; failure of absorption of adequate amounts of hematopoietic factor because of the intestinal stricture was considered the underlying predisposing cause by these authors.

Atrophy or disease of the intestine.—It seems quite clear that atrophy or diffuse inflammation of the mucosa of the intestine might seriously interfere with the absorption of adequate amounts of essential nutrient materials from the intestine. Many of the changes accompanying sprue have been explained on the basis of some such failure of absorption. We have omitted from discussion most of the cases of sprue which have been seen at the clinic and reported by one of us (Snell) in which the principal gastro-intestinal changes were demonstrated roentgenologically to be in the small intestine and pathologically to consist of atrophy of the mucosa. The following case, in which diffuse gastro-enteritis seemed to be the only reasonable explanation for the deficiency states which were present, illustrates the effect of diffuse changes in the mucosa in the development of such conditions:

Case 8. Diffuse gastro-enteritis with pellagra and sprue (mechanism of deficiency uncertain; lack of essential secretion? failure of absorption?). A man, aged thirty-seven, had intermittent diarrhea fifteen months before his admission to the clinic. His stools were profuse, frequent, and of the fatty type. On examination, emaciation and dehydration were outstanding, the patient's weight being 82½ pounds (37.4 kg.). His tongue was reddened and its appearance suggested sprue; his hands presented a dermatitis, typically pellagrous in appearance, and the rectal mucosa bled easily. Gastric analysis revealed achlorhydria. Roentgenograms of the stomach were negative; those of the head revealed osteoporosis. The serum calcium was 9.6 mg. per 100 c.c. The stools contained an excess of fat. The patient's course was one of progressive failure, delirium and death. At necropsy the only significant finding was diffuse gastro-enteritis.

Internal fistulas: short circuiting.—Fistulas which short circuit the small intestine entirely or in part are a very interesting but fortunately uncommon cause of deficiency disease. In spite of the fact that the intake of food is adequate, so little of the gastric contents may reach the small intestine that inadequate absorption results. Gastrocolic or duodenocolic fistula, or entero-enterostomy, may be responsible for avitaminosis; there are reports in the literature of several cases in which the clinical picture of sprue had as its pathologic basis a gastrocolic fistula, and we have records of one case in which a latent sprue syndrome was precipitated by gastro-enterostomy. Urmy and his associates have reported a case of beriberi in which all but 20 inches (50.8 cm.) of the small bowel had been sidetracked by entero-enterostomy. We have observed four cases of gastrocolic fistula with associated deficiency states, all of which presented different clinical pictures. In one instance there was nutritional edema alone, and in another edema was associated with tetany and a low serum calcium; in the others, night blindness and a sprue-like syndrome were present.

Case 9. Gastrocolic fistula with nutritional edema and night blindness* (inadequate absorption of vitamin A). A man, aged forty-eight, had undergone gastro-enterostomy for duodenal ulcer sixteen years previously. Eleven years later diarrhea developed and, the following year, night blindness. The patient could see perfectly by day, but at night vision was poor and he was unable to drive his car or to walk without colliding with various objects. His diet had been adequate in every respect. Examination of the eyes revealed no local disease. Moderate edema of the legs was present. Following repair of a gastrocolic fistula, complete recovery resulted and the night blindness disappeared.

In this case of night blindness there was an adequate dietary intake of vitamin A, but because of its failure to reach the small intestine as a result of the gastrocolic fistula it is presumed that inadequate amounts were absorbed.

Case 10. Gastrocolic fistula with sprue (inadequate absorption). A man of forty had undergone gastro-enterostomy for duodenal ulcer five years previously. Eight months prior to his admission to the clinic diarrhea, with five to six watery stools daily, developed. Subsequently, edema of the legs, lower abdominal pain and distention occurred. Examination revealed emaciation, edema of the legs and ascites. He had macrocytic hypochromic anemia. The serum protein was 4.1 gm., and the calcium 7.8 mg. per 100 c.c. Roentgenograms of the bones showed osteoporosis, those of the stomach gastrocolic fistula. Free

*Previously reported by Wilbur and Eusterman.

hydrochloric acid was present in the gastric contents. Jejunostomy was performed for feeding purposes, but death occurred subsequently from perforated gastric ulcer.

This remarkable clinical picture closely resembling sprue was not associated, as is usually the case, with atrophy of the gastric and intestinal mucosa but with a gastrocolic fistula which sidetracked the small intestine, thus interfering with intestinal absorption and leading to a characteristic clinical picture of sprue. Similar cases have been reported by Fairley and Kilmer.

ALTERATIONS IN METABOLISM

Alterations in the metabolic activity of some of the organs of the gastro-intestinal tract may theoretically predispose to the development of a deficiency state. The relationship is not as yet definitely established, however. Since the liver is apparently essential to the conversion of carotene to vitamin A, and since it it such an important storehouse of the vitamin, it is readily conceivable that extensive hepatic damage might lead to deficiency of vitamin A. Such a case was reported by Blegvad, and we have also observed a case of pellagra in which one of the underlying pathologic changes was extensive carcinoma of the liver. It is also quite likely that metabolic activity of the pancreas, and perhaps of the mucosa of the stomach and small intestine, may be significant in conditioning deficiency states under certain circumstances.

One possible rôle by which the gastro-intestinal tract may influence the development of a deficiency disease is that which leads to destruction of the vitamin by bacterial or chemical activity. Practically nothing is known of the clinical significance of such a possibility in man; but there is some evidence to suggest that in animals, certain vitamins are destroyed in large quantities in the gastro-intestinal tract.

Relation of diseases of the colon to deficiency states.—It is surprising how frequently deficiency states may be associated with diseases of the colon, and conversely, how frequently evidence of colonic disease or dysfunction is found in deficiency disease. Mackie has recently reported a group of cases of chronic ulcerative colitis, in 62.6 per cent of which there were symptoms interpreted as evidence of deficiency states. The etiologic relationship of these various factors and the sequence of their development is often impossible to elucidate. Is the ulcerative colitis which is seen in cases of pellagra a secondary or primary condition; or, if it is primary, how does the disease of the colon lead to the development of the deficiency state? It may do so because the diet has been inadequate or because of loss of essential substances or food resulting from the diarrhea, or because of reflex disturbance in function of the stomach or small intestine. We have observed a variety of deficiency states in association with diseases of the colon (Table I).

The difficulties which may arise when one attempts to evaluate the sequence of events in some of the cases is well illustrated by the following report:

Case 11. A man, aged forty-one years, was examined because of diarrhea which he had had intermittently for two years and steadily for eight months. He had been on a somewhat limited diet and had used alcohol in fairly large quantities at intervals during this time. Examination revealed a loss of weight of 40 pounds (18.1 kg.) but was otherwise negative. The stools were watery and cultures and examination failed to show significant organisms or parasites. The rectal mucosa viewed through the proctoscope had the appearance of diffuse proctosigmoiditis. Roentgenologic examination of the colon revealed an atypical form of ulcerative colitis in the sigmoid, transverse colon, cecum and ascending colon, and this was the clinical diagnosis which was made at that time. During the course of dieting and vaccine therapy, stomatitis developed and, three months later, the patient presented the characteristic cutaneous lesions of pellagra and the typical symptoms and findings of multiple neuritis. There was gradual improvement following treatment, with disappearance of the cutaneous and nervous symptoms.

While in light of subsequent developments it seems most likely that the patient's symptoms were due to pellagra following an inadequate intake of food and the use of alcohol, nevertheless, early in the disease, before the development of cutaneous, oral and neurologic changes, the clinical picture resembled that of an atypical chronic ulcerative colitis.

COMMENT

In this paper, in order to be certain of the diagnosis we have limited the discussion to those cases in which the deficiency disease was obvious and clearly recognizable. In so doing we have omitted many cases in which the symptoms of a deficiency syndrome were apparently early and not clear cut. Obviously, in the past, many such cases presenting early or preclinical states of vitamin deficiency have been overlooked or misinterpreted. With the further development of clinical experience and laboratory methods of examination, however, the diagnosis of these early conditions will be made with greater certainty and confidence. It will quite likely be found that the mechanisms by which the gastro-intestinal tract may predispose to such states of mild deficiency are similar to those we have presented.

In the development of deficiency states a large variety of factors may be significant. While the fundamental change is due to a failure in the supply of vitamins or other essential substances to meet the demands of the tissues, this failure or inadequacy may come about as a result of many widely-differing pathologic or physiologic changes. It seems quite likely that many factors other than those which have been mentioned may be significant predisposing causes of deficiency states. Why occasionally in a patient with obstructing pyloric carcinoma pellagra should develop, while in the majority of patients with a similar condition it does not develop although the diet may have been apparently equally limited or the degree of obstruction equally great, cannot as yet be ascertained. The problem seems quite similar to that presented by the failure of most patients with extensive carcinoma of the gastro-intestinal organs who have had a very limited intake of food over a considerable period of time to reveal evidence other than emaciation or cachexia of a deficiency disease. It is also difficult to explain the fact that patients with the same type of lesion, such as a gastrocolic fistula, may exhibit very little evidence of nutritional disturbance, or else may present a variety of deficiency states such as nutritional edema, sprue, night blindness and tetany. Factors such as the antecedent diet, a previous storage of the esential substances, and the size, location and

duration of the fistula, may account for this interesting phenomenon. Doubtless, however, this is not the whole story.

We have also been impressed by the fact that a single deficiency disease, such as pellagra, for example, may be associated with a variety of different gastro-intestinal abnormalities (Table I). The relationship between the pellagra and the associated disease is not always easy to establish; in some cases it seems clear that the pellagra is of the secondary type, whereas in others, the evidence is less definite and a coincidental association is entirely possible.

A review of the material which we have presented reveals that pellagra is by far the most common deficiency disease which we have encountered in association with gastro-intestinal lesions. This is probably best explained by the fact that pellagra is actually one of the most common clinically recognizable deficiency diseases in man, and that the components of the vitamin B complex are most susceptible to the influence of altered gastro-intestinal function. However, the relative ease in recognizing pellagra and the difficulty in recognizing other, less well-known deficiency diseases must be taken into consideration.

One important practical aspect of this problem is the serious prognostic importance of the deficiency diseases in those cases in which a surgical attack on the gastro-intestinal lesion is contemplated. It was our early experience that patients with such complications tolerated major surgical procedures very badly, and in four of the five cases we have reported in which operation was performed after the development of the deficiency disease, death followed soon afterward. In this respect these patients resembled those with uncontrolled Addison's disease or diabetes, in which case any major surgical procedure is very hazardous. Since the unfortunate early surgical results just noted, it has been our experience that, if operation is contemplated, it should be done only after the deficiency state is adequately controlled and treated; under such circumstances the surgical risk is not excessive.

SUMMARY

The rôle of the gastro-intestinal tract in the development of conditioning of deficiency states may be: (1) the result of an inadequate intake of food, due to anorexia or an incomplete diet; (2) the result of a loss of essential secretions or of food, due to vomiting, diarrhea, or external fistulas; (3) the result of a lack or decreased production of essential substances (for example, the hematopoietic factor, bile, or other digestive juices), and (4) the result of inadequate intestinal absorption, due to obstruction, short-circuiting produced by fistulas, and atrophy or disease of the intestinal mucosa.

Pellagra has in our experience been the most commonly observed deficiency disease associated with gastro-intestinal abnormalities. This suggests, and it has been the experience of others, that the components of the vitamin B complex are most susceptible to the influence of altered gastro-intestinal function.

There is as yet no good explanation for the very interesting observations that a single deficiency disease, such as pellagra, for example, may be associated with or produced by a variety of different gastro-intestinal disturbances. On the other hand, several distinct deficiency syndromes may be observed in patients with the same gastro-intestinal lesion.

DISCUSSION

DR. GEORGE R. COWGILL (New Haven, Conn.): Mr. Chairman and Friends: This paper presents several points worthy of comment. It has taken a long time for clinicians to appreciate the fact that one of the best treatments of many conditions is the maintenance of a proper nutritive state. Of course, this means thinking about foods instead of new and interesting drugs and similar remedies. In his interest in these more novel kinds of treatment the clinicians too often forget the obvious fact that unless the organism is provided with an adequate supply of all of the dietary essentials, it can not recover as the clinician may desire.

The paper just presented summarizes many interesting conditions which quite obviously are due to failure to supply the organism with proper amounts of various dietary essentials, chiefly those in the vitamin group. Assuming that adequate diets were offered, the lesson seems to be that individuals with an abnormal gastro-intestinal tract resulting in surgical treatment of one kind or another may be unable to absorb the requisite amount of administered vitamin.

Considering some of our own recent experiments with dogs, it occurs to me that clinicians ought to consider the possibility that different pictures, different symptom complexes, may be due to the same fundamental cause. Let me illustrate this by citing the behavior of some of our dogs subsisting on diets deficient in vitamin G, or riboflavine, as we should now call it. When the dogs subsist on diets markedly deficient in this factor, they develop a profound collapse after about one hundred and thirty days. This collapse may be treated successfully and with striking results by parenteral administration of the vitamin, the animals recovering sufficiently in about six hours to be able to stand; on the following day they are able to run

around and appear to be normal. On the other hand, when the animals receive as supplement to the basal diet one-half the daily amount of the vitamin found to be adequate for the normal controls, they never exhibit this collapse. They live more than twice as long as the "acute" animals —two hundred and fifty and more days—but they do develop a true ataxia associated with lesions in the posterior columns of the spinal cord. These two conditions, the collapse without ataxia characteristic of the severe and acute deficiency and the ataxia exhibited by the "chronic" animals, are evidently due to the same fundamental cause, namely lack of vitamin G, operating however to a different degree, the acute condition resulting from a marked shortage and the chronic condition from a moderate lack of vitamin maintained over a much longer period. May you not have this situation in many of your clinical cases? May this not serve to explain some of your controversies over the interpretation to be given various symptoms?

With the development of new methods for detecting lack of vitamin B as well as of other vitamins, it should be possible eventually for the clinician to apply these tests and to determine where a state of vitamin subnutrition exists, in which case particular care can be taken to insure that these patients receive sufficient amounts of the vitamins. Clinicians will do well to watch the developments in this field because of their significance in practical work.

It seems pertinent to point out that not all preparations of vitamin B are of equal value in clinical work, particularly if given through a fistula in the large intestine. We have made some observations on dogs provided with a valvular cecostomy and have had occasion to put various vitamin B preparations into the valve. We were quite astonished to find that not all preparations were of equal value. Therefore, if a surgeon wishes to administer vitamin B via a fistula in the large intestine, he should remember that the preparation must be properly selected. Curiously enough, the fullers earth adsorbent used in preparing the present international standard for vitamin B does not readily yield its adsorbed vitamin to the organism. Evidently the conditions in the large intestine do not favor ready elution of the vitamin from the mineral material. It is not unlikely that similar facts will be discovered concerning the other vitamins.

Another practical point occurs to me. If clinicians are to provide these special cases with sufficient amounts of the various vitamins, it is necessary to know about how much of each is required by the individual. If we know, for example, that a normal adult human being needs as a minimum from one to two milligrams of pure vitamin B per day, then, in the face of an abnormal alimentary tract, we can allow for some factor of safety and give many more milligrams in order to allow for wastage due to imperfect absorption. How about the other vitamins? Present indications are that the average person requires at least 3500 international units of vitamin A daily, and probably about one milligram of ribo-flavine (vitamin G) per day. Mere recitation of these figures should suggest to you that we have here a field of knowledge most important to clinicians treating these cases; and if this knowledge is to be properly applied, the clinicians must become familiar with it or else see that some of their colleagues have the requisite information applicable to these particular cases.

How are we to give all of these vitamins? I know that it is clinical heresy to suggest that we should give "mixed remedies" or so-called "shot-gun prescriptions." However, it seems to me that we are perfectly justified in giving these vitamins in the form of mixtures. The Council on Pharmacy and Chemistry of the American Medical Association has ruled definitely against such mixtures of vitamins. If these physiologically important substances were like drugs in their action, then this attitude would certainly be correct. However, the vitamins are essentially foods, and all of them are required. To my mind the only serious argument which can be advanced against the use of mixtures of them is that in such mixtures some of the vitamins may inactivate others, but this is a matter amenable to laboratory and clinical tests, and the results of such tests already at hand do not afford convincing support for the position taken by the Council. Since mixtures of the vitamins are not to be permitted, the clinicians are necessarily forced to give to their patients, who cannot very well handle materials via the alimentary tract, parenteral injections, first of one vitamin, then of another, and so on. This is a most impractical and seemingly unnecessary procedure, especially when suitable mixtures containing at least the daily requirement of all of these essentials can doubtless be provided. When dealing with fundamental food factors instead of drugs, as in this situation, it seems to me that we are justified in subscribing to what is clinical heresy in suggesting that it is proper at times to administer vitamin mixtures in clinical work.

DR. GEORGE B. EUSTERMAN (Rochester, Minn.): I was interested in the discussion by our Chairman. The Boston school which he represents has done outstanding work in this field. One point of practical importance to all of us who come in daily contact with patients with gastro-intestinal lesions complicated by deficiency disease is to make sure that those who are obliged to submit to operation have adequate pre-operative preparation. The essayist referred to a contribution by O'Leary and myself published some years ago in which this feature was greatly emphasized. Inadequate preparation presupposes a high surgical mortality.

In the second place, one must always be on the lookout for evidences of deficiency in the conditions cited by Doctor Wilbur. Just before my departure to attend this meeting I saw a young Canadian woman who undoubtedly had an unnecessary gastro-enterostomy for a functional type of dyspeptic complaint. This procedure was followed by a rather persistent diarrhea and achlorhydria. There was adequate pre-operative gastric acidity. In addition to a marked loss in weight she developed a suspicious dermatitis on the dorsum of both hands, which had practically disappeared when she came under our observation. However, on questioning her she stated that she had been treated for pellagra by a competent internist in a neighboring city. Now it is highly essential in this case that before the gastro-enterostomy is taken down, adequate pre-operative preparation with the essential vitamins, etc., should be carried out. The surgical mortality is particularly high in pellagrous types of deficiency disease.

DR. JOHN L. KANTOR (New York, N. Y.): If there is time, Mr. President, I should like to compliment the speaker on his beautiful method of presentation. He followed the old three-way rule of telling his audience what he was going to tell them, then telling them, and then telling them what he told them, so he drove home every point.

The discussion by Dr. Cowgill was all too short in proportion to its importance. He referred to tests for vitamin deficiency. I am not sure how perfect or how clinically effective these are, but such tests should be more generally known by the profession.

The daily requirements of vitamins are again not universally known by the profession, and here also is a field for popularization of the available knowledge.

DR. CHESTER M. JONES (Boston, Mass.): I should like to say that this paper interests me a good deal. It seems to me it is a timely one because of the fact that nowadays we are able to make diagnoses of gross diseases and treat them adequately, but now it come to a point of really bringing about a satisfactory convalescence in many instances, or shortening convalescence, or carrying

on a case of stricture of the esophagus under a long period of undernutrition.

I have jotted down several cases of patients I can recall quite distinctly who bring up the points Dr. Wilbur and Dr. Cowgill have made. One patient had a cancer of the tongue which was resected in part. He was told to limit his diet and did so voluntarily, living on crackers and chocolate ice cream sodas for nearly two years. Then he was sent to me because he was jaundiced, and I was asked whether he had metastases to the liver. He had slight jaundice, his tongue showed a definite stomatitis, and there was a blood picture of pernicious anemia, although there was plenty of acid in his stomach. The admission of adequate amounts of liver by mouth in a very short time restored his blood to normal and caused his jaundice to disappear as well as the stomatitis. That case represents a deficiency due to an inadequate dietary intake.

We see little adult scurvy nowadays, but I recall one patient on an ulcer regime which he maintained for a year beyond the time his physician required it. This patient came in with swollen joints and subsequently developed perifollicular hemorrhages and typical scurvy, due to a deficient diet. The entire clinical picture cleared up rapidly following the administration of orange juice.

Another case suggesting the possibility of sub-vitamin deficiency was that of a youngster with ulcerative colitis and a story of prolonged undernutrition because of his mother's dietary suggestions which amounted to a food fad. This child had skin lesions which were purplish and erythematous, and was generally undernourished. Because he scratched the skin lesions, they became infected, and healed only after a period of months, rather than days as they would normally have done. We suspected a Vitamin C deficiency, though not full-blown scurvy. The Vitamin C content of his blood was low, and he was at once given a Vitamin C concentrate in adequate amounts. With the administration of this specific substance the skin lesions cleared up rapidly.

A fourth patient, with a duodenal ulcer, had a gastro-ileostomy performed by mistake. An ulcer and stricture resulted at the lower end of the ileum. This patient came in with definite signs of a peripheral neuritis, and in addition, was mentally disoriented and difficult to manage. He had definite neurological signs, and the diagnosis was made of a peripheral neuritis and possibly an intracerebral lesion, or beriberi with cerebral manifestations.

A lumbar puncture was performed, and the fluid showed an increased protein content with a cell count of 300 cells per cubic millimeter. At first the neurologist refused to believe it might have been due to dietary deficiency. We found in the literature that beriberi, as reported in the French Colonial literature, occasionally was associated with evidences of meningeal irritation. Vitamin B in this instance cleared up the patient's symptoms, with a return to normal of the spinal fluid.

Another patient presented the rare clinical picture of ulcerative colitis and full-blown Graves' disease. He came to the clinic because of failing vision, and the ophthalmological consultant said that he had an optic neuritis which was definite. There were some signs of peripheral neuritis, which were not so marked as optic neuritis.

We questioned as to whether the optic neuritis was a manifestation of the diet deficiency, but in the first place we successfully treated the Graves' disease by operation, and his ulcerative colitis improved proportionately. At the same time we fed him large amounts of Vitamin B, with almost complete restoration of function of the optic nerve.

I should like to ask Dr. Wilbur whether he has seen a proctoscopic picture similar to that of ulcerative colitis with bleeding following prolonged undernutrition. I recently saw a young woman who apparently presented such a picture. The patient, a girl of 25, had lost 90 pounds in about six months' time by voluntary dietary restriction. She then tried to stop the loss in weight but continued to lose in spite of an apparently adequate diet. During the later months she developed an intractable diarrhea, and by proctoscope had colonic lesions typical of ulcerative colitis. She is at present getting better on adequate diet and intensive vitamin therapy.

Physicians practicing in the South tell me that they do not see intestinal lesions in sprue, but it seems to me that the intestinal lesions in this case might have been due to a deficiency state.

I should like to call attention to the fact familiar to all of us and not too greatly stressed, that the appearance of the tongue is not frequently enough noted. Our forebears always talked about the tongue, but I am not sure they always knew what it meant when they described it. Nowadays there are many changes in the tongue which may be the first symptoms of deficiency disease of the pernicious anemia type, or sprue, or certain other syndromes not so well known. I think its importance can't be too much emphasized.

DR. DWIGHT L. Wilbur (Rochester, Minn.) (closing the discussion): I appreciate the discussion which this paper has received and am glad that, in the discussion, emphasis was placed on some important points in regard to deficiency diseases which I did not have time to mention.

We selected cases in which the deficiency state was very obvious in order that there might be no question as to the diagnosis.

The points Dr. Cowgill brought out are exceedingly important. As yet, not very much advance has been made by clinicians in the recognition of what are called preclinical or early states of vitamin deficiency. In the next ten years we hope great advances will be made in the diagnosis of such conditions with the help of Dr. Cowgill and other investigators who have done so much experimental work in this field.

At the present time very little is known of the actual requirement of man for the various vitamins. Apparently, there are both minimal and optimal requirements. It seems very obvious that in many of the cases we have reported the intake of vitamins was deficient; in other words, the intake of certain vitamins was less than the minimal requirement. There is apparently a wide zone between such a minimal requirement which one would expect to be associated with a clinically recognizable deficiency state and the optimal requirement which one would expect to be associated with a state of excellent health. We do not know how wide this zone actually is nor what its limitations may be, but Dr. Cowgill and other investigators are helping us in elucidating this problem.

The requirement of man for each vitamin probably will best be expressed in future years as are the requirements for protein today, namely, as minimal and optimal requirements.

It is a curious fact, difficult to explain, that most patients who have extensive malignant disease of the gastro-intestinal tract and who live for long periods of time on diets which are obviously inadequate in vitamins fail to show signs of a deficiency state other than emaciation or cachexia.

I think that all of us as clinicians will appreciate the fact that the best way for a patient to secure an adequate supply of vitamins is in the natural state, namely, in foodstuffs. If it seems advisable to supplement foods with vitamin preparations this may easily be done.

Dr. Jordan brought out a very important point in this connection, and I believe it illustrates the attitude that the modern physician should take, namely, to emphasize

to the patient those foods which he should eat rather than to place emphasis, as has been done for generations, on those foods which he should not eat.

Dr. Jones raised the question of disturbance of the colon in relation to deficiency states. In two of our cases we found evidence of chronic ulcerative colitis. What the relationship may be between disease of the colon and deficiency states, in other words, which is primary and which is secondary, is impossible to state in many instances.

The Diarrhea of the Pancreatic Insufficiency*

By

J. ARNOLD BARGEN, M.D.† JESSE L. BOLLMAN, M.D.‡

and

EDWIN J. KEPLER, M.D.§

ROCHESTER, MINNESOTA

THERE are innumerable causes of diarrhea. Many diseases and functional disturbances of the body are associated with this symptom. Often, the cause is some form of intestinal disease, but the cause of a diarrhea frequently is found at points distant from the intestine. In many cases no real cause of this symptom can be found. It is difficult, for instance, to account for the diarrhea which occurs during a thyroid crisis. Unfortunately, in the minds of many persons, the terms "diarrhea" and "colitis" have been considered synonymous. This is so common that the clinician often finds it difficult to disabuse the patients of the idea that all diarrhea originates in the colon. The diabetic who has diarrhea feels certain that his diarrhea indicates a disease of the intestine. Eventually, this type of diarrhea may be proved to be an entirely independent entity which has no relation to diabetes or to the mechanism responsible for it.

Steatorrhea is a form of diarrhea in which the loose stools contain an abundance of fat. There also are numerous causes of steatorrhea. The two which are probably most commonly encountered are pancreatic insufficiency and sprue. It is more than likely that the mechanism of production of the steatorrhea in these two conditions is different. In sprue, pancreatic enzymes are present in the duodenal contents and the steatorrhea probably results from a failure of proper absorption of fat by a damaged small intestine. In the steatorrhea of pancreatic insufficiency, pancreatic enzymes cannot be demonstrated in the intestinal contents of the duodenum. The steatorrhea in this case probably results from improper splitting of fats taken in.

In cases in which the diarrhea of pancreatic insufficiency is associated with steatorrhea, the stools are bulky, have an offensive odor, and contain excessive amounts of fat. Diabetes, if present, is mild most of the time, except during episodes of acute inflammatory changes in the pancreas, which may be characterized by severe abdominal pain and occasionally by chills and fever in cases in which the condition is severe. Roentgenographic evidence of diffuse calcareous changes in the pancreas may be present.

The treatment of steatorrhea which is the result of pancreatic insufficiency has been most unsatisfactory in the past. Symptomatic measures and the administration of commercial pancreatic preparations have either failed to produce relief or at best have produced only transient relief. Then, too, the diabetes usually becomes difficult to control because of the necessity for dietary changes and the difficulty in estimating the optimal dose of insulin.

In these cases one obviously would search for trouble in the pancreas. In the cases of steatorrhea, there is evidence of a disturbance of the external secretions of the pancreas. It has been suggested that in some of the diarrheas associated with diabetes, there may be a relative decrease in the flow of pancreatic juice and therefore an intestinal disturbance without steatorrhea. A careful analysis, however, of the two types of diarrhea impressed us with the fact that in cases of severe diabetes associated with watery diarrhea, pancreatic enzymes exist in the duodenal contents whereas in cases of steatorrhea, the enzymes might be absent.

It is a well known fact that in diabetes produced in animals by complete pancreatectomy, difficulty in their management has been encountered because of the occurrence of diarrhea. It also has been found that this diarrhea may be fairly well controlled by the addition of bone ash and raw pancreas to the diet. As soon as diets which do not contain pancreas are administered, diarrhea again becomes a serious complication. Various preparations made from pancreatic tissue have not proved satisfactory substitutes for raw pancreas nor has the feeding of pancreatic juice been of great benefit in these animals. On the other hand, the addition of precipitates containing some of the active enzymes of pancreatic juice has given better results. These facts suggested to us that the administration of pancreatic juice or its active substances would be worth a trial in the treatment of the diarrhea of pancreatic insufficiency which affects human beings.

Because of the enzymatic nature of the active substances of pancreatic juice, small quantities may act on a relatively large quantity of food in the intestine and may produce nearly complete digestion. The effectiveness of small amounts of pancreatic juice was demonstrated in the case of animals whose pancreatic ducts were almost completely occluded. Patency of one small duct prevented the development of all the signs of pancreatic insufficiency which are characteristic of complete pancreatic occlusion. The effectiveness of

---

§Division of Medicine, The Mayo Clinic.

small amounts of pancreatic juice was likewise shown by Elman and McCaughan in studies on animals which had pancreatic fistulas from which all secretions were drained. Such animals secreted great quantities of pancreatic juice, and symptoms and changes in the chemical composition of the blood which were similar to those found in cases of obstruction of the upper part of the intestine developed. Death occurred within the first week unless large amounts of physiologic saline solution were administered, but the administration of a few cubic centimeters of pancreatic juice greatly reduced the secretion of pancreatic juice and the subsequent occurrence of symptoms, and prolonged life more or less indefinitely.

METHOD OF PREPARATION AND ADMINISTRATION OF PANCREATIC JUICE

Pancreatic juice for administration to patients was prepared in the following manner: With an aseptic surgical technic, a cannula was tied in the major pancreatic duct and the minor pancreatic duct was ligated while the dogs were under ether anesthesia. A sterile rubber tube was passed through the skin to connect the cannula in the pancreatic duct to a sterile rubber bag placed in a small basket on the animal's side. The pancreatic juice then was removed from the bag once or twice daily. The animals maintained themselves well if a small amount of pancreatic juice was administered by mouth.

Administration of whole pancreatic juice by means of a duodenal tube proved efficacious in the treatment of patients with this type of diarrhea. Because of the inconveniences of this method and the bulk of whole pancreatic juice, we then tried administration of dried precipitates which represented less than 0.5 per cent of the whole pancreatic juice. The following types of precipitates have been found to be active: (1) material precipitated from pancreatic juice by the addition of five volumes of alcohol at a temperature of — 20° C.; this precipitate was dried with cold alcohol and ether; (2) material precipitated by the addition of picric acid; this precipitate was dried and the picric acid was removed with alcohol and ether, and (3) material precipitated by the addition of a 5 per cent solution of trichloracetic acid; this precipitate was dried and the trichloracetic acid was removed with alcohol, acetone and ether. At present, we are using the last preparation.

RESULTS OF TREATING STEATORRHEA WITH PANCREATIC JUICE

The following cases exemplify the results of substitution therapy in the treatment of steatorrhea which is the result of pancreatic insufficiency:

Case 1. An unmarried man, aged thirty-six years, came to the clinic March 9, 1935. For eight years he had had periodic attacks of pain in the upper part of the abdomen, which had been associated with chills, fever and sweats. Between attacks there had been constant soreness in the upper part of the abdomen. The attacks had lasted about four days, and had been initiated by anorexia and abdominal discomfort. The pain had been situated in the epigastrium and had extended to the right and left side and at times to the back, between the shoulders. It had been severe and hypodermic injections of morphine frequently had been required for relief. With the coming of an attack, the patient had felt restless and irritable. During the attack the abdomen had become tight and distended, but had not been sore to touch. Relief had been obtained by crouching or bending forward, or by sitting in a tub of hot water. Vomiting had occurred occasionally, but had produced relief. The chills and fever had continued for several days after the pain had gone. No food had been taken during the attack.

A year before the patient came to the clinic these attacks gradually had subsided, but they had recurred six weeks prior to his admission. An exploratory laparotomy had been performed a year after the onset of the attacks. The preoperative diagnosis had been peptic ulcer, but none had been found. The abdominal organs had been normal, except the pancreas, which had been inflamed. The attacks had continued to occur about eight to ten times each year after the operation. The patient had gone to a hospital for four or five days during most of the attacks. Six weeks before he came to the clinic diabetes had been discovered following one of the attacks of pain. A diet had been instituted and for a time 40 units of insulin had been given daily. The patient had noticed for a long time that his stools had appeared greasy and foamy and had floated on water; they had contained much undigested food but no blood. The diarrhea had been severe until six weeks before his admission to the clinic, when some improvement had occurred.

When the patient arrived at the clinic he seemed ill enough to be hospitalized at once. The value for the blood pressure, measured in millimeters of mercury, was 130 for the systolic and 80 for the diastolic, and his weight was 121½ pounds (55 kg.). The value for the hemoglobin was 13.3 gm. per 100 c.c. of blood; the erythrocytes numbered 4,100,000 and the leukocytes 7,900 per cubic millimeter of blood respectively. The differential blood count was approximately normal. The value for blood sugar was 163 mg. per 100 c.c. A serologic test for syphilis was negative. The urine contained a trace of a reducing substance. Subsequent urinalyses revealed from 1 to 2.4 per cent of sugar. The results of tests of liver function were normal and there was no retention of dye. The value for the bilirubin was 1 mg., that for the calcium was 9 mg., that for the phosphate was 4 mg. and that for the protein was 6.4 mg. per 100 c.c. of serum respectively. Roentgenologic studies revealed a normally functioning gall bladder and extensive pancreatic lithiasis. As a result of a strict diabetic program the urine became free of sugar but the distress in the upper part of the abdomen continued.

After a medical regimen had been employed for two weeks, an exploratory operation was performed (March 22, 1936). An operative diagnosis of chronic pancreatitis with calcification was made by the surgeon, who described the pancreas as being about three times the normal size and diffusely indurated throughout. The common bile duct was dilated to about twice its normal size. Choledochostomy and cholecystostomy were performed. No stones were demonstrated in the gall bladder or its ducts. The postoperative convalescence was satisfactory although somewhat prolonged. The expected improvement, however, did not result and the patient returned to the clinic July 15, complaining of nausea, vomiting and a heavy feeling in the right upper quadrant of his abdomen, but he thought the pains had decreased somewhat in severity. His urine had remained free of sugar. His bowels moved every two or three hours throughout the day and night, the stools being light brown, soft to liquid, frothy, bulky and fatty; they had an offensive odor.

The patient was then given the prepared pancreatic juice through a tube which was passed very cautiously into the duodenum. We began by giving 1 c.c. every hour; the maximal amount given at one time was 2 c.c. In twenty-four hours the number of stools had been reduced from twelve or fifteen to four, and this status was maintained by continued administration of a measured amount of pancreatic juice. In a few days, the stools became

nearly normal. The patient was then dismissed from the clinic and instructed to take minute capsules containing the concentrated pancreatic juice. The patient continued to improve so long as he took these capsules; if he stopped taking them the trouble recurred. It was ultimately found that a minimal quantity of the dried juice was necessary to maintain normal intestinal function.

Case 2. A man, aged sixty-five years, came to the clinic December 4, 1935, because of progressive loss of weight and diarrhea. Five years previously he had weighed 150 pounds (68 kg.). When he came to the clinic he weighed 100 pounds (45.4 kg.). He said that he formerly had been very energetic and had taken a good deal of physical exercise, but that he had gradually become weak, tired and had lacked energy. His stools had been soft or liquid and had contained a great deal of oil and fat. At the time of his admission he was having four to six large, oily stools every twenty-four hours. Sugar first had been found in his urine in 1931. At that time the value for the blood sugar had been 170 mg. per 100 c.c. He had been given an adequate diet and his urine had been free of sugar, but in spite of this he had gradually lost weight.

Examination at the clinic revealed that the diabetes was mild. The value for the blood sugar while the patient was fasting was only 101 mg. per 100 c.c., and the urine was free of sugar. He was constantly hungry and always ready to eat. He commented repeatedly on the fact that the fat he took was not digested. The value for the systolic blood pressure was 120 mm. of mercury and that for the diastolic pressure was 80 mm. The patient appeared exhausted and emaciated. Numerous stools were examined and all contained oil or fat in excess. Their gross appearance was that of an oily fatty mass. Meat fibers were present. Results of examination of a typical stool revealed 21.2 per cent of total fat, 13.8 per cent of which was fatty acid and 7.4 per cent of which was neutral fat. The value for cholesterol was 139, that for the cholesterol esters was 82, that for the total fat was 421, and that for fatty acids was 282 mg. per 100 c.c. of plasma respectively. The value for the serum protein was 5.4 mg. per 100 c.c. The duodenal contents did not contain amylase and trypsin. Proctoscopic examination revealed a normal rectal lining. Roentgenologic studies of the stomach, colon and small intestine did not disclose any intrinsic organic disease. The gall bladder was reported as normally functioning, but there were multiple stones in the pancreas.

We started treatment of this patient by giving a capsule containing the pancreatic extract every four hours. Improvement started on the second day, and by the fourth day, his stools had become nearly normal. We have been able to maintain the normal stools by administering two capsules daily, each of which contains a fifth of the amount of pancreatic extract given at one dose when treatment was started. The diabetes has been readily controlled.

You will recall that this patient was under our observation in December, 1935. For many months, capsules of the pancreatic juice were supplied him. Because of the difficulties of maintaining the supply, he was advised from time to time to try commercially prepared pancreatic enzymes. He has tried every available product. In March, 1937, he wrote that none of them had helped appreciably. After each trial of a new one and its failure, prompt and complete relief followed the use of the one capsule, as described, twice a day. Less than this would not produce striking or lasting results.

COMMENT

It should be emphasized that the results obtained have been gratifying only in the type of diarrhea associated with steatorrhea. One would expect the best results in cases in which there is marked interference or total inhibition of the external secretions of the pancreas. Such a condition exists when obstruction of the pancreatic ducts, as by a stone, occurs.

Fortunately, the association of diarrhea and diabetes is infrequent. With the exception of some of the serious organic causes of diarrhea, it represents one of the most distressing conditions confronting the present day practitioner. The diet advisable for the diabetic is so obviously not the kind one would offer an individual who has diarrhea. Hence, the dietetic problem becomes a real one. Furthermore, the problem of the evaluation of the amount of insulin necessary for control of the diabetes is intensified. Loss of weight may be great and its control is exceedingly difficult.

These experiments bid fair to offer help to at least one type of patient who suffers from steatorrhea. Intensive dietary studies on animals whose pancreatic ducts have been evulsed are under way and we hope these may offer further leads which will point to the control of other phases of this difficult problem.

DISCUSSION

DR. J. PAUL QUIGLEY (Cleveland, Ohio): Dr. Bargen has called our attention to the fact that diarrhea may occur from some disturbance in the gastro-intestinal tract located higher than the colon. I want to go a step further. Dr. Einsel and I prepared a series of dogs from which the body and fundus of the stomach had been removed and the esophagus anastomosed to the pyloric antrum. The only striking appearance in these animals was the condition emphasized by Dr. Bargen, diarrhea and excessive fecal fat. Practically all the fat in the diet of the animals passed on through.

We haven't developed a complete explanation for this condition. The portion of the gastro-intestinal tract which produces the essential factors of gastric juice has been removed. However, the diarrhea and steatorrhea are not essentially the result of absence of hydrochloric acid and pepsin but are related to the deficient reservoir function of the stomach and the consequent excessively rapid propulsion of food through the intestine.

Our results emphasize the possibility of diarrhea and steatorrhea developing from a disturbance not primarily located in the colon or pancreas.

DR. A. C. IVY (Chicago, Ill.): Dr. Bargen's report implies that pancreatic juice, dried or extracted, is more potent or more favorably administered than pancreatin. I doubt the truth of that implication and, before I believe it, a lot of good experimental evidence will have to be supplied.

I know of nothing at present in pancreatic juice that is not present in properly prepared and potent pancreatin; as a matter of fact, there is something present in pancreatin that is not present in pancreatic juice, which we do know is of value to the organism, namely, lecithin, which contains choline.

Why have a number of physicians been disappointed with the results obtained on the administration of pancreatin to patients with suspected pancreatic achylia? The first reason is that the pancreatin given the patient has not been a potent preparation. At the drug stores in Chicago a year ago, I bought six different preparations of pancreatin. We found only three preparations out of the six worthy of presentation to a patient.

The second reason is that adequate quantities of pancreatin are not administered. Two, three, or four tablets

after a meal are usually given. In our animals in which we have been studying oral enzyme therapy, we have given 25 grams of pancreatin a day in the form of powder or enteric coated tablets, and we have shown that the enteric coating increases the effectiveness of the orally administered pancreatin.

When we give pancreatin to our patients, we must know that it is potent. We can't rely on the Council of Pharmacy and Chemistry for such potency, because they do not accept pancreatin or any other enzyme for oral administration, and the U.S.P. requirements in regard to pancreatin are not to be praised; so, if we are going to give pancreatin, we should know first, by having a competent chemist test it, that it is potent, and, when we give it, we must give it in adequate quantities.

We have two patients with pancreatic achylia and we have demonstrated that 25 grams of pancreatin, or 75 five-grain tablets, given per day, with and after meals, is effective. I say that on the basis of reliable evidence, and not on the basis of the patient's feelings or reports.

I was glad to see that Dr. Bargen showed the absence of enzymes from the duodenal drainage in his patients, but he did not say he had analyzed the stools chemically for fats, protein, and starch.

I think the only reason why the Council of Pharmacy and Chemistry of the American Medical Association does not accept pancreatin for oral administration is that there is very little good evidence in the literature showing that pancreatin is effective in man. There is plenty for the dog, which now demonstrates that it is effective. In many of the reports in which pancreatin has been used in man, analysis of duodenal drainage has not been done, to prove that a case of pancreatic insufficiency is actually being treated; and, secondly, the stools have not been examined chemically under dietary control before and after treatment with pancreatin.

The only way that one can establish scientifically that pancreatin is or is not effective in a particular patient, is to place the patient on a diet, collect the stools and analyze them for fat, nitrogen, and carbohydrate, and then repeat the analysis after pancreatin. When this is done on a sufficient number of patients, then we will have data which will establish, I believe, that oral enzyme therapy is effective in human subject suffering pancreatic insufficiency.

DR. WILLIAM C. BOECK (Los Angeles, Calif.): I have enjoyed hearing Dr. Bargen's paper which has brought the subject of steatorrhea before us again. I trust that the new method of treatment will be available to the rest of us who have such patients under our care.

I have the excuse of appearing before you simply to recount the history and treatment of another case in which steatorrhea was the prominent finding but which apparently was due to extrinsic factors outside of the organs of the gastro-intestinal system.

This case was that of a physician, 45 years of age whose illness lasted for one year. He had a persistent diarrhea which proved to be a steatorrhea, for the stools were made up mostly of fatty acid crystals. They were as plentiful as to appear like the sediment of a turbid specimen of urine.

He had abdominal distention and marked tenderness in the left upper hypochondrium. There was adenopathy of the axillary and inguinal glands. He had lost some twenty-five pounds in weight.

Physical examination and X-rays were negative for tuberculosis. Achlorhydria was present. The small intestine showed "laking" of barium in the jejunum and upper ileum suggestive of that described in cases of sprue. The blood picture was that of a moderate secondary anemia, with erthryocytes varying from 3,500,000 to 4,000,000, and hemoglobin from 75 to 85 per cent (Sahli) most of the time; a persistent leucopenia of 2,500 to 3,500 leucocytes was present all the time until one month before his death when it became normal.

Biopsy of an inguinal gland revealed a picture somewhat resembling tuberculosis, but no pathologist would agree that it was. Later, laparotomy was performed. The mesenteric glands were all enlarged, especially in the area of the jejunum and pancreas, but not in the region of the terminal ileum. A large mass of mesenteric glands was found at the origin of the mesentery near the pancreas. The small intestine and colon appeared to be normal.

The biopsy examination of one of the mesenteric glands showed almost complete disappearance of all lymphoid tissue with replacement by fat present in reticulocyte cells and deposits of cholesterol crystals. The microscopic preparations of this tissue were examined by several prominent pathologists throughout the country but no one made a definite diagnosis. It was thought that the condition was some form of lymphoma.

As to treatment, liver extract was used extensively, along with dilute hydrochloric acid, a fat-free diet, then later a normal diet, but no benefit occurred until the patient was given X-ray treatment. Then the diarrhea ceased almost entirely and also the steatorrhea. The adenopathy and abdominal distention disappeared. The patient gained 7 pounds in the next four months, but weakness persisted. One month before he died, his white cell count became normal and we were hopeful that his change portended a better prognosis. However one month later he suffered from acute cardiac decompensation and died a few days later.

Autopsy findings were those of cardiac dilatation. The pancreas, liver, adrenals, and mesenteric glands all appeared to be normal. There was no evidence of fat and cholesterol deposits in the glands, but some occurred in the walls of the small intestine with some mucosal atrophy.

Whether or not his case belongs in the category of those described as acute or chronic mesenteric adenitis or as some form of lymphoma I do not know but it illustrates the occurrence of steatorrhea from some disturbance extrinsic of the gastro-intestinal system, which vanished after X-ray treatment but the treatment did not cure the patient.

DR. J. ARNOLD BARGEN (Rochester, Minn.) (closing the discussion): I appreciate the discussion of Drs. Boeck, Ivy and Aaron. I tried to bring to your attention only one other method of aiding some of these very miserable people.

I believe, after hearing Drs. Aaron and Ivy, that in the past we have at times not used enough pancreatic extract. This very simple method came through Dr. Bollmann's work on animals and we were able to control the diarrhea of man. We were able to control it in one case by administering two small capsules of the powder daily. The patient had tried all kinds of drugs on the market, including very large amounts of pancreatic extract. Whole pancreas has been used sporadically but not enough to permit us to conclude how it would compare with this pancreatic juice. However the second patient received 75 to 100 grains daily of pancreatic extract of a preparation supposedly potent without effect, whereas two small capsules of the dried juice controlled his symptoms.
how it would compare with this pancreatic juice.

The pancreatic juice is not a cure-all. Some patients have not received adequate relief. A minister from the South received what we thought was an adequate quantity of these capsules but he was not particularly helped. All persons who have these types of diarrheas are thoroughly miserable and a certain number of them, I think most of them, will be helped when the pancreatic ducts have been occluded. Whether there are enough of them even to

warrant making such a preparation commercially, I do not know. In reply to Doctor Ivy's question about stool analysis, I should like to say that in all these individuals careful chemical analysis was made in all, as indicated in the second case.

Regarding the different causes of steatorrhea, Dr. Boeck mentioned an entirely different type. I think we must keep in mind that there is a steatorrhea which is probably due to a failure of the proper splitting of fats, and a steatorrhea which probably is due to failure of absorption. The latter may be associated with sprue. I saw a patient who had a definite clinical picture of sprue and tuberculosis of the abdominal lymph nodes. At necropsy there was marked atrophy of the intestinal mucous membrane. That patient presented a picture such as Dr. Boeck has described, but the course of the disease was not affected in the slightest by these capsules.

I hope this study may result in a stimulation to further study of this type of diarrhea and a trial of an adequate quantity and an adequate type of pancreatic product.

The Diagnosis and Treatment of Acute Non-Hemorrhagic Pancreatitis*

By

ROBERT ELMAN, M.D.
ST. LOUIS, MISSOURI

THE current conception of acute pancreatic disease is usually confined to the lesion often called pancreatic necrosis or acute hemorrhagic pancreatitis. The pathology of this remarkable condition is well known, its course is nearly always progressively downward and is associated with a high mortality even when an emergency operation is carried out. Acute pancreatic necrosis is, however, a relatively rare disease and in recent years has not evoked much interest in spite of the mystery which still surrounds its pathogenesis.

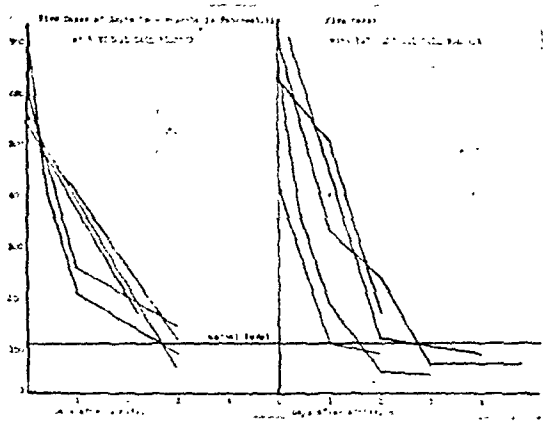
Acute pancreatitis which is not associated with necrosis, i.e., nonhemorrhagic pancreatitis, has from time to time been discussed in the literature as a mild type of pancreatitis which stopped short of actual destruction of the gland and subsided. In general, this group of patients comprises those operated upon with a diagnosis of pancreatic necrosis (or some other acute abdominal condition) but in whom at laparotomy the pancreas presented no hemorrhage or necrosis, but merely an edema or induration particularly of the head of the gland (1, 2). The possibility, however, that the pancreas is very often the site of acute inflammation which subsided has never been very widely held, in spite of the fact that surgeons, during the course of cholecystectomy, have frequently found the pancreas to be indurated and enlarged. This association of pancreatic with cholecystic disease has, of course, been repeatedly observed and may account for the fact that the lesion in the pancreas has consistently been afforded little consideration in favor of the more well known lesions in the gall bladder and liver. It has been my experience that this type of pancreatitis is relatively frequent but that it nearly always masquerades as another lesion; because of these considerations I have made a clinical study of a number of these cases. Review of the literature has been made in previous papers (1, 2, 3).

The present observations concern patients who suffered acute subsiding attacks of epigastric pain due undoubtedly to an acute process in the pancreas, most likely an inflammation, in most cases at least, but not of the hemorrhagic type and without evidence of necrosis. In most of these patients the original diagnosis did not refer to the pancreas; many were suspected of suffering from biliary colic, others of acute cholecystitis, perforated peptic ulcer, acute appendicitis, acute intestinal obstruction, and a few, coronary thrombosis. In the first cases observed the true diagnosis was revealed only at operation when the lesion in the pancreas was noted. Later it was possible to make a clinical diagnosis by studying the blood for its concentration of amylase. This determination when made at the height of the patient's symptoms and repeated as the clinical manifestations subsided, revealed a striking correlation with the course of the attack. In a few patients both objective evidences of pancreatitis were obtained, i.e., the rise and fall of the blood amylase and anatomical changes through biopsy of the pancreatic lesion.

As far as the clinical behavior itself is concerned the bed-side manifestations frequently gave only suggestive indications of the true nature of the disease. In all cases, the attacks were severe and disabling, the patient seeking bed rest at once. The pain was often cramp-like in character and nearly always accompanied by vomiting. While located in the mid epigastrium, the pain was often more severe to the right or to the left of the midline and occasionally was diffuse. A nearly constant feature was the reference of the pain to the small of the back, i.e., over the spines of the lumbar vertebrae. Occasionally the pain was referred to the mid-scapular region. Attacks varied in severity and duration, but rarely did they exceed four days before subsidence. Only occasionally were patients seen in their first attack; a history was fre-

*Read at the Annual Meeting of the American Gastro-Enterological Association, Atlantic City, June 7-8, 1937.
From the Department of Surgery, Washington University, School of Medicine, and Barnes and St. Louis City Hospitals, St. Louis.

quently obtained of a few to many previous attacks, sometimes extending back for many years.



On examination, these patients, when seen at the onset of the attack, were in obvious distress due to severe pain; though prostrated they were not in shock as shown by a normal pulse and blood pressure; there was no cyanosis or evidence of circulatory collapse. The temperature, however, in a few cases became moderately elevated. The abdomen was often slightly distended and diffusely tender but nearly always revealed on careful palpation a transverse zone of more marked deep tenderness in the epigastrium over the region of the pancreas. In a few cases I was also able to outline a Head-zone of skin hyperesthesia along the left costal margin. In nearly all patients a mild scleral icterus could be made out especially if the examination occurred during daylight; others showed more evident jaundice. Aside from the blood amylase findings to be described in detail below, the laboratory tests were non-specific. A leucocytosis was frequently observed but often absent; routine urine examination was negative. However, a high icteric index was noted when looked for and in many cases urobilin was found in the urine. Although I feel that the above outlined clinical picture may perhaps enable a reasonably accurate impression to be made, I have refused to make a definite diagnosis of acute pancreatic disease unless a high blood amylase was found in a specimen obtained while the patient was suffering from acute symptoms; with subsidence of the attack the concentration of the ferment progressively decreased. In all the cases herein reported such determinations were made.

The basis for the use of the blood amylase in the diagnosis of pancreatic disease rests on many experimental observations, which show, in general, that obstruction of the pancreatic duct and inflammation of or injury to the pancreas is associated with a marked elevation in the normal level of the amylase in the blood. This correlation has been so uniformly confirmed that it really does not matter whether the amylase in the blood is wholly or merely in part of pancreatic origin. For diagnostic purposes it suffices that the blood amylase reflects, very rapidly and markedly, acute changes in the pancreas. I had occasion to note this fact many years ago while working with dogs, in whom a complete external pancreatic fistula had been installed. The tube draining all of the secretion was clamped, producing a sudden total obstruction. Within 15 minutes the blood amylase had doubled in value; in an hour it had quadrupled. After 24 hours of total pancreatic obstruction the blood amylase was 20 times above its normal level. It has also been shown (Somogyi) that mere palpation of the pancreas during a laparotomy is associated with a transient but marked increase in the level of blood amylase.

SUMMARY OF CASES

(All showed characteristic blood amylase curves, shown in accompanying charts)

	Case age, sex)	Duration of attack (days)	Previous Attacks	Admission Diagnosis	Jaundice	White Blood Count	Highest Temp. (F)	Cholecystogram	Remarks
Chart 1a	39 F	10	many	Biliary Colic	+	9,200	99°	normal	—

Blood Amylase (as mg. of glucose per 100 c.c. blood)

Chart 1a (see page 87) Chart 1b

In all of the patients herein reported a marked elevation of the blood amylase was found at the first examination. The highest values were noted in those examined early in the course of their attack and in those with the severest attacks. In all, however, a progressive fall in the blood amylase was observed, often within a matter of hours, more commonly after a day or two, but in most instances in striking correlation with the subsidence of the patient's symptoms. Whenever the serum was examined for bilirubinemia it was found in moderate degree, which, however, with the amylase, returned to normal.

TREATMENT

The therapy advised and carried out in these patients (after the attack had subsided) depended upon the presence or absence of associated cholecystic disease as revealed by clinical and laboratory study, especially by cholecystography. They may be divided into three groups, those with, those without cholecystitis, and those who had already been cholecystectomized.

1. If stones were demonstrable or if an abnormal shadow or no shadow followed the intravenous test operation was usually advised. I say usually because in a few instances the cholecystogram became normal with the lapse of time. When operation was carried out soon after an attack the existence of a diseased pancreas was detected, provided that the gland was exposed adequately. Visualization of the pancreas (by separation of the gastrocolic omentum) frequently revealed fat necrosis, and biopsy of the indurated tissue showed interstitial inflammation, edema and fibrosis. The diseased gall bladder was removed and the common duct explored through the cystic duct; in each instance I have observed an impediment to the passage of a bulb-tipped probe into the duodenum. This I interpreted as a spasm of the sphincter of Oddi which was dilated with bulbs of increasing caliber. A cysticocholedochostomy, i.e., drainage of bile through the cystic duct was then carried out.

2. When cholecystography revealed a normal shadow without stones, a medical regime consisting essentially of a liberal diet taken, however, in small frequent feedings was instituted; a mild sedative such as phenobarbital was also prescribed, because I felt that the fear of these attacks in many patients may have played a role in initiating some of them. These patients eventually got well; the attacks subsided in frequency and thus far many of them have required no further therapy. The follow-up has, however, been too recent to draw any definite conclusions.

3. When the patient has already had a cholecystectomy the same medical regime was followed. One must, to be sure, exclude the existence of stone in the common duct in this group of patients; this differentiation can usually be made on clinical grounds alone. If a stone is present a secondary operation is obviously indicated. It has been my observation, however, that in most instances operated upon for such a reason, no stone was found in the common duct but that the pancreas showed evidence of inflammatory disease.

DISCUSSION

DR. JULIUS FRIEDENWALD (Baltimore, Md.): Dr. Elman has presented a highly interesting and important paper. It is a well accepted fact that certain instances of acute pancreatitis are occasionally observed which, although ushered in with fulminating symptoms, soon lose their intensity and continue as milder types of the disease. Among such cases, without doubt, may be included some referred to by Dr. Elman.

There are, however, other cases which are extremely stormy in their onset, in which operation is contemplated, but delayed due to shock or other complications which also occasionally recover even without surgical intervention.

Up to recently most of the milder instances of this affection have been incorrectly diagnosed or have been recognized only at operation. It is to these milder forms that Dr. Elman has called special attention in his presentation, and in which the diagnosis was confirmed by means of the determination of the amylase concentration in the blood.

In our experience many of the cases of acute pancreatitis are affected at the onset with intense pain in the upper abdomen, with tenderness in this region associated with shock, often suggesting the presence of perforation and at times of obstruction. The pain is usually constant, though occasionally it is intermittent. Vomiting is excessive, followed later by anorexia. Hypoglycemia is observed in the stage of shock in addition to leukocytosis. As the disease, however, progresses into the subacute

Blood Amylase (as mg. of glucose per 100 c.c. blood)

Chart 2a (see page 87) Chart 2b

stage, or in the milder types, hyperglycemia may be encountered. In this form, subsidence of symptoms with recurrences is not infrequently noted, and the symptoms appear as mild manifestations of anorexia, weakness, upper abdominal distress, and pain often to the left of the mid-epigastrium and back, with constipation or diarrhea associated with fatty stools. Tenderness over the entire epigastrium is noted.

Many of these cases are complicated with cholelithiasis and present a history of previous attacks of gall stone colic. All of our operated cases, as well as a few in which surgery was not undertaken, presented this complication.

In the milder instances of this disease, conservative management is advisable at least for a certain period of time, especially in the absence of gall stones instead of undertaking a surgical procedure at an inopportune time. In many of these cases, under proper dietetic restrictions, with the addition of occasional duodenal drainages and symptomatic medication, the acute stage lessens in intensity and finally subsides.

Inasmuch as the symptomatology of this affection, especially in the milder types, is by no means characteristic, Dr. Elman has contributed a valuable lesson in the diagnosis by emphasizing the importance of the presence of a high blood amylase content in the acute stages of the disease and its gradual decrease and disappearance with the subsidence of the attack and improvement in the patient's condition. It seems evident, therefore, that if this test be applied more frequently, many hitherto undetected instances of this affection can be recognized at an early stage. Attention should be directed to the fact, as Mahner, as well as others, has pointed out, that a high diastase content likewise occurs in the urine of relatively mild cases of acute pancreatitis, which is also an indication and gives further proof of organic disease of the pancreas.

Another test, the serum lipase reaction, is similarly of diagnostic value especially in the acute or subacute cases, and may likewise be taken advantage of in the diagnosis of obscure cases.

DR. M. A. McIVER (Cooperstown, N. Y.): I was very much interested in Dr. Elman's paper and the very interesting group of cases he described. I don't doubt for a moment, in fact I think it is universally recognized, that there is a group of cases of mild acute pancreatitis that really constitutes a clinical entity; but I think it is often very difficult to be sure of the diagnosis, and I take it that in a great many instances it would really come down to dependence on the amylase test.

I should like very much to ask what Dr. Elman's experience has been with this test in cases of frank hemorrhagic pancreatitis. I have been rather disappointed in it as a diagnostic test in the few cases of the hemorrhagic type in which we have tried it.

DR. GEORGE B. EUSTERMAN (Rochester, Minn.): Von Bergman and his associates have reported this type of condition for the last several years and have made valuable contributions to the diagnosis of the disease. They classified it as a subacute pancreatitis and I am wondering whether the entity described by the essayist is not identical. One should always be cognizant of the possibility of this condition. Aside from metastatic infections, there are four commonly accepted etiological factors giving rise to subacute and acute forms of pancreatitis, namely, cholecystic disease, obesity, perforated ulcer of the stomach and duodenum implicating the pancreas and syphilis. The last case of this type which I saw, that was convincing from a purely clinical standpoint, was about a year and a half ago in a middle aged obese male. For five months prior to his admission he had been treated on the basis of a high, perforating ulcer of the stomach, the presence of which we were unable to confirm. Other diagnoses were left renal stone, spondylitis, gall bladder disease with transposition of symptoms, etc. We had the good fortune to see him in one of his subacute seizures, at which time he had the characteristic radiation from the upper left epigastrium through to the back, hyperasthesia, marked tenderness, elevation of serum lipase and urinary diastase, etc. Cholecystographic examination was negative.

On dietary restrictions, with marked reduction in fat and protein, and increased carbohydrate, he made a prompt recovery and has not been troubled since.

DR. HENRY A. RAFSKY (New York, N. Y.): Dr. Elman has presented a distinct clinical entity. These cases are very often difficult diagnostic and therapeutic problems. This was graphically illustrated in a patient who was admitted to the Gastro-Intestinal service at the Beth Israel Hospital. The case presented the clinical picture of intestinal obstruction. The surgical division refused to operate upon this patient because it was thought that he would not survive. Medical treatment was then tried. I shall discuss the treatment shortly, but first I would like to point out some interesting phenomena which were noted. The patient ran a febrile course for several days with daily fluctuations of his temperature. When fever was present a hyperglycemia and glycosuria were observed. When the temperature fell, the blood sugar and urine were normal. The treatment consisted in decompressing the stomach and duodenum by duodenal instillations. His symptoms subsided. It was thought of interest to stop the treatment to see what would happen. The symptoms recurred. Then duodenal instillations were again instituted and the patient made an uneventful recovery. He has not had a recurrence of the symptoms. An X-ray of the gall bladder showed it to be enlarged; no stones were found.

DR. JOHN R. TWISS (New York, N. Y.): I should like to ask Dr. Elman, in regard to the treatment of these conditions, whether he does not feel there is a certain element of danger in doing a cholecystectomy. In our experience this type of pancreatitis is likely to be recurrent. The common bile duct goes through the pancreas and, in the absence of the gall bladder, a serious problem is likely to be presented at a future date. For that reason, in the New York Post Graduate Hospital, we have preferred to do a cholecystostomy rather than a cholecystectomy.

DR. ROBERT ELMAN (St. Louis, Mo.). (closing the discussion): I wish to thank the discussers for the many interesting points brought up in regard to the paper.

As to Dr. McIver's question, the blood amylase is also elevated in acute pancreatic necrosis; the curve is perhaps more prolonged in the beginning, but drops very rapidly after a few days. This drop, however, is not due to subsidence of the inflammation, as revealed by the cases that have come to autopsy. Two cases of pancreatic necrosis died without operation which was refused in both instances. At autopsy the entire pancreatic gland had become destroyed, i.e., there was no pancreatic tissue to produce amylase. This brings up the question as to the source of blood amylase; there is much evidence to show that the pancreas is the source of a large amount of it, if not all.

Although the high blood amylase does not reveal the nature of the process in the pancreas, there has been no difficulty in our cases in saying here that this is a patient that has non-hemorrhagic pancreatitis, and that operation isn't necessary; the decision is made on clinical grounds alone, solely because of the circulatory collapse which is so characteristic of pancreatic necrosis and which is absent in non-hemorrhagic pancreatitis.

In regard to Dr. Eusterman's question, many of the reports of subacute and other types of pancreatitis are based upon purely clinical surmises; disease of the pan-

creas is so difficult to diagnose at best that I haven't considered any of the reports in the literature except those in which amylase studies or lipase studies have been made, or in which the organ was observed anatomically at operation or at autopsy; otherwise one has difficulty evaluating many observations which rest upon rather inconclusive evidence in regard to the presence of a lesion in the pancreas.

Dr. Rafsky's question in regard to the temperature is interesting because most of our patients showed at one time or another an increase in temperature, sometimes as high as 102 or 103 degrees F., which usually subsided though sometimes recurrent, in the course of forty-eight hours.

The large gall bladder is also an interesting point. Although I have not made such an observation, many of the cases reported in the literature showed a dilated viscus during operation, when performed during the acute attack; many of them, moreover, contained no stones. An obstruction at the lower end of the common duct, as it traverses the head of the inflamed pancreas, may be a mechanism in the production of the dilated gall bladder as well as of the jaundice.

Dr. Twiss brought up the question of cholecystectomy. I believe that in itself cholecystectomy has a beneficial effect; there is evidence from a number of sources that the common duct and the sphincter of Oddi dilate and the sphincter becomes insufficient following removal of the gall bladder. This is perhaps the explanation of the fact that many of these patients do not have a recurrence of symptoms. However, Dr. Twiss' observation that they may have recurrent pain (I cited above three such patients) indicates that this mechanism does not operate in all instances. I have felt that if spasm of the sphincter of Oddi is the etiological mechanism, dilatation at the time of operation should also be carried out, as well as the cholecystectomy; doubtless further research will indicate the proper procedure.

Back Pain in Lesions of the Gastro-Intestinal Tract, with Particular Reference to Duodenal Ulcer*

By

WILLIAM JASON MIXTER, M.D.
BOSTON, MASSACHUSETTS

ALMOST all the ills that flesh is heir to may cause pain in the back. We have come to recognize at a glance, and to pigeon hole back pain of certain types and back pain in association with other symptoms with hardly an error. Nine times out of ten we are right, but occasionally pain in the back will lead us astray and even with all the aids that medical science affords we fail utterly to arrive at the correct diagnosis. It is also true that lesions of the back, particularly lesions of the spinal meninges may cause abdominal discomfort simulating disease of abdominal viscera. Without going over the records I can recall two gall bladders, two appendices, one fibroid and one kidney that had become surgical specimens prior to the removal of the true cause of pain; namely, a tumor of the dorsal cord.

As a neurosurgeon I see a good many cases of intercostal neuralgia, tumor of the spine, and what not and have learned to be wary of pitfalls but errors in diagnosis will creep in. We all recognize the existence of and fear the silent ulcer of the duodenum which strikes murderously, without warning; the first evidence of which is hemorrhage or perforation. We must not forget the frequency with which ulcer will conceal its presence behind a smoke screen of back pain.

Your President, Dr. Chester M. Jones, has been much interested in the production of pain by means of a balloon in the gastro-intestinal tract and his experimental data fits in perfectly with the small group of cases I wish to report. In all seven of these patients the main symptom was pain in the back with little or nothing that would suggest a lesion of the duodenum.

Case one happens to be myself. Many years ago, I began having quite severe pain in my back. This pain usually began in the late afternoon and was particularly noticeable if I had driven my car a good deal during the day. The pain was dull in character, seemed to centre at my 5th or 6th dorsal vertebra and was not associated with any abdominal discomfort. I wore a back brace for nearly a year and did posture exercises with fair regularity. Finally it was noticed that the pain was relieved by taking food. This fact made us suspicious and on X-ray evidence a diagnosis of pyloric spasm and later of ulcer was made. During the years which followed I tried to keep track of my pain, observing its location and its association with other symptoms. I had a good deal of abdominal pain, but many times for no apparent reason the pain would be solely between my shoulder blades, sometimes to the right and sometimes to the left. A most interesting and often repeated experience was a rather sharp tingling pain streaming down the ulnar surface of my left arm. This pain was always associated with a sense of chilliness and usually with such active gastric peristalsis that I could feel it. Another peculiar symptom was excessive salivation associated with pain just to the left of the 5th or 6th dorsal vertebra. It may be of interest to you to know that since resection of the ulcer seven years ago, I have been perfectly well. My ulcer was of the saddle type, involved both the duodenum and pylorus and had evidently leaked a little posteriorly at some time.

Case two was that of a woman of 48, sent to me by Dr. Richard Ohler. She had a history of attacks of pain in the back and left chest running back to 1907. She was said to have had pulmonary tuberculosis but there is no history of any positive evidence of that disease. Four years ago the pain was so severe that she was in bed or on the sofa for four months. The attack for which I saw her had been going on for seven months. The pain was increased by exertion and by driving her car. The pain was in her left back, circled around the 5th or 6th rib and stopped sharply at the midline in front. She stated that the pain would vary in intensity and that the skin in the region involved was tender. There was some pain in the arm at times and deep breathing caused sharp twinges

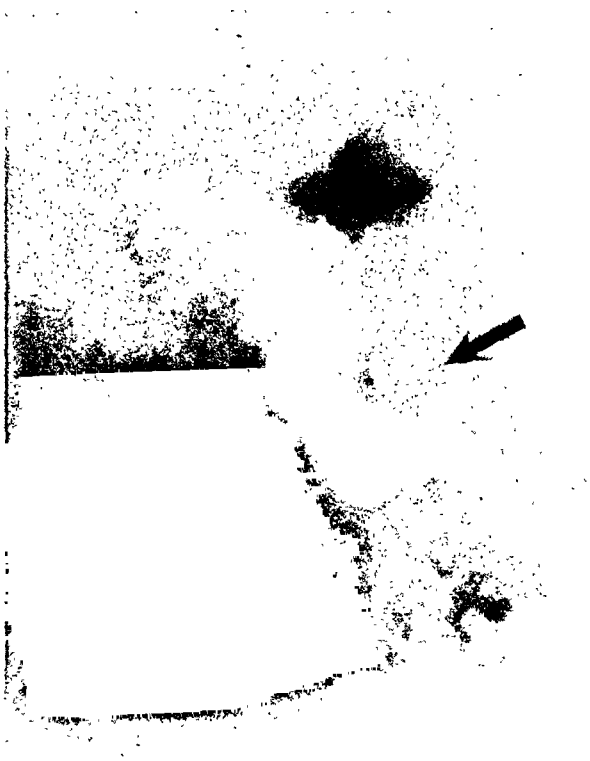

Fig. 1. X-ray Case No. 3. Showing ulcer. (M. G. H. U47867).

of pain in her left chest. She denied indigestion or abdominal distress. Her bowels were constipated. She was taking a good deal of codeine and some morphine to control the pain.

Examination was negative except for definite hyperesthesia girdling the left side of her chest at the level of her pain. She was carefully studied in hospital and all tests including lumbar puncture and electrocardiogram were negative except for an X-ray diagnosis of arthritis of the spine and a white count of 11,000 to 13,000. Gastro-intestinal X-ray examinatioan was not done. A week after she left the hospital she had a massive hemorrhage and after repeated transfusions was operated on by Dr. R. H. Smithwick as an emergency. Exploration revealed a large ulcer of the posterior wall close to the ampulla of Vater with hemorrhage from a vessel in the pancreas. The vessel was tied, pylorus and first portion of the duodenum resected and a posterior gastro-enterostomy performed as it was impossible to resect the ulcer. Her convalescence was stormy but complete and at no time has she had any return of her old pain.

Case three followed within a few weeks. The patient was a physician aged 60 with a history of rheumatic heart disease eighteen years before. As he was recovering from this illness he began having attacks of "neuralgia" starting with a stabbing pain in the back and encircling his chest on both sides to the substernal region. These attacks were brought on by exertion, excitement or fatigue and relieved only by morphine. At times he was unable to sleep on his left side. His history states under gastro-intestinal tract, "Appetite good. Well rounded diet. No acid eructations, tarry stools, gas, constipation, or deep abdominal pain."

He was carefully studied and lumbar puncture done. As his total protein was 77, a lipiodol examination was made which was negative. His spine showed arthritis. X-ray examination of the gastro-intestinal tract showed a small hiatus hernia and duodenal ulcer with a deformed cap.

He was put on a gastric regime and on account of the severity of his pain was given a bilateral paravertebral alcohol injection with marked relief. He did not believe that ulcer played any part in his condition, went back to his regular diet as soon as he left the hospital and nearly died of hemorrhage a few weeks later. Since then he has been on a definite gastric regime and recent X-ray examination shows that his ulcer has healed. He is having no pain in his back.

There is no need to cover in detail the other four cases. Case four had right sided pain extending round to the lower end of his sternum and no gastro-intestinal disturbance. He also had a posterior wall ulcer in the second portion of the duodenum. He was operated on by Dr. R. H. Smithwick, the procedure being similar to that carried out in case two, except that there was no necessity of controlling hemorrhage. He has had no return of his old pain since operation.

Cases five, six and seven were found for me in his own files by Dr. Chester M. Jones. In number 5, the story is very similar to the others, pain coming on after rowing on a college crew late in the afternoon. There is, however, a history of mild indigestion. After a long period of orthopedic treatment which was of no avail, X-ray examination was made of his gastro-intestinal tract. This was done largely for purposes of exclusion. The examination revealed the presence of a frank ulcer.

Cases six and seven are similar except that in both instances there was a history of indigestion. Number six insisted that the back pain could have no connection with the ulcer pain which he had had for years. In both of them the back pain was out of all proportion to the rest of the picture. Both showed typical ulcer. These last two cases are not so startling as the first five, but they are suggestive.

These cases fit in very well with Dr. Jones' experiments with the balloons. Of 24 subjects in which the balloon was in the duodenal cap only one felt pain in the back alone and three had pain that went through from the xiphoid to the back.

Thus in the balloon experiments back pain is rare, as it is in the clinical cases, but it does occur. The level of the back pain coincides with the level in our patients. In the second portion of the duodenum six individuals referred the pain straight through to the back or around the costal margin. You will remember that one of our cases had proven ulcer of the second portion of the duodenum. The level in the balloon experiments would seem to be slightly lower than in our patient.

There are two other factors that may be of interest. One is the posterior position of the ulcer in at least four of our cases and the fact that three and possibly four had eroded through the posterior wall, involving the pancreas in at least two.

The more I theorize on the pain pathways from the duodenum and the reasons for the wide variation of the position of the referred pain the less do I feel we know about this subject. We know that the splanchnic nerves enter the cord from the 5th to the 12th dorsal levels and it would be reasonable to suppose that stomach and duodenum would be represented in the upper part of this portion of the cord.

Also we know that divulsion of the splanchnic nerves under local anesthesia causes severe pain.

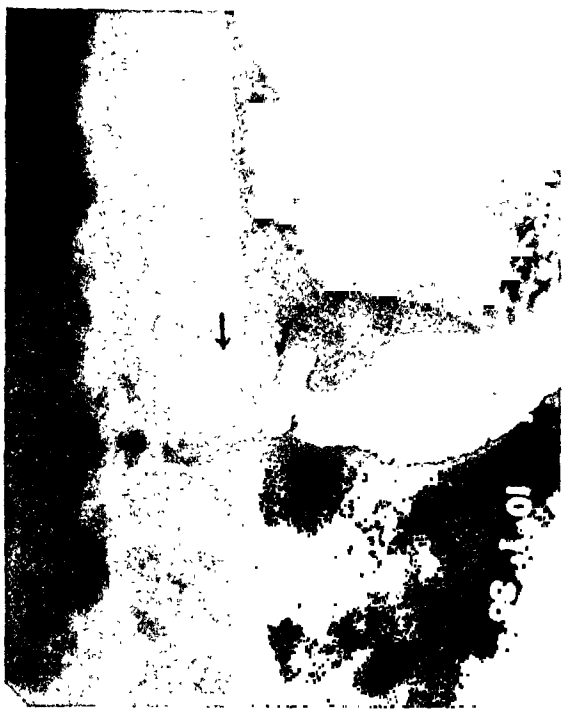

Fig. 2. X-ray Case No. 4. Showing ulcer. (M. G. H.-B. M. 25489).

Unfortunately, the preoperative medication used in operations for splanchnicectomy prevents these patients from giving an accurate description of the pain. But if this pain represents the somatic distribution of splanchnic fibres why should it vary so much? Why should it not always be substernal? And also why should not pain from the back wall of the duodenum be referred to the right side of the body and not the left. It seems that we must fall back on other factors. It would seem probable that the pain is due, in part at least to spasm of the muscle of the gut. If so, the actual position of the ulcer in the circumference of the intestine would not be so important. Perforation with involvement of the pancreas and possibly the posterior portion of the parietal peritoneum may tend to throw the reference of pain through to the back. We must admit our own weakness and hope that further experimental work will clear this matter up.

I have had far less experience with patients in whom back pain has been caused by lesions of other portions of the gastro-intestinal tract. We all know that pain in the low back may be caused by lesions of the rectum and our colleagues in the Genito-Urinary Department are all familiar with the peculiar pains caused by lesions of those systems. It seems to me that these examples, the extraordinary distribution of cardiac pain and our knowledge of gall bladder pain permits us to generalize on referred pain from any part of the intestinal tract. I believe we can expect that a certain small percentage of lesions anywhere in the gastro-intestinal tract will be signalized by pain in the back without the signs we usually associate with gastro-intestinal disease.

Certain it is, that pain in the back or pain radiating about the chest may be the only sign in duodenal ulcer, even in extensive perforating ulcer of the posterior wall of the duodenum. It behooves us, gastro-enterologists, orthopedists, neurosurgeons and general practitioners alike, to remember this fact.

It is by our errors that we learn. The fact that I, and others with me, have erred in diagnosis in this group of patients is my reason for addressing you. I have brought you nothing that is new. If I have impelled you as gastro-enterologists to warn your colleagues in other branches of medicine to remember the duodenum, this paper is justified.

DISCUSSION

DR. RALPH C. BROWN (Chicago, Ill.): Dr. Mixter has made a valuable and timely contribution, for I am sure that not sufficient emphasis has been laid upon the frequency with which pain in the mid-dorsal region, and often very severe pain, may be caused by peptic and especially duodenal ulcer.

There are certain duodenal ulcers which are not easily recognizable by X-ray, and it is possible that it is precisely this type which because of its anatomical relationships is most likely to involve the pancreas. I refer to lesions far out at the tip of the cap where the first portion of the duodenum so often turns abruptly downward and backward. The flouroscopist sees a large, well filled, symmetrical cap, but unless he uses great care, may overlook the canalization existing at the flexure, just where it turns down. If the clinician is not at hand with strong clinical evidence of ulcer, a lesion so situated may easily escape X-ray recognition.

A case in point was referred for diagnosis by one of the ablest internists in Michigan. The clinical picture was that of ulcer, but a highly competent roentgenologist could find no evidence of ulcer. Pain in the back led to a tentative diagnosis of gall bladder disease. Operation was advised, but the surgeon was reluctant, on the evidence, to operate. Our roentgenologist at the Presbyterian Hospital also missed the lesion at his first examination, the cap appearing perfectly normal. However, clinically the man had duodenal ulcer with a marked degree of pyloric obstruction, our evidence being gained by the fact that during the night time he had such severe pain that we were forced to empty his stomach and secured very large amounts of retained food, and at operation an inflammatory mass about the ulcer the size of an egg was found, involving the pancreas, illustrating the extent of pathology that may exist in a case where two or three highly competent roentgenologists had failed to recognize *the ulcer.*

Again we see, although certainly not very often, duodenal ulcer involving the pancreas, causing severe pain which *originates* in the mid-dorsal area, and, while it may radiate to the abdomen, is localized by the patient chiefly in the back.

I recently saw a striking instance of this, a case I had seen in consultation with Dr. Herrick some twelve years ago. The patient was gastro-enterostomized eight years ago with relief for one year, but since then for seven years she has had recurrent periods of excruciating mid-dorsal pain, high mid-dorsal, occurring with clock-like regularity in relation to food-taking. This was believed by one of my colleagues, for whom I have the utmost respect as an internist, to be on the basis of a spinal arthritis. More recently she has had not only complete relief, but also has been in an excellent state of general health on sufficiently careful ulcer regime.

Fortunately, the pancreas is to a marked degree resistant to peptic digestion, but the fact that the back pain of ulcer may be related to an associated pancreatitis is shown by a case seen two years ago in a robust young man who, six months prior to my observation, had had,

as an initial ulcer experience, a formes frustes type of perforation. A typical ulcer symptom picture developed. The perforation occurred while he was on a vacation in Bermuda, and, as stated, during the succeeding weeks and months a typical epigastric ulcer type of pain developed. He also had very severe pain precisely in the left lumbar region which we found extremely difficult to interpret. This would keep him awake during all the hours of the night, and for a brief period he suffered greatly. Pyelograms and X-ray films of the kidney were negative. Because of a demonstrable duodenal obstruction due to the ulcer he was operated upon and the surgeon reported that the duodenum was shortened and bound down to the pancreas with a mass on the posterior duodenal wall. The surgical report states: "The pancreas was as wide as my three fingers, at the head, and considerably thickened." It is obvious that we could account for the left lumbar pain on the basis of a diffuse, subacute pancreatitis. The surgical diagnosis was: "Acute duodenal ulcer with acute pancreatitis."

I wish to strongly emphasize the point that an essential requisite in diagnosis in the group of ulcer cases with back pain is accurate history-taking.

DR. SARA M. JORDAN (Boston, Mass.): I think the society is to be congratulated on this idea of Dr. Jones's that we should have at this meeting a correlation of internal medicine and gastro-enterology. Dr. Mixter has just given us a paper which demonstrates the importance of back pain in gastro-enterology. In our experience at the clinic, we feel when we have a patient who has backache, that if the orthopedic, the neurological and the gynecological services are convinced that the cause of the backache is not to be found in their fields, we should investigate the gastro-intestinal tract.

We often find that backache is due to some condition in the colon, frequently just a functional condition, spasm or dilatation. I think Dr. Mixter also mentioned spasm of the colon as causing backache. We find it frequently relieved completely by the relief of the functional condition in the colon.

Low dorsal backache we have come to regard with a good deal of importance from the gastro-enterological standpoint inasmuch as we find that an ulcer either of the duodenum or of the stomach, which has involved the posterior wall and penetrated into the pancreas, is often the cause of backache and may indicate that an ulcer cannot be healed with medical measures because it involves the adjacent pancreas.

Acute Abdominal Pain from Upper Urinary Tract Lesions*

By

ALEXANDER RANDALL, M.D.

and

BOLAND HUGHES, M.D.

PHILADELPHIA, PENNSYLVANIA

ACUTE abdominal pain is often the first symptom of upper urinary tract disease. Frequently the abdominal pain and associated gastro-intestinal symptoms, though entirely renal or ureteral in origin, are so typical of the acute surgical abdomen that laparotomy is performed. This is more likely to occur if upper urinary tract symptoms are minimal or, as is often the case, completely absent.

In studying the viscero-visceral reflex that permits this 'transfer symptomotology' we are primarily concerned with two factors:

1. Conditions under which painful stimuli arise in the upper urinary tract.
2. Mechanism by which this pain is referred to abdominal cavity.

Painful stimuli from the upper urinary tract have either an intrinsic or extrinsic origin. Intrinsic stimuli arise from irritation of the vegetative nerve endings within the urinary tract; extrinsic from irritation of the cerebrospinal sensory nerve endings in the peri-urinary parietal peritoneum. Both intrinsic and extrinsic pain may masquerade as symptoms of acute intra-abdominal disease, each, however, by a different anatomical-physiological mechanism.

INTRINSIC PAIN STIMULI

Intrinsic pain can arise from the renal pelvis, renal capsule or ureter. The vegetative nerve fibres which accompany the renal blood vessels into the parenchyma apparently transmit only vaso-motor and not pain impulses. We know surgically that, when operating under local anaesthesia, we can incise the kidney parenchyma without causing pain. We also know that *ordinary* stimulation of the capsule, pelvis or ureter does not cause any sensation. This, of course, is true of all tissues which are innervated by the autonomic nervous system in contradistinction to those tissues innervated by the cerebro-spinal system. Painful stimuli, however, do arise: (1) if the renal pelvis or ureter are suddenly distended due to urinary obstruction, (2) if the renal capsule is suddenly distended due to parenchymal swelling, (3) if the renal capsule is involved in an acute or sclerotic inflammatory process. If distension of the renal pelvis, ureter or capsule be gradual pain usually does not occur.

These intrinsic painful stimuli are mediated through the visceral afferent fibres which traverse the renal plexus. In man the renal plexus is composed principally of branches from the coeliac ganglion which in turn receives connections from the vagus and splanchnic and also from the superior mesenteric ganglion and aortic plexus. Jost was able to demonstrate in the rabbit a definite connection between the abdominal sympathetics and the renal plexus and this connection was clearly shown in man by the careful anatomical dissections of Hirt. In addition, the splanchnic minor always sends a direct branch to the kidney—the post-renal nerve (Henle). We see, there-

From the Department of Urology Hospital of the University of Pennsylvania.

fore, that, through the sympathetic system, the upper urinary tract enjoys direct nervous contiguity with the gastro-intestinal tract. Kölliker and later Langley have proven histologically that the sympathetic system contains afferent senory fibres. The actual viscero-visceral reflex of intrinsic pain transfer from the upper urinary tract to the gastro-intestinal tract occurs in the spinal cord but, differing from viscero-sensory and viscero-motor reflexes, the irradiation is not confined to one segment but is transmitted through the entire cord and brain stem. This multi-segmental cord irradiation explains the variegated systemic manifestations of upper urinary tract pain.

We must consider the entire question of upper urinary tract symptomotology not from a standpoint of individual disease entities but from that of system-physiology. Any pathological process may produce intrinsic pain stimuli if any of the three pre-requisites already outlined are satisfied; any pathological process may remain symptom-free if they are not satisfied. Thus we may have slow-growing stones completely filling both renal pelves and causing great impairment of kidney function without ever producing intrinsic pain. We also see the severest renal colic resulting from temporary blockage by a minute stone fragment dislodged from the renal papilla.

We must also consider the question of pain transfer to the gastro-intestinal tract in the same manner. There are anatomical, physiological reasons and clinical data to support the statement that any lesion of the upper urinary tract which produces intrinsic pain stimuli may be referred by means of a viscero-visceral cord reflex through the sympathetic system to the abdominal cavity as indefinite non-localizable pain. Considering the fact that in this pain transfer to the abdominal cavity, true upper urinary tract symptoms may be minimal or absent, we should accept as a diagnostic necessity the urographic examination in all cases of abdominal pain which is not explained by definite intra-abdominal pathology.

This diagnostic axiom, however, is even more applicable to those cases of upper urinary tract disease causing extrinsic pain stimuli. Let us consider this more in detail.

EXTRINSIC PAIN STIMULI

As already mentioned, painful stimuli from the upper urinary tract can also arise from irritation of the sensory nerve endings in the parietal peritoneum by peri-renal, peri-pelvic or peri-ureteral inflammation. Whereas the visceral layer and serous surface of the parietal layer of the peritoneum are insensitive, the outer surface of the parietal layer is abundantly supplied by sensory cerebro-spinal nerve fibres.

Chronic infectious processes of the peri-pelvic or peri-ureteral structures do not, as a rule, sufficiently irritate the sensory nerve endings in the parietal peritoneum to cause pain. An exception to this, however, occurs in chronic perinephritis, particularly in the sclerotic type associated with the contracted pyelonephritic kidney.

Often, however, a chronic peri-pelvic or peri-ureteral inflammation is the deciding factor as to whether sufficient acute distension will result from a renal ptosis to cause painful stimuli to arise from the intrinsic vegetative nerve endings. In this case the pain would be entirely of the intrinsic variety.

Typical extrinsic pain practically always occurs if the peri-renal, peri-pelvic or peri-ureteral inflammation is acute or sub-acute in character. We have known clinically that acute perinephritis or peripyelitis produces pain which does not radiate and which the patient can always definitely localize to the renal region. This same localization of the pain occurs in acute or sub-acute peri-ureteritis.

It is this peri-ureteral syndrome that simulates, more than any other lesion of the upper urinary tract, acute inflammatory or obstructive gastro-intestinal disease. Capps has shown that stimulation of the parietal peritoneum gives rise to direct pain which is accurately localized by the patient at the site of irritation. It is this accurate localization which distinguishes extrinsic from intrinsic upper urinary tract pain. It is the location of the peri-ureteral inflammation which determines whether the pain resembles that arising from acute disease of the right or left upper abdomen or right or left lower abdomen.

To illustrate this, we have selected the following cases of peri-ureteral inflammation for presentation because in each case the outstanding, and for a time the only symptom was abdominal pain simulating that of the acute abdomen.

It is impossible, however, by urogram alone, to diagnose an acute or sub-acute peri-ureteritis. Roentgenologically there are the same findings as in a chronic peri-ureteritis plus the clinical evidence of fever and acute pain localized to the area of parietal peritoneum directly affected by the inflammatory process. On urogram, however, the following findings are significant: (1) fixation of the ureter (on more than one plate), (2) dilatation of the ureter or pelvis above the affected area, (3) impaired or absent kidney function in those cases in which a chronic peri-ureteritis slowly occluding the ureter has existed previously. When kidney function is impaired or absent, we can only obtain the roentgenological evidence of peri-ureteral pathology by retrograde pyelogram.

Case 1. Survey film of abdomen and intravenous urogram of male patient fifty-eight years of age, admitted to the hospital with diagnosis of beginning intestinal obstruction. Acute constant pain in extreme lower abdomen. Temperature 100° F. Survey film shows distension of large intestinal loops. Urogram shows poorly functioning right kidney, no visualization of right ureter, distension of left ureter to point of narrowing in extreme lower portion. History of suprapubic prostatectomy three years previously. Minimal urinary symptoms, though residual urine found to be 350 c.c. Patient treated with indwelling catheter with subsidence of acute abdominal pain within twenty-four hours. Subsequent cystoscopy revealed a definite ureteral constriction on the right side 5 cm. above ureteral orifice. Constriction also on left side at point indicated on urogram. Vesical orifice shows fibrotic contraction. Endovesical resection performed later. Acute abdominal pain relieved, however, by catheter drainage. Etiology of abdominal pain—acute exacerbation of bilateral chronic peri-ureteritis resulting from infection of adnexa.

Case 2. Intravenous urogram of female patient, age sixty-two, who was admitted into the hospital with acute pain in lower left abdomen. No urinary symptoms or signs. Slight elevation of temperature. Abdominal pain so severe that exploratory laparotomy was performed,

suspecting an acute diverticulitis. Urogram done post-operatively reveals a non-functioning left kidney. At cystoscopy it was impossible to insert catheter beyond the ureteral meatus though the meatus itself was perfectly normal. Diagnosis—acute exaceration of chronic occluding peri-ureteritis. Complete absence of kidney function. After prolonged febrile course, patient discharged symptom-free.

Case 3. Air-pyelogram revealing a ureteral constriction on the right side opposite the lower border of the fourth lumbar vertebra. Constriction due to peri-ureteritis apparently originating from within the ureter itself due to ureteral stone which, at time of cystoscopy, was pushed by the catheter to the renal pelvis. At time of admission main symptom, acute constant pain in right mid-abdomen. No history of definite lumbar pain, though patient had complained for past two years of occasional vague backache. Survey film taken because of microscopic hematuria. Acute abdominal pain due to acute peri-ureteritis at point of ureteral constriction.

Case 4. Survey film and intravenous urogram of patient admitted to hospital with diagnosis of acute appendicitis. Acute constant pain in right mid-abdomen for twenty-four hours previous to admission. History of dull, intermittent pain in same location for three months previously. No lumbar symptoms. Temperature 100-3/5° F. Urine showed moderate amount of pus cells and red blood cells. Survey film and urogram show renal stone with blockage at pelvo-ureteric junction due to peri-ureteritis, which was found at time of pyelolithotomy.

CONCLUSIONS

1. Extrinsic upper urinary tract pain due to peri-urinary inflammation may resemble the pain of the acute abdomen due to its localization at the point of irritation of the sensory cerebro-spinal nerve endings in the parietal peritoneum.

2. Intrinsic upper urinary tract pain due to irritation of the vegetative nerve endings in the renal pelvis, renal capsule, or ureter may resemble the pain of the acute abdomen due to its radiation through the sympathetic nervous system to the gastro-intestinal tract.

3. Considering the fact that in this pain transfer to the abdominal cavity, true upper urinary tract symptoms may be minimal or absent, urographic examination should be a diagnostic necessity in all cases of abdominal pain which are not explained by definite intra-abdominal pathology.

DISCUSSION

DR. LEON BLOCH (Chicago, Ill.): About six years ago I presented a paper on this subject before the Chicago Urological Society, calling attention to the fact that gastro-intestinal manifestations of urologic origin might be divided into four groups, with gastro-duodenal, biliary, colonic or appendiceal symptoms.

I shall restrict the discussion simply to that type of patient in whom the symptoms are of renal origin. One of the things we have to pay particular attention to is the finding of occasional white or red blood cells in the urine, in patients who come for gastric disturbances, because the existence of these abnormal cells in the urine should arouse our suspicions that the trouble comes, not from the gastro-intestinal, but from the genito-urinary tract.

Occasionally one encounters patients who have gastro-intestinal symptoms, in whom the urine does not show anything. An example, is the case of one of our internes who had typical symptoms of duodenal ulcer in whom, on X-ray examination, a suspicious defect was found in the duodenum, but who did not respond to treatment. The symptoms became acute and on X-ray examination of the abdomen a large kidney was found. The intravenous urography revealed a large congenital hydronephrotic kidney. Following a retrograde pylography, a temperature and chill developed.

After a nephrectomy all his gastro-intestinal symptoms disappeared. In another patient whose symptoms began acutely with very severe abdominal pain, nausea and vomiting, presumably after a meal of shellfish the night before, the diagnosis of ptomaine poisoning was made. No urine examination had been made. On the first examination in our office a few red cells were found. The patient complained of neither burning nor pain on urination.

An impacted stone in the lower end of the ureter was found on X-ray examination and when the stone was ultimately passed, he became free of all his symptoms.

Not infrequently a small stone may not be found on X-ray examination and still the patient will complain of regularly recurring distress which is sometimes very severe. An example in point is my own case. I had several attacks of renal colic and have had X-ray examinations made in several laboratories in Chicago, but no stone was ever demonstrated. It was not until after I had passed three small calculi that I became completely relieved of all my gastro-intestinal symptoms.

The important thing to remember is that in those patients in whom there are symptoms of gastro-intestinal disturbance, in whom no pathology is found in the gastro-intestinal tract on fluoroscopic and film examination, and in whom an occasional red cell or a few white blood corpuscles are found in the urine, attention should be directed to the genito-urinary tract rather than to the gastro-intestinal tract.

DR. B. B. VINCENT LYON (Philadelphia, Pa.): I should like to discuss this paper of my old classmate, Dr. Randall, from a little different view in regard to silent renal pathology.

There was a gentleman whom we reported about fifteen years ago, who was then fifty, who went through a series of passings of renal calculi without much pain, merely hematuria, and the recovery in his urinary secretion of multiple small calculi. We persuaded him finally to be studied, although he was not suffering pain and we found he had a hydronephrotic kidney with numerous stones left behind.

The interesting thing in connection with that case was that he was a polycythemic. He had a blood count of about 11.4 million, Hb. 115% and a white count of about 12,000.

This was at a period when we could find nothing in the literature as to whether polycythemia was a contra-indication for major surgery. I remember we called up most of the authoritative men in Philadelphia in medicine and surgery to find out whether we could legitimately advise him to undergo operation because of polycythemia. There was no information available. The situation was explained to the patient and he was operated upon.

Now, it is interesting that he claims himself to be a Spanish Basque, and he attributed the fact that he felt no pain in the passage of renal calculi to the supposed fact that in the Spanish Basque area they are stoics, like our American Indians. He was operated on by Dr. Leon Herman, and it was a very trying operation. The right kidney was bound down in adhesions. The man should have suffered an enormous amount of pain. I was called to the hospital that evening because the nurses could not control him five or six hours after operation, and he was sitting up in bed smoking innumerable black Havana cigarettes, and he said, "Dr. Lyon, something happened. You didn't take out my kidney."

"Yes, your kidney is in the laboratory."

He said, "I don't feel any pain."

His wound healed very rapidly. He insisted on being

out of bed on the eighth day and requested his discharge from hospital. It was not granted.

That part was interesting but the effect on the polycythemia was even more interesting. Daily blood counts were carried through and immediately after operation his red blood cells began to reduce toward a normal five million, but his white blood cells went up to 260,000. We could not interpret this. Three weeks after operation the blood count showed Hb. 88%, R.B.C. 4.4 million, W.B.C. 22,800.

I have followed this gentleman now for fifteen years and there is no longer any evidence of any remaining polycythemia. His blood counts in recent years have been within normal limits.

DR. PAUL W. ASCHNER (New York, N. Y.): Mr. President, Ladies and Gentlemen: It is with great pleasure that I greet my colleagues, Dr. Randall and Dr. Hughes, of the American Urological Association, here, and who have seen fit to bring to our attention a phase of the subject of differential diagnosis in which I have been *interested for a long time.*

For many years the urologists have been attempting to educate the surgeons in the importance of excluding urinary tract pathology in all cases of unclear abdominal catastrophes. It now seems no more than fitting and proper that the gastro-enterologists should be so educated, who are very likely to see the patient before the surgeon is called in.

As Dr. Randall has properly said, we have two types of cases to deal with, the cases of acute abdominal symptoms, and the cases with subacute or chronic abdominal symptoms. As to the acute cases, they are most likely to occur in such a manner as to simulate perforated ulcer, acute cholecystitis, acute pancreatitis, and acute appendicitis, and, lastly, intestinal obstruction.

As Dr. Randall has shown, many renal lesions come about by virtue of radiation through the nerve pathways stimulating these conditions.

In the acute case it is not feasible nor practicable, to my mind, to resort to excretory urograms for the differential diagnosis. In the first place, one hesitates to give catharsis to a patient in an abdominal condition and, to get good urograms you must have good catharsis and no gas in the intestinal tract.

In the second place, one cannot dehydrate these patients, which is also esential for good urograms; so it has been my practice, where I have an acute abdominal condition in which I wish to exclude urinary tract pathology, and I think it is the safest practice, to use the cystoscope and observe whether there is good influx from the two ureters and any evidence of retention in the pelvis of the kidney or in the ureters.

In subacute cases it is true one can use the excretory urographic methods.

There are a few types of kidney lesions one is likely to forget about, which produce violent conditions, and in which the urine is absolutely negative, and in which even the cystoscopic and urographic evidence may be misleading. One of these conditions is the condition of a septic infarction of the kidney which occurs with mitral stenosis and can produce all these symptoms of acute upper abdomen.

Another type is cortical infection of the kidney with staphylococcus of a metastatic variety. Intestinal obstruction occurs in two forms in this group of cases. In one way you have a stone in the left lower ureter, producing a marked sigmoid spasm with intestinal distention, and distention of the cecum. These are frequently operated on for intestinal obstruction. Then you have the other type of cases in which there is silent renal pathology, and the patient has uremia and retrograde fecal vomiting, and these cases are not infrequently operated upon under the misapprehension of acute intestinal obstruction.

DR. BOLAND HUGHES (Philadelphia, Pa.) (closing the discussion): Perhaps a word in defense of the acute surgical abdomen would at present be appropriate and this is mentioned in connection with the etiology of acute periureteritis. We know clinically that acute periureteritis arises either, (1) extrinsically from extension of chronic infection in the adnexia, or, (2) intrinsically from ulceration of the ureteral mucosa due to the presence of a stone. On the right side of the abdomen, however, one of the principal reasons for acute periureteritis is extension of an infection from an inflamed appendix. This extension of infection from the appendix gives us all the roentgenological signs of an acute periureteritis with the clinical picture of the acute abdomen. We should amend therefore the diagnostic axiom that Dr. Randall mentioned, to say that in all cases of gastro-intestinal pain, be the case acute or chronic in character, a urogram is necessary, but in right-sided periureteritis in which the pathology and etiology is questionable, even though you have urinary signs and symptoms, removal of the appendix is the proper therapy to be employed.

Intubation Studies of the Human Small Intestine: VII. Factors Concerned in Absorption of Glucose from the Jejunum and Ileum*

By

W. OSLER ABBOTT, M.D.,† WALTER G. KARR, Ph.D.

and

T. GRIER MILLER, M.D.

PHILADELPHIA, PENNSYLVANIA

THE absorption of food is regarded as occurring chiefly in the small intestine. Selecting glucose as one of the simplest food substances and one which has been extensively studied in lower animals, we have attempted a quantitative study of its absorption in the jejunum and ileum of normal human subjects. This has necessitated an investigation of various aspects of the behavior of glucose in those parts of the small bowel: (a) its normal range of concentration in the small gut after a glucose meal, (b) the variations in the osmotic pressure of the intestinal contents result-

ing from its presence, (c) the power of the intestinal mucosa to control its concentration by dilution with hypotonic fluid, (d) the motor response of the intestine to hypertonic solutions of it and (e) the effect of its concentration in the intestinal contents on the rate of absorption. Because of the diversity of the methods required for those procedures, we are presenting the material in five parts.

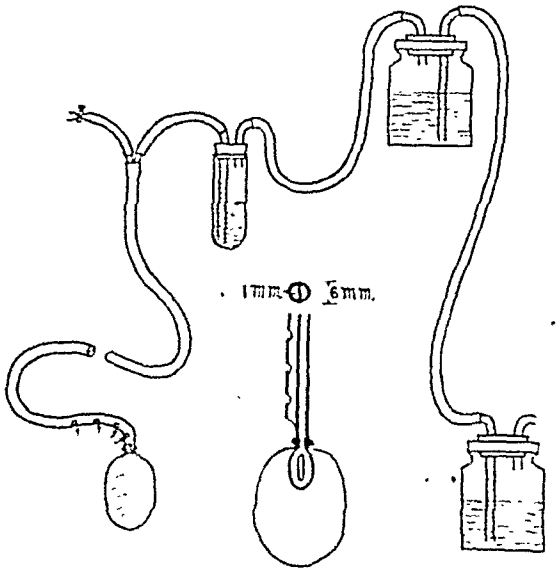

Fig. 1. *The Apparatus for Sampling Small Intestinal Contents.* The intestinal tube has a longitudinal partition giving one lumen for inflating the balloon which is done after the tube enters the duodenum to stimulate propulsive peristalsis and a second lumen through which intestinal contents are drawn up into a collecting test tube. Suction is maintained by syphon bottles usually set to give 70 cm. hydrostatic pressure.

PART I

Question: What range of glucose concentration occurs in the jejunum and ileum following its ingestion in solutions of varying strength?

Method: Using as subjects normal healthy adults and some hospital patients free from digestive disorders, we passed long rubber tubes having two lumina and a terminal balloon, by the method of Miller and Abbott (1), to selected points between the duodenum and the cecum (Fig. 1). Sugar solutions were given by mouth, and from above the balloon, which acted as a dam, intestinal contents were drawn off by constant suction. Small individual specimens were collected, which permitted a study of the rise and fall of sugar concentration at the chosen points.

The specimens were cleared by the zinc precipitation method of Somogyi (2) and after appropriate dilution were analyzed for glucose by the Benedict (3) colorimetric method.

Results: Table I gives the maximal concentrations attained at various levels of the intestine after various volumes and amounts of sugar had been ingested. This was generally less than 5 per cent.

Discussion: The drop in concentration of the glucose solution between the time of its ingestion and its subsequent recovery from the jejunum is the striking feature in these results. A far more rapid drop in concentration must, therefore, have taken place in the stomach and duodenum than we have demonstrated in the jejunum and ileum, a point which has been investigated separately (4). Since a 5.4 per cent glucose solution is isotonic with the blood plasma, the figures also raise a question as to the total osmotic pressure of these specimens which must contain, besides glucose, an appreciable electrolyte content.

PART II

Question: What is the total osmotic pressure of the small intestinal contents after glucose has been introduced (A) into the stomach, whence it may advance normally through the digestive tract and (B) into washed loops of small gut isolated from the remainder of the intestine?

A. GLUCOSE INTRODUCED INTO THE STOMACH

Method: Specimens were collected at chosen points throughout the jejunum and ileum by constant suction after the ingestion of glucose as in Part I.

The chloride and bicarbonate ions were determined as described in a preceding paper (5) in which it was also shown that in a fasting subject twice the sum of the milliequivalents of these anions was an approximate estimation of the total osmotic pressure. When this approached 300 milliosmoles it was considered to be isotonic with blood plasma. When glucose was present the number of millimoles per liter was added to twice the sum of the mEq. of chloride and bicarbonate to obtain the total osmotic pressure in milliosmoles.

Results: Table II gives the results in 13 of 20 experiments performed on 17 subjects. It will be noted that the contents of the duodenum and upper jejunum were usually hypertonic while isotonicity was maintained below these areas. Such conditions were usually found without regard to the various volumes and concentrations of the solutions ingested. Case 50 exemplifies the behavior of glucose when administered in a moderately hypertonic solution. When 250 c.c. of a 10.8 per cent solution was swallowed, the concentration of glucose in the ileum rapidly rose and slowly fell again to zero. The osmotic pressure remained close to 300 mOsM. throughout by virtue of a diminution of Cl

(Selected from 26 experiments performed upon 17 subjects).

as the glucose increased and a rise in Cl as the glucose disappeared. The bicarbonate value remained approximately the same. In certain instances the bicarbonate content was high, as in Case 50. When this occurred the Cl ion again maintained isotonicity by its reciprocal relationship. In subject 46 the extreme concentration of 9.5 per cent glucose in the jejunum indicates, however, that with sufficient glucose ingested the mechanism can be broken down.

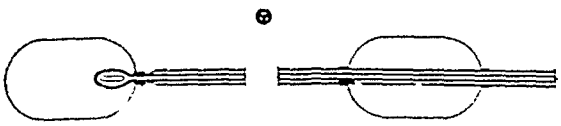

Fig. 2. *The Tube Used in Isolating Small Intestinal Loops.* The tube lumen is divided into three passages. Two lead to the balloons placed 30 cm. apart. The third leads to the gut lumen between the balloons. When these balloons are distended sufficiently to prevent the passage of material into or out of the segment of gut between them the third lumen is used to inject or withdraw test solutions.

B. GLUCOSE INTRODUCED INTO ISOLATED SMALL INTESTINAL LOOPS

Method: By the method of Abbott and Miller (6), which consists of the introduction of a three-lumened tube bearing an upper and a lower delimiting balloon 30 cm. apart, between which test solutions can be quantitatively injected and withdrawn, isolated segments of intestine were studied (Fig. 2 and 3). Into these loops glucose solutions of varying concentration were rapidly injected and after 15 minutes withdrawn.

Results: The average results of 38 experiments are shown in Chart I.

Discussion: These results, obtained after glucose was given (a) by mouth and (b) into closed segments of gut, confirm in general the observations of Groen (7) on human subjects, which showed the balance of electrolytes and glucose after the introduction of test solutions into the open small intestine above a balloon. Since he did not determine the bicarbonate content his total osmotic pressure of 275 mOsM. is somewhat below isotonicity but if the average of our bicarbonate findings is added a figure of 303 mOsM. is obtained. In the ileum the close adherence of the total osmotic pressure to approximately 300 mOsM., as shown in Table II, is very striking.

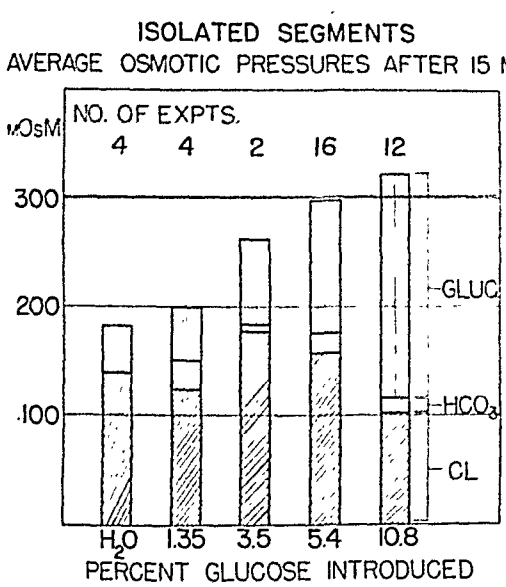

Chart I

Fig. 3. *An Isolated Small Intestinal Segment.* A roentgenogram of 30 cm. of lower jejunum isolated by inflated balloons and filled with a barium sulphate suspension.

Experiments have shown (8) that the contents of the stomach after concentrated glucose ingestion usually remain hypertonic until the stomach is nearly empty. While the stomach dilutes the sugar solution it does not continue to do so to the point of isotonicity with the blood plasma. The duodenum receiving hypertonic glucose from the stomach also remains hypertonic although the glucose concentration may be as low as 1.7 per cent while with a similar or higher concentration after isotonic glucose has been introduced into the stomach it will remain isotonic (Table II, Subject No. 140). The condition of hypertonicity may remain in the upper jejunum, but isotonicity is usually attained in the lower jejunum remaining so throughout the ileum. The maintenance of these conditions, however, implies the ability of the gut rapidly to mobilize a hypotonic fluid to dilute incoming hypertonic solutions.

PART III

Question: How rapidly can the small intestine dilute a hypertonic solution?

Method: The isolated loop technique described in Part II-B was used in this study also. Into the loops were injected 50 c.c. samples ranging from water to a 43.2 per cent glucose solution. At the end of 15 minutes the volume of each was measured.

Results: Chart II, compiled from 48 experiments, indicates that while solutions of a concentration producing an osmotic pressure below that of the blood plasma slowly lost volume, the isotonic solutions were unchanged and those of high concentration rapidly grew larger. Thus within 15 minutes solutions of twice the isotonic concen-

tration almost doubled in volume, while those of eight times isotonicity increased threefold.

Discussion: These figures give the rate at which dilution proceeds and present a picture of the role of this factor in the rapid reduction of glucose concentration in the jejunum and ileum when the solution enters in a hypertonic state. Similar results have been obtained by London and Polowzowa (9) in dogs with fistulae in the upper jejunum and lower ileum. When a 200 c.c. solution with the isolation of a segment between balloons as described in Part II-B was used. Instead of maintaining a fixed volume of air within the balloons, however, they were connected to recording instruments as formerly described (6). Hydrostatic units in the system maintained a constant pressure of 30 cm. of water which was fairly efficient in preventing leakage past the balloons and still allowed satisfactory recording. (Fig. 4). Uniform volumes of water, of 0.9 per cent NaCl and of glucose, ranging

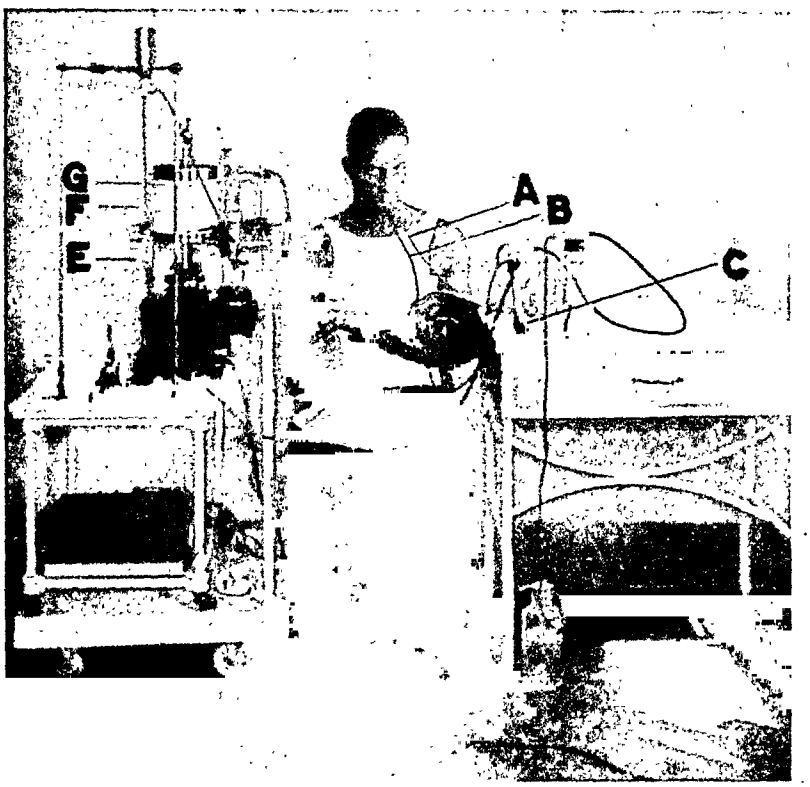

Fig. 4. *A Small Intestinal Intubation Experiment in Progress.* The subject has swallowed a gastric tube A for sampling the stomach contents and a small intestinal tube B for recovery of ileal contents C being aspirated by syphon suction D. The lumen leading to the balloon passes to a leveling bulb E which maintains a 30 cm. H_2O pressure against the intestinal wall. Contractions of the gut are recorded on the electric kymograph F. A pneumograph G detects body movements.

of 65.8 per cent was introduced in the upper fistula it gave a return of 1100 c.c. of 8.6 per cent glucose from the lower level in 110 minutes. In the duodenum, however, the rate has been shown to be even more rapid (8). The method of study, moreover, was such that if the most likely error, that of leakage of loop content, had occurred, it would have tended to give an erroneously low rate. The chance of this error increased tremendously as the concentrations used were increased until finally the method broke down completely at the highest concentrations. This suggests that the motor reactions of the bowel may likewise have a part in controlling the tonicity of the intestinal contents.

PART IV

Question: What is the motor response of the intestine to the introduction of glucose solutions of widely varying concentration as studied (a) by balloon records (b) by roentgenological methods and (c) by chemical analysis?

A. KYMOGRAPHIC STUDIES

Method: The procedure of small intestinal intubation from an isotonic solution to one of four times that concentration, were introduced.

Results: Fig. 5 gives the results of experiments considered typical for the various concentrations studied. Little difference occurred between the behavior of an empty loop and one containing 50 c.c. of water. When an isotonic glucose solution was injected there was a tendency for the loop to empty downwards as indicated by an increase in the activity of the distal balloon. When the initial concentration was doubled this activity of the distal balloon was also disturbed slightly. With four times the isotonic concentration both balloons were rapidly affected, a deep strong peristalsis being established.

B. FLUOROSCOPIC STUDIES

Method: Two subjects used repeatedly in these studies underwent a complete roentgenological study of the digestive tract by E. P. Pendergrass* and subsequently were

*We wish to express our appreciation of the many kindnesses performed by Dr. Pendergrass and his staff in assisting us with certain phases of this study.

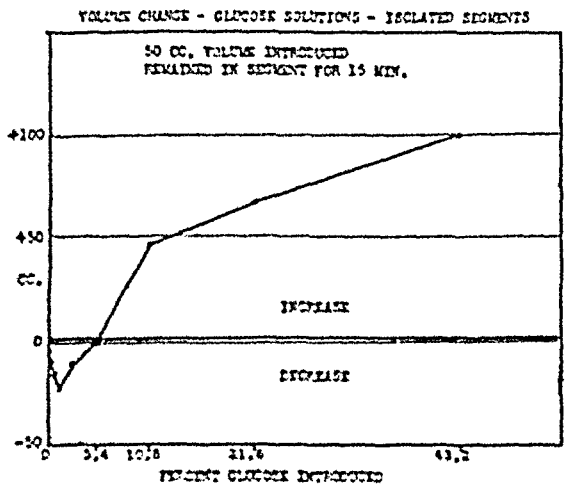

Chart II

examined again by him with a mixture of barium sulphate in 50 per cent glucose. Observations were carried out until all of the opaque material had entered the colon.

We have fluoroscopically observed the behavior of an ingested mixture of barium sulphate in 50 per cent glucose upon its initial entry into the jejunum in 11 normal students.

Results: Fig. 6. No delay in the initiation of gastric emptying or of jejunal filling was observed. The glucose meal at first advanced more rapidly than the barium alone, showing the rapid development of a haziness which is undoubtedly due, as suggested by Pendergrass, to dispersion of barium by the rapid entry of diluting fluid into the gut lumen. Later the delay in final gastric emptying and slowing of the advance of the barium-glucose meal to the colon was seen to occur at a time when the rapid influx of fluid increasing the volume of the gut contents had ceased.

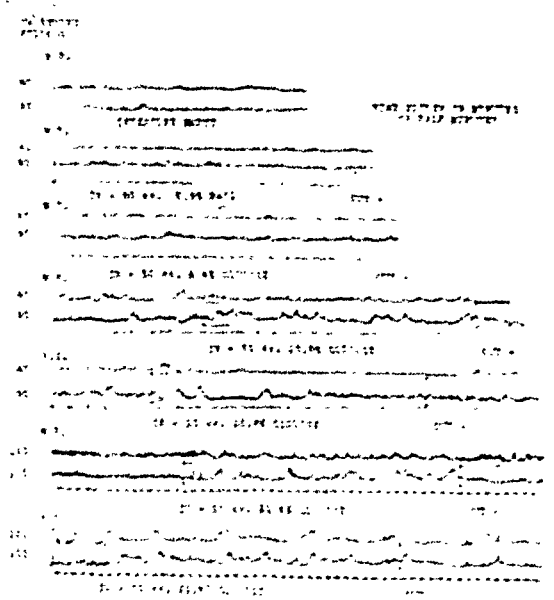

Fig. 5. *Balloon Tracings from Isolated Intestinal Segments.* These tracings were selected as 15 minute studies of the effect on intestinal activity of glucose solutions retained within the segments. The pneumograph records indicated that each subject had rested quietly throughout the experiment. With the higher concentration cramps were frequently complained of synchronously with the stronger intestinal contractions.

In the 11 cases fluoroscoped in the Gastro-Intestinal Section delay in the entry of the barium-glucose meal into the jejunum was observed only twice. In the remaining experiments the advance of the opaque material and the changes in the mucosal pattern observed were as described for the comparable period in the cases studied by *Pendergrass.*

C. CHEMICAL ANALYSIS

Method: The time of the first appearance of glucose in the recoveries made from the intestine after a glucose meal when using the two-lumened tube (Fig. 1) were recorded.

Results: Table III summarizes the data on 7 cases in which the time of the first appearance of glucose at the level under observation was accurately recorded.

Discussion: The roentgenologic findings were essentially as described under similar conditions by Pendergrass, Ravdin, Johnston and Hodies (10). The evidence yielded by all three methods is in complete agreement, showing that ingested glucose may reach the ileum in a very few minutes and that similarly a hypertonic glucose solution placed directly in the gut is rapidly dispersed. The result is to spread a thin layer of glucose in a very brief period of time over a very wide mucosal surface. Thus the motor reaction and the inflow of hypotonic fluid work together to lower the concentration of the gut contents with minimal delay. In a word all the evidence so far produced agrees in suggesting that if the absorption of glucose is to be studied it should be from solutions at or below isotonicity.

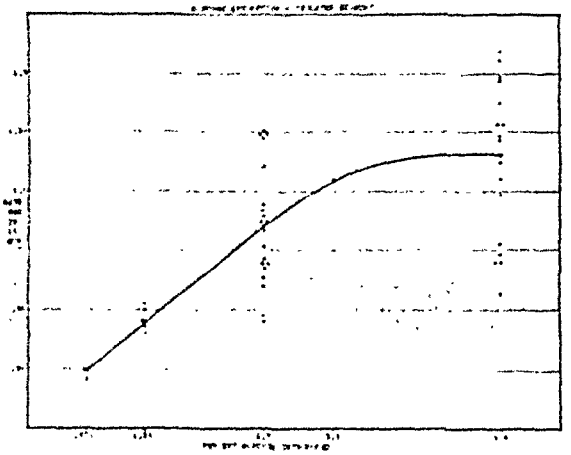

Chart III

PART V

Question: Using concentrations at or below isotonicity to reproduce the conditions normal for the small intestine, what is the relation between the concentration and the rate of absorption of glucose?

Method: Many of the observations were made by the isolated loop technique described in Part II-B. The glucose was introduced into the loop and after 15 minutes withdrawn. The loop was then washed twice with 50 c.c. volumes of tap water. The danger of error from leakage into or out of the loop being of great importance here be-

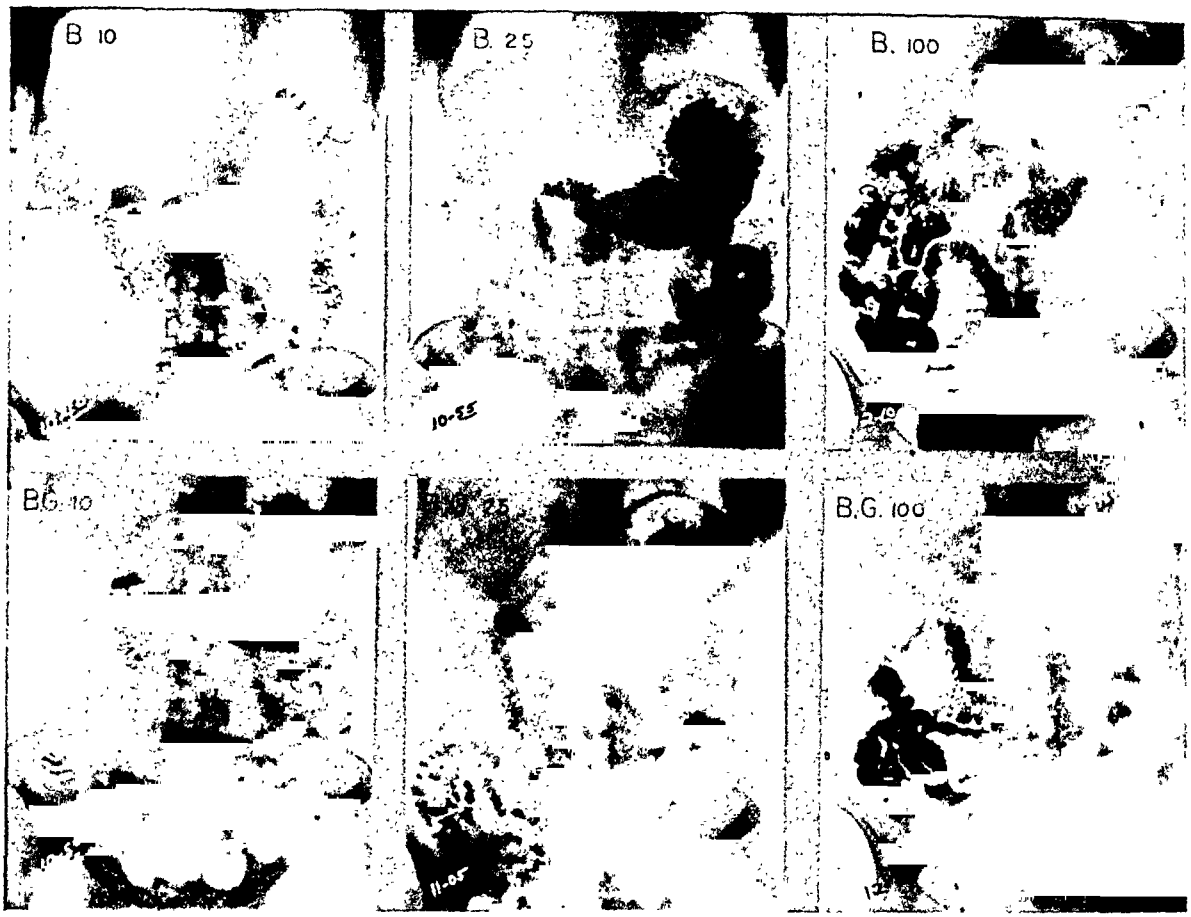

Fig. 6. *Small Intestinal Roentgenograms of Subject F. S. Showing the Effects of Glucose in the Opaque Medium.* Two studies were carried out three days apart, the first with barium in water, the second with barium in 50 per cent glucose solution. From a series of films three representative periods were selected. At 10 minutes the barium-glucose meal (B. G. 10) had advanced to a considerably greater distance than the barium meal. The haziness of the image in the advancing part of the column is due to the rapid inrush of fluid (see Part III) dispersing the barium. At 25 minutes the glucose meal is already far down the ileum, a speed of passage perhaps due to the stimulus produced by the inrushing fluid stretching the gut wall as occurs after a dose of Epsom salts. At 100 minutes when the entire tract probably contains isotonic contents the barium meal can be seen to have outrun the glucose meal. The stomach is more nearly empty and the head of the column is in the transverse colon. This is in keeping with the known actions of glucose per se prolonging gastric emptying time and inhibiting intestinal movements.

cause of absorption accounting for less than two grams of glucose at most, a second and more elaborate technique was devised. With this procedure, which differs in that it allows throughout the experiment constant aspiration of intestinal contents from immediately outside of the loop, we were in a position to detect even a trace of glucose lost past the balloons (Fig. 7). This method being more difficult to carry out was tried occasionally with each dilution studied.

Results: Chart III indicates that from approximately 0.25 to 1.5 grams of glucose are absorbed per 15 minutes from a 30 cm. loop of small intestine presented with a physiologically justifiable glucose solution. More glucose was taken up from the high concentrations than the low.

Discussion: These results imply that within the physiologically occurring range of concentration the amount of glucose absorbed increases with the concentration of the solution administered. This was shown by Omi (11) to occur in dogs when solutions of 1 to 6 per cent were used. The curve of Chart III, therefore, fills in the missing part of the curve which Verzar (12) gives for glucose absorption in relation to concentration in rats and agrees with what he supposed the shape of the curve would be had he been able to determine it. The spread of the figures at the right hand side of Chart III is interesting. Probably this is due neither to leakage past the balloons, which would have been detected (Fig. 7), nor to failure to recover glucose from the lumen of the loop, since the washes checked too evenly. It is possibly due to differences in the area of intestinal mucosa exposed between the balloons, since this is always variable and may change over a period of time as peristalsis slides the gut wall over the balloons. Roentgenological observation and tracings from balloons, however, have failed to suggest that 5.4 per cent glucose causes much pleating of the gut between the balloons. Probably, therefore, the spread of these figures is due to jejunal and ileal studies being lumped together and to the differences in size and age of the subjects. When subdivided the figures seem to suggest a greater absorption from the jejunum, though this may be due simply to the greater surface per unit length in that part as compared to the ileum, rather than to any inherent difference in the epithelial cells of the two regions.

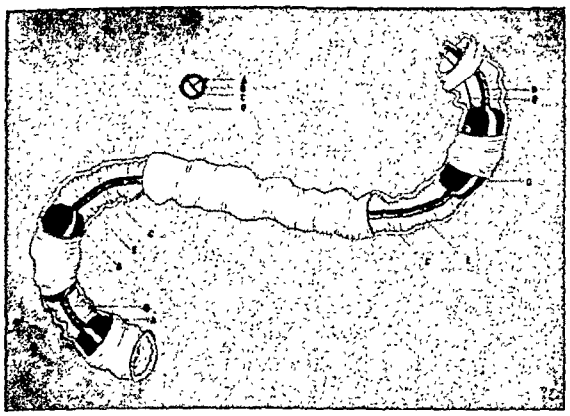

Fig. 7. *Special Three Balloon System for Isolating Intestinal Segments.* The device consists of a standard three lumened tube with a very fine single lumened tube beside it. When in the desired region of the intestine the balloons A-A are inflated through lumen A. Balloon D is inflated through tube D and the test solutions are introduced through lumen C into the isolated loop C. Suction is maintained on lumen B from before the start until after the finish of the experiment. Thus B will retrieve any of the test solution leaking out of the loop up past D or down past A and any general intestinal contents which might enter the loop from above D or below A. All experiments were considered failures in which the material collected through B contained glucose.

GENERAL DISCUSSION

The reviews dealing with carbohydrate problems written by Magee (13), Cori (14), Pierce (15) and Verzar and McDougall (16) have so completely brought the subject up to date that a further review would be a tour de force. One point of fundamental importance, however, is Cori's contention in 1925 that glucose is absorbed at a fixed rate without regard to the concentration of the solution (17). This hypothesis has at times been extended from the conditions under which he worked, that is to say with the digestive tract as a whole, to apply similarly to the small intestine alone. Ravdin, Johnston and Morrison (18) in experiments on dogs, having isolated small intestinal loops, showed that absorption increased as concentration increased, which is essentially what Part V of this study has shown for man, although in contrast to the present work they used concentrated solutions. The use of a loop isolated by balloons, however, has supplied a means of making certain observations of importance with regard to the normal physiology of glucose absorption which is not offered by the surgically isolated loop of an experimental animal. Outstanding is one's ability to withdraw intestinal contents from a given area of the small gut as fast as it reaches that point after the ingestion of a glucose meal, to isolate that area for quantitative study of absorption by a mucosal surface which up to that moment was functioning normally as an integral part of the digestive tract and, finally, to study the peristaltic response of the gut to the introduction of solutions of the concentrations normally occurring or to any that may be desirable. The evidence thus derived, when taken together, has shown that as glucose enters the gut, tonicity of the fluid is maintained by (1) a shift in the electrolyte contents, (2) the absorption of glucose, (3) an inflow of hypotonic fluid and (4) a propulsive type of peristalsis which varies in intensity with increase of concentration above isotonicity. Whether the motor response is due to mucosal irritation or to the stimulus of inpouring fluids stretching the gut, the result is a rapid dispersal of nutrient material prior to the period of depressed peristalsis (Fig. 6 BG 100) which Quigley and Phelps (19) have emphasized. Thus the intestine is equipped with a set of very effective mechanisms for disseminating and for reducing the concentration of hypertonic fluids in the shortest possible time.

From this it appears that any experiment in which hypertonic glucose solutions are placed directly in the jejunum or ileum and retained there is unphysiological. Moreover, Magee and Reid (20) have shown that hypertonic glucose solutions stop the movement of the villi, slow the blood flow through the mucosal vessels and cause an outpouring of mucus which throws a blanketing layer between the solution and the absorbing surface. Also it is apparent that due to the rapid influx of water the concentration of glucose in contact with the epithelial cells is variable and is far lower than either the mean concentration or the concentration of the fluid withdrawn.

In view of these considerations and observations elsewhere reported (4) we are led to believe that, save in extreme cases, the stomach and duodenum are able

TABLE III

to deliver without delay a dilute solution of glucose and electrolytes to the jejunum and ileum. Thereafter the small intestine rather slowly extracts the sugar from the fluid as its contents are propelled toward the colon. If solutions that are definitely hypertonic do enter, or are placed in the jejunum and ileum a out regard to the volume or concentration of the glucose solution ingested.

2. As the stomach evacuates a concentrated glucose meal the duodenal and upper jejunal contents, although markedly diluted, usually are found to be hypertonic with regard to the body fluids, while with

coordinated process of dilution and distribution in a very short time restores the fluid to about the osmotic pressure of blood plasma.

This succession of events implying as it does that the stomach and duodenum merely prepare the food for the remainder of the small intestine, while probably true for foods requiring digestion, can not be left unchallenged in the case of pure glucose. In Table I it may be seen that the major fall in concentration has already taken place before the solutions enter the jejunum. When, however, the total amount of sugar recovered from a duodeno-jejunal junction is determined (4) it proves to be but a small fraction of the total amount ingested. We must therefore assume that, in the case of a concentrated glucose solution, the stomach and duodenum play the major role in absorption. Whether this takes place in the stomach or duodenum or both is now open to question in view of the work of Holtz and Schreiber (21), Ravdin and Morrison (22) and of Shay and Cohen (23) upon gastric absorption of glucose in animal and man respectively. Thus the changes in concentration which take place above the ligament of Treitz must be looked upon not as a preparation of the chyme for jejunal and ileal absorption but in this case as an end in itself, the part played by the jejunum and ileum in absorption of glucose being of relative minor importance.

SUMMARY

1. Within wide limits the jejunal and ileal contents usually contain 5 per cent glucose or less with-

the rise and fall in the glucose content that may occur in the lower small intestine isotonicity is maintained.

3. If hypertonic solutions are placed in the small intestine the rise in volume and fall in concentration proceeds with great rapidity.

4. The propulsive activity of the small intestine increases with the concentration of glucose above 5.4 per cent in the gut contents.

5. Using solutions containing glucose in concentrations naturally occurring in the jejunum and ileum, (5 per cent or under), the rate of absorption is found to increase with the concentration.

We wish to take this opportunity of expressing our appreciation of the assistance rendered us in this study by Dr. Arthur P. L. Tsu, Dr. Alice D. Chenoweth, Dr. George Jennings and Dr. Olive D. Hoffman to whom our thanks are extended.

DISCUSSION

DR. JOHN L. KANTOR (New York, N. Y.): It seems to me a great pity that new things are reported so near the end of the meeting when time is short and fatigue increases.

I think this work is most fundamental, and that the avenues opened up by the new technic are so impressive that we are at last bound to learn a great deal about the small intestine.

Many years ago in reading Sherman's book on nutrition, I noticed a statement that all the calcium we need is absorbed from the duodenum. It seemed almost a weird and eerie thing that this important substance could be taken up so quickly from so small an area. Along come the authors and tell us that in the same area, and presumably at the same rate, most of the sugar is absorbed as well. At last we are beginning to have a little of the vision of what does take place in the small intestine, whereas up to now, we have been overimpressed by the functions of the stomach.

DR. THEODORE L. ALTHAUSEN (San Francisco, Calif.): Mr. Chairman, Ladies and Gentlemen: There are two points in Dr. Abbott and his collaborators' paper that deserve special comment. In the first place, the rate of absorption which has been considered by the Coris not to depend on the concentration of glucose, has been found to depend on the concentration of glucose. This question is important, and I think that the two findings do not necessarily conflict, because the Coris did their work with high concentrations of glucose (from 20 to 80 per cent), whereas Dr. Abbott and collaborators have been working with concentrations of glucose below 10 per cent. It may well be that this accounts for the difference in findings.

The second point I should like to comment on is the fact that Dr. Abbott and collaborators found that almost all of the sugar is absorbed in the duodenum. This bears on the mechanism of absorption of sugars. Sugars that are utilized in the body, chiefly glucose and galactose, are absorbed by simple diffusion which is greatly accelerated by conjugation with phosphates in the intestinal mucosa. Sugars not used in the body, such as pentoses, are absorbed only through simple diffusion. Tannhauser has recently shown that two substances serve to activate phosphatase: bile and ascorbic acid. It is very interesting that in the duodenum, a portion of the intestine where we expect to find the greatest concentration of bile, the maximum rate of absorption of glucose was found. I think this work confirms, indirectly, the phosphorylation theory of the absorption of utilizable sugars.

DR. HARRY SHAY (Philadelphia, Pa.): Mr. Chairman and Ladies and Gentlemen: I believe that the method devised by Drs. Miller and Abbott represents one of the real advances of experimental procedure for investigation of the physiology of the small intestine. It bids fair to permit them to solve many of the mysteries about this portion of the gastro-intestinal tract. It is particularly pleasing with an entirely different experimental approach to be able to confirm practically everything that Drs. Abbott, Karr and Miller have presented to us this after-

noon. Time will not permit me to touch upon all of their findings. I have selected, therefore, just one or two points I should like to stress.

(Slide) Table I. The first of these deals with the question of absorption from the stomach and upper small intestine. This slide is taken from some of our data concerned with absorption of glucose by the stomach. The second column represents the amount of glucose ingested. The pylorus in these cases was shut down completely by the duodenal instillation of the various substances listed in column one.

After a half hour we were able to recover from the stomach amounts of glucose shown in column three, while column four represents the quantity of glucose absorbed by the stomach during that interval.

We assured ourselves that none of the glucose had passed the pylorus, in two ways: In the first place, the glucose meal was mixed with barium, and frequent and careful roentgen examinations were made for barium beyond the pylorus, secondly, for five minutes during each of the fifteen-minute periods of observation, the duodenal contents were removed and the material tested for glucose; with the high concentrations of glucose in the stomach, we felt that negative duodenal reactions for glucose gave additional proof that none of the glucose had passed the pylorus.

Incidentally, we studied gastric absorption of glucose in dogs by mechanically closing off the pylorus, and we found that this sugar in high concentration was absorbed from the dog's stomach in amounts varying from 11 to 18 grams in one hour. The stomach was completely removed at the end of these experiments and all the gastric contents carefully recovered.

(Slide 2) Three years ago we had the opportunity to study a patient who had a high jejunal fistula, produced quite by accident. This man had had intestinal obstruction seven years before. Apparently so much distention had been present at the time of operation that the surgeon did a jejunostomy instead of an ileostomy as intended.

Through this jejunostomy we fixed a rectal tube held in place by a balloon and were thus able to collect the material from the proximal jejunum. In some experiments we intubated the duodenum in the usual manner as well and were able to collect specimens simultaneously from both areas. We administered various meals by mouth. In the first experiments we found that after a 250 c.c. meal of 29.4% glucose, we recovered from the duodenum after fifteen minutes, a concentration of glucose of 13.8%, in the next fifteen minutes 16.1%, and at 45 minutes 11.9%, while from the jejunal fistula the glucose recovered during the same intervals ran 6.6, 7.1, and 5.3%. I should like to call your attention to the volumes recovered in the first fifteen minutes, 345 c.c. and 340, and so forth, a total of 895 c.c. collected in 45 minutes from the fistula when only 250 c.c. had been given by mouth on an empty stomach.

Experiment 2 shows essentially the same low concentrations of glucose in the jejunum that Dr. Abbott has pointed out. Again the large volume collected from the jejunum after a meal of 31.7% glucose, in spite of the fact that for thirty minutes before the experiment was started, the collection from the jejunal fistula was only 5 c.c. Here we would like to draw attention to the difference in the amount of fluid probably added by the stomach, on the one hand, and the duodenum and upper jejunum on the other. In Experiment 4, fifteen minutes after 250 c.c. of 36.5% glucose had been given by mouth, 285 c.c. were recovered from the stomach. From the jejunal fistula we obtained 205 c.c. of a 3.4% glucose solution during that period.

We are inclined to believe from experiments of this type that in the human stomach, glucose solutions of high concentration are readily absorbed and that dilution plays a less important role than it does in the duodenum and upper jejunum. With a concentration of glucose of 25.6% in the stomach, (Experiment 4) at which concentration the stomach, we know, could not be emptying rapidly. At this point only 285 c.c. of fluid were present, yet through the fistula we obtained 205 c.c. The same holds true for the next 15 minute period. At this point with a 19.4% solution and a 210 c.c. gastric volume, 300 c.c. had come through the jejunal fistula. This indicates to us that in high concentration the stomach absorbs glucose quite rapidly and while the jejunum does, also, its chief function seems to be to dilute the glucose and bring it to isotonic conditions for admission to the jejunum, as Dr. Abbott has pointed out.

Deposition of Glycogen in Normal and in Experimentally Damaged Livers After Oral and Intravenous Administration of Dextrose*

THERE are several reasons why the comparative merits of oral and of intravenous administration of dextrose deserve investigation by modern experimental means. First, dextrose is used more and more extensively in treatment especially of diseases of the liver. Second, there is difference of opinion as to whether the oral or the intravenous method is more effective for therapeutic administration of dextrose. Third, in experiments to determine the comparative deposition of hepatic glycogen after oral and after intravenous administration of sugar, normal animals have been used almost exclusively. Since the author has found (1) previously that in animals damage to the liver influences the response of hepatic glycogen to administration of insulin and dextrose, there is a possibility that injury to the liver may influence also the effectiveness of the two methods of administration. Fourth, the reported experiments which have

than that which had been anticipated at the beginning of this work, and that a significant excretion of sugar took place in rats that were given dextrose intravenously. For this reason a second experiment was conducted with normal rats and with rats receiving 6 mg. of phosphorus per kg. of body-weight in which corrections for these factors were introduced. In order to equalize the amounts of dextrose actually utilized in the body after oral and after intravenous administration the rats receiving sugar by stomach-tube were done first. After the average amount of dextrose absorbed by these animals in 3 hours was ascertained the rats receiving dextrose intravenously were given in 6 equal doses the same amount of sugar plus the average amount excreted by similar animals in the first experiment. In the final calculation of the utilized amounts of dextrose the urinary excretion of sugar by the same rats was taken into account.

A third experiment was performed in order to test the effect of maximal doses of dextrose on the glycogen content of damaged livers. In this experiment, rats treated with 6 mg. of phosphorus per kg. of body-weight were given dextrose orally as well as intravenously, and the level of their hepatic glycogen was compared to that of rats similarly treated but receiving only the oral dose of sugar.

RESULTS

Normal rats. The rats that received dextrose intravenously excreted in the urine an average of 28 ± 2 mg. of sugar per 100 gm. in 3 hours. The animals given dextrose by stomach-tube had no glycosuria.

From Table I it is seen that when care was taken to adjust the intake of dextrose in such a way that oral and intravenous administration led to the actual utilization of nearly equal amounts of this sugar in the two groups of rats, the quantity of new glycogen deposited in the liver of normal rats was the same regardless of the route by which the sugar reached the liver. Further, the method of administration of dextrose was found to have no influence on the proportion of retained sugar which was deposited as new glycogen.

In normal rats that were given intravenously a dose of sugar exceeding by 65 per cent the maximal rate of intestinal absorption the hepatic glycogen was found to be almost doubled. The fact that the proportion of retained dextrose deposited as glycogen was approximately equal in the two groups showed that the greater amount of sugar given by vein and not the method of administration accounted for the difference.

The hepatic glycogen was found to be higher in rats during the Spring than during the Fall and Winter seasons. This is a well known phenomenon.

Rats treated with phosphorus. All rats treated with phosphorus showed sluggishness of movements and loss of weight. In the group injected with 8 mg. of phosphorus per kg. of body-weight these changes were most noticeable, and in addition more than one-half of the animals receiving this dose died before the end of 48 hours after the first injection. Rarely a rat receiving 6 mg. of phosphorus per kg. of body-weight failed to survive the period of preparation for the experiment.

Grossly, the livers of rats receiving 4 mg. of phosphorus per kg. of body-weight appeared normal. The livers of the animals injected with 6 mg. of phosphorus were pale and often friable; and those of rats receiving 8 mg. of phosphorus per kg. of body-weight were yellow and very friable, and on being hydrolized with 30 per cent potassium hydroxide yielded large amounts of fat.

Sections of the livers from these animals were examined by Dr. J. F. Rinehart of our Department of Pathology to whom we are indebted for the following pathological report: The hepatic cells of rats receiving 4 mg. of phosphorus per kg. of body-weight showed a moderate infiltration of fine fat droplets within the cytoplasm, occasional small zones of necrosis with leucocytic infiltration, and small zones of hemorrhage in areas of degenerated cells. These findings indicate very definite injury to the liver. In the livers of animals injected with 6 mg. of phosphorus per kg. of body-weight the cytoplasm was overfilled with fine fat droplets and showed scattered zones of necrosis with leucocytic reaction. In the livers of rats receiving 8 mg. of phosphorus per kg. of body-weight the same changes but somewhat more marked and more widespread were noted.

Table II shows that in this experiment rats treated with phosphorus absorbed somewhat smaller amounts of dextrose from the intestine than did the normal animals. The excretion of sugar in the urine of rats receiving dextrose intravenously averaged 27 ± 3 mg. per 100 gm. of body-weight in 3 hours. Animals that were given dextrose by stomach-tube excreted no sugar. When the intravenous dose of dextrose was adjusted to equal the amount of dextrose absorbed from the intestinal tract in the other group of rats plus the amount lost through the kidneys the hepatic

TABLE II

Hepatic glycogen in normal rats and in rats treated with phosphorus after oral and after intravenous administration of dextrose in amounts equal to the maximal rate of intestinal absorption

Experimental condition	Method of administration	No. of rats	Range of weight after fasting 24 hours	Dextrose given in 3 hours per 100 gm.	Dextrose utilized in 3 hours per 100 gm.	Standard deviation	Hepatic glycogen per 100 gm. of body weight	Standard deviation	% of dextrose deposited as new glycogen
Normal	Oral	16	Gm. 210-300	Mg. 600	Mg. 366	39	Mg. 53.0	14	13.9
	Intravenous	15	218-335	405	376	5	55.7	19	14.3
Phosphorus poisoning 6 Mg. per Kg.	Oral	8	122-160	600	323	22	48.0	11	15.1
	Intravenous	9	130-160	351	324	6	48.0	6	14.8

reported finding in human beings (9) that even the seriously injured liver does not lose its ability to acquire glycogen when an excess of sugar is available in the body. However, when an extreme degree of injury was inflicted on the liver by doses of phosphorus, which proved fatal within 48 hours to over

On the other hand, the importance of this observation of ours on normal rats is diminished by the fact that when animals with damaged livers were made to utilize amounts of dextrose which were more than double the maximal rate of intestinal absorption the additional increase in hepatic glycogen was statisti-

TABLE IV

Hepatic glycogen in rats treated with 6 mg. of phosphorus per kg. of body-weight after oral and after combined oral and intravenous administration of dextrose.

Method of administration	No. of rats	Range of weight after fasting 24 hours	Dextrose absorbed in 3 hours per 100 gm.	Dextrose injected intravenously in 3 hours per 100 gm.	Dextrose excreted in the urine in 3 hours per 100 gm.	Dextrose utilized in 3 hours per 100 gm.	Hepatic glycogen per 100 gm. of body weight	Standard deviation	% of dextrose deposited as new glycogen
Oral	5	Gm. 212-285	Mg. 278	Mg. —	Mg. —	Mg. 278	Mg. 42.0	15	15.1
Oral and intravenous	5	210-286	313	400	86	627	53.6	17	8.5

one-half of the rats this organ failed to increase its content of glycogen with the amounts of dextrose administered in our experiment regardless of the method of administration.

The equal effectiveness of both ways of giving dextrose to animals with normal and with damaged livers was also shown in our experiments by the approximately equal proportion of administered sugar which was retained in the liver as glycogen regardless of the route by which the sugar was given.

In so far as experimental findings in animals can be applied to therapeutic procedures in human beings our results indicate that the method of administration of dextrose for diseases of the liver is a matter of convenience. Consequently the giving of dextrose by mouth is preferable unless vomiting or other contraindications to the use of the oral route are present. Administration of dextrose remains indicated even in the severest forms of hepatic disease, when from analogy with our experiments with phosphorus apparently no deposition of hepatic glycogen is possible, in order to prevent dysfunction of other important organs, such as the heart, from want of sugar due to impairment of gluconeogenesis on the part of the liver.

When normal rats were given more sugar intravenously than they could absorb in 3 hours from the alimentary tract, the glycogen content of the liver rose in proportion to the added amount of sugar. This was confirmed by the unchanged proportion of dextrose converted into hepatic glycogen. Apparently within certain limits, in normal rats the newly formed glycogen of the liver is proportional to the total amount of sugar entering the body even when the latter exceeds the maximal rate of intestinal absorption. This suggests intravenous in addition to oral administration of dextrose in patients with severe hepatic damage. Such a procedure seems also attractive in view of the work of Woodyat, Sansum and Wilder (10) who showed that normal persons are able to utilize without glycosuria about 850 mg. of dextrose per kg. of body-weight per hour for periods up to 12 hours, while estimates of the maximal rate of intestinal absorption in man indicate that only about one-fifth of this amount can enter the body from the alimentary canal.

cally insignificant. This was shown to be true also by the progressively smaller proportion of dextrose deposited as glycogen which declined to about one-half of the normal figure when the amount of dextrose entering the blood stream was doubled (Table IV). We interpret these observations as indicating the existence of a limit which varies according to species and degree of hepatic damage and above which even the administration of a large excess of sugar is unable to increase the glycogen of the liver. Such a limit appears to be reached in rats under our experimental conditions when amounts of dextrose approximately equalling the maximal rate of intestinal absorption are given.

SUMMARY

1. Dextrose was administered to one group of rats by stomach-tube and to another group by intravenous injection. Determinations of hepatic glycogen were made three hours after giving the sugar. Control experiments with water and saline solution were performed.

2. In normal rats and rats with hepatic damage produced by injections of phosphorus, oral or intravenous administration of equal amounts of dextrose led to an approximately equal deposition of glycogen in the liver.

3. In animals with extreme damage to the liver, very little glycogen was deposited when either method was used.

4. By increasing the amount of dextrose given intravenously above the maximal rate of intestinal absorption, the deposition of glycogen in normal rats was increased. Under similar conditions in animals with hepatic damage, the increase in glycogen was insignificant.

5. The application of this study to the treatment of diseases of the liver with dextrose is discussed.

DISCUSSION

DR. VICTOR C. MYERS (Cleveland, Ohio): Mr. Chairman and Members of the Association: It is quite natural that this Association should be vitally interested in the function of the liver, since this organ is the reservoir and storehouse for materials, both foods and poisons, taken up from the intestinal tract. As first pointed out by Claude Bernard, in his great period of activity between 1850 and 1860, the liver under normal conditions serves as a balance wheel in regulating the metabolism of carbohydrates. The preëminent role that the liver plays in regulating carbohydrate metabolism, however, was not recognized until a few years ago, when Frank Mann and his associates at Rochester discovered that after the extirpation of the liver, dogs died from hypoglycemia. Having recognized this fact, he found it possible to elucidate many of the liver's functions, since he was not able to keep his dogs alive a reasonable length of time by intravenous glucose therapy.

With this background, Dr. Althausen has made many studies on the influence of the liver and the mobilization of glucose, and the storage of glycogen, his present report being the latest. It seems to me his studies on the deposition of liver glycogen particularly deserve commendation. This is a function of the liver which can be accurately measured and in consequence, one can make interpretations about the utilization of glucose. From blood sugar tolerance curves alone, one's interpretation may obviously be incorrect.

One should do as Dr. Althausen and the Coris have done, carry out studies on small animals, such as the white rat. It is then possible to sacrifice the animals and determine the glycogen and thus get an exact determination of this important function. It is evident from the charts that Dr. Althausen showed on the screen, that in severe liver damage from phosphorus poison, the ability to deposit glycogen is markedly impaired.

He has emphasized the value of sugar therapy in liver disease in a previous paper, and his latest conclusion seems logical, namely, that if one is going to give glucose therapy, the simplest, and easiest way, and the most practical way, is to give it by mouth.

How is the glucose deposited in the liver as glycogen? How is the glycogen broken down in the liver to glucose when the body needs it? We know as a result of the work of Claude Bernard, to which I have already referred, that in the normal individual, glucose content of the blood is kept constant, pretty close to 0.1 per cent in the blood. It has always seemed to me that the probability was pretty good that this transformation was carried out under the action of a diastatic enzyme, perhaps one that has a reversible action.

We know in the digestion of starch in the alimentary tract it is broken down by enzyme action to glucose in which form it is absorbed. It seems perfectly logical that some similar mechanism may exist for the building up of this monosaccharide to glycogen in which form it is stored for relatively immediate use.

We know that if we collect blood and allow it to stand a short time, some of that glucose goes over to lactic acid and we have a fall in the sugar concentration of the blood. This is due apparently to an enzyme that is present in the leukocytes.

We also know that a diastatic ferment is present in the blood. Some years ago Dr. Killian and I carried out a study on the diastatic activity of the blood in normal individuals, diabetics, and other conditions, and found that the diastatic activity of the blood was quite markedly increased in diabetes. This was before the discovery of insulin.

More recently Dr. Eric Reid, sent to my laboratory from Aberdeen by Dr. J. J. Macleod, repeated this work with the same findings that Dr. Killian and I got in 1916. He also found that the diastatic activity was reduced to normal in the diabetic by the administration of insulin.

We thought when insulin was discovered that we would very soon be able to reveal the mechanism by which energy was obtained from carbohydrate, but we really do not know much more now than we did then. We know that insulin will enable a diabetic to burn carbohydrate in the normal manner, but we cannot go very far beyond this. Through some work that Dr. Reid and I carried out in cooperation with Dr. Quigley, on dogs, we came to the theoretical conclusion that probably the insulin acts in some way upon the diastatic activity of the blood through the liver.

I personally believe before this story is completely elucidated that we need to have some information upon the chemical mechanism upon which Dr. Althausen has made pathological studies. To be sure one can recognize liver pathology under the microscope, but, after all, being a biochemist, I feel that the things that one cannot see, which are producing the changes there, are a great deal more important than the things one actually sees with the microscope.

I do not know that I can suggest to Dr. Althausen how I would begin such a study, since every effort I have made with studies on the diastatic activity of the liver has been unfruitful, but I thoroughly believe in the remarks that I have made in this connection. Observations have been made in recent years that throw an entirely different interpretation upon the utilization of glucose. We know that in the muscle, for example, the immediate source of energy apparently is phosphocreatine, and that its break down furnishes the energy. Then there is a resynthesis of the phosphocreatine at the expense of adenosin triphosphate, and apparently resynthesis of this compound occurs at the expense of hexophosphate.

Recently Dr. Tannhauser made a rather interesting analogy in this connection that rather amused me. He suggested that phosphoric acid acted in this particular case like a basketball player. First it would catch the glucose, then the adenylic acid, and finally the creatine, and then the process would be repeated. Through some mechanism such as this, apparently, glucose indirectly furnishes energy for muscular action. Although this is a little remote from the problem in question, it is extremely important since the liver is very vitally concerned here, as it is the organ that keeps the flow of glucose constant.

Galactose has been used for a long time as a functional liver test, ever since Bauer discovered in certain cases of cirrhosal liver that galactose was excreted after the ingestion of milk.

It seems to me it would be interesting if Dr. Althausen would continue his work, also using galactose and fructose with his rats. As I recall, according to Dr. Cori, although galactose is well utilized, it is not quickly converted to glycogen in the liver. I believe that perhaps something interesting might come out of further studies.

Dr. Althausen is to be congratulated upon this study and I believe that although sometimes the topic appears devoid of all clinical interest, the first thing we know there is a practical application that wasn't at all apparent when the work was begun.

DR. FRANKLIN W. WHITE (Boston, Mass.): There is one practical and important side of this work of Dr. Althausen's which he may have been too modest to stress. He has shown the importance of glucose in protecting the sick liver cell in laboratory animals. Let us take this information into the hospital wards: When we have a sick liver case with jaundice, vomiting and drowsiness, we must use intravenous glucose; but later on when this patient is no longer drowsy and nauseated but is getting better and is able to take liquids and food by mouth, I notice that the house officers are quite likely to carry on the *intravenous* glucose medication with the feeling that there is something mysterious or especially useful about giving it in an intravenous way, perhaps with the idea that a greater percentage is absorbed or utilized. Now that Dr. Althausen has shown (if I have interpreted his figures aright) that when the patient is able to take it and it can be given by mouth, it is utilized just as well as if given by the intravenous method; we have information which saves a great deal of time and trouble and does the patient just as much good.

DR. THEODORE L. ALTHAUSEN (San Francisco, Calif.) (closing the discussion): I merely want to thank the people who discussed my paper and I think that it does have a clinical application, as Dr. White has said.

Editorials

DISSOCIATION OF BACTERIA

ADAMI (Brit. Med. Jour., 2:1215, 1898) contended that bacteria were constantly invading the body from the gastro-intestinal tract. He contrasted the organ cultures as determined by bacteriological technic with the histological examinations and concluded that many bacteria were present but few were able to grow. Adami's co-worker Ford (Jour. of Hyg., 1:277, 1901) examined tissues from normal animals and found three-fourths of the cultures positive after three weeks' incubation. He was unable to grow these forms in subcultures.

Florey (Jour. Path. and Bact., 37:283, 1933) describes the fate of bacteria when brought in contact with the intestinal mucosa. When B. aertryche is introduced, in the form of a thick suspension into an intestinal loop in a guinea pig, there is a considerable exudation of phagocytic cells into the intestinal lumen, and in places the epithelial cells desquamate leaving bare the underlying stroma. The detailed study of paraffin sections, appropriately stained, indicated that the bacteria not infrequently enter the epithelial cells themselves. These intracellular bacteria in many, but not in all cases, show signs of degeneration. The invaded epithelial cells show no histological evidence of death. How the bacteria gain entrance to the cells is uncertain, but it does not seem to be through any phagocytic activity, as usually conceived, since inert particles or non-pathogenic bacteria remain in the lumen of the intestine.

Gulbrandsen (Amer. Jour. of Hyg., 22, No. 2:257, 1935) cultured the organs from normal dogs, guinea pigs, rabbits and rats in broth. He found a slight clouding at the bottom of the tubes or flasks after incubation. Stained smears revealed a pleomorphic type of bacteria present. He could not obtain growths from these primary cultures on any media. In as much as almost all normal tissue gave these results, it was impossible to determine if living tissue was necessary for their work.

Gulbrandsen resorted to the use of mature guinea pig fetuses delivered by caesarean section. The organs of such animals were sterile of this pleomorphic flora. Bacteria were fed by mouth to these full term sterile guinea pigs and organ cultures made fifteen to sixty minutes later. B. typhosus, B. paratyphosus, B. Staphylococcus aureus and B. diphtheriae were the bacteria used for oral feeding. Pleomorphic bacteria could be demonstrated in the organs of these young animals fifteen minutes after feeding of the living cultures. These resembled the forms found in adult animals. These pleomorphic bacteria are non-antigenic and biochemically inactive. B. typhosus or B. diphtheriae were altered in their passage through the wall of the sterile intestinal tract so as to produce a tissue growing symbiotic form of bacterial flora which was non-pathogenic.

Adami's and Ford's observations were therefore substantiated. Every bacteriologist has encountered dissociation of bacteria and many are engaged in the study of this problem. The tissue symbiotic bacteria studied by Gulbrandsen are dissociated types. Meyer and Ryan (Jour. of Lab. and Clin. Med., 22, No. 2:113, 1936) using a different technic found such types in the blood of normal persons as well as certain pathological cases.

Dissociation seems to be one of the important mechanisms of defense of the body against infection by bacterial invasion. More questions are raised than answered by Gulbrandsen's work. The gastro-intestinal tract is indeed a complex biological environment for microorganisms.

Lloyd Arnold, Chicago, Ill.

BILIRUBINEMIA

AS ROUS and Drury demonstrated some years ago, the degree of bilirubinemia in animals which have been subjected to experimental biliary obstruction is a direct expression of the physiologic wastage of corpuscles; anyone who has noted the deepening of jaundice after transfusion or its fading after hemorrhage can confirm this observation. In cases in which human beings have jaundice there are two additional factors which modify the degree of bilirubinemia, namely, the completeness of mechanical blocking of the bile passages and the degree of parenchymal injury of the liver. The question naturally arises as to whether there are, or will be, methods by which these three factors can be distinguished from each other. To approach the subject, one may first consider the two types of bilirubin found in the blood, that is, the indirect-reacting type which is normally present and which exists in increased quantities in the hemolytic forms of jaundice, and the direct-re-

THE Aristocrat..

Among the agents used for the correction of constipation and allied colon disorders, Kondremul is outstanding for thoroughness with which the microscopic particles of oil remain emulsified within the bowel.

The selection of Irish Moss (Chondrus Crispus) as the emulsifying agent in Kondremul accounts for the tough film which surrounds each oil particle, resists coalescence and prevents leakage.

This superior emulsion mixes with and softens the fecal content, thereby rendering natural elimination easier.

3 Types

KONDREMUL Plain—A safe corrective for children and adults.

KONDREMUL with Cascara—Tonic laxative and regulator.

KONDREMUL with Phenolphthalein—For more resistant cases.

acting type, the presence of which characterizes the obstructive and hepatogenous forms of jaundice. Rich has designated as "retention jaundice" those types in which there are indirect van den Bergh reactions and acholuria and has characterized those types in which there are direct-reacting bilirubin and bile in the urine as "regurgitation" jaundice. The inference of this classification is obvious.

Exactly what chemical differences exist between these two types of bilirubin is still unknown; one theory holds that bile acids, which are presumably present in excess in the blood of patients who have obstructive or hepatogenous jaundice, lower the surface tension of the bilirubin molecule and thus change its chemical behavior. Another theory is based on the assumption that indirect-reacting bilirubin is in combination with protein which retards the direct van den Bergh reaction and inhibits renal filtration. Supporters of this view hold that passage of indirect-reacting bilirubin through the hepatic cells removes this combined protein and leaves the "regurgitated" bilirubin in a form free to pass the kidney and alter in color when Ehrlich's diazo reagent is added to the serum. The recent studies of Duesberg lend support to the latter hypothesis; his observations indicate that in the degradation of hemoglobin iron is first split off while the globin fraction remains in combination as far as the formation of bilirubin.

Is all of the bilirubin present in the blood of patients with obstructive or hepatogenous jaundice in the direct-reacting form? That is, has it all passed through the cells of the liver and been regurgitated into the blood stream? If current conceptions of dysfunction of the cells of the liver in the presence of obstruction or toxic injury are correct, this should not be the case, but part of the bilirubin in the circulation should be the indirect-reacting form which is produced by physiologic wastage of corpuscles and dammed back into the circulation because of the physiologic or pathologic inability of the hepatic cells to take it up. The photolometric studies recently reported by Osterberg appear to indicate that a part of the circulating bilirubin in cases in which jaundice is due to mechanical obstruction and parenchymatous lesions of the liver gives an indirect reaction, while another fraction apparently has passed through the liver cell, as shown by a direct van den Bergh reaction. While further chemical and spectrophotometric studies of differences existing between directly and indirectly reacting bilirubin will doubtless be required to establish the authenticity of these methods, it does seem clear that the quantitative determination of the two forms of bilirubin in a single specimen of serum is not beyond the bounds of possibility. Such information when it becomes available will probably be of considerable clinical importance. It may be that the amount of one or the other types of bilirubin present in the individual case is of prognostic significance and may give information which the total figures, now in use, do not supply. These and similar studies naturally will lead to some revision of present views regarding the mechanics of "regurgitation" jaundice; they emphasize the importance of learning what disposition is made of the porphyrin and iron-containing complement of the hemoglobin molecule, and, finally, they indicate that the complexity of the problem of bilirubinemia increases as more is learned of its essential chemical nature.

THE ETIOLOGY OF PEPTIC ULCER

A NEW statement on the etiology of ulcer is possible in the light of recent developments in gastric physiology. Mann's experimental production of ulcer, now widely confirmed, showed the paramount importance of the acid factor in the immediate causation of ulcer in dogs. There is good evidence of a similar mechanism in man. Experience with really continuous, night and day, neutralization of gastric acidity as by the aluminum hydroxide drip in the clinical treatment of uncomplicated ulcer indicates that Mann's experimental results may be fairly satisfactorily duplicated. That is to say, healing occurs quite regularly within one to two weeks. This would seem to establish the fact that the erosive action of acid gastric chyme is the *sine qua non of actual ulceration* and the whole immediate cause of clinical ulcer and that all others factors act as predisposing causes. From the practical standpoint the predisposing causes may be of great importance, quite overshadowing the immediate and specific cause, since, when they are removed, *the ulcer may heal spontaneously* or on account of the restoration of the normal neutralizing mechanism of duodenal regurgitation. Moreover, proved cases of peptic ulcer in proved cases of constant anacidity with histamine probably do not exist. Reports of such cases even on single examinations are so rare as to negative their significance.

Etiological factors in ulcer have usually been referred to as neurogenic, vascular, infective, toxic, glandular, traumatic and others including a mysterious X factor. The old physiological query of "why doesn't the stomach digest itself?" is probably best answered by the statement that it does when its defenses are down. The above predisposing factors lower local resistance or disturb the normal neutralizing mechanism so that acid peptic digestion occurs. A localized arterial occlusion might lead to ulcer in the stomach wall while the same process in less exposed tissues might cause no lesion or an innocent infarction. Likewise, an organic lesion in the sub-thalamic area of the brain or purely functional psychic impulses may induce vasomotor or trophic changes in the gastric mucosa with a profound lowering of local resistance. Nervous factors, which every mature clinician knows are most important in ulcer may operate in part by inducing pylorospasm and retaining acid secretions for abnormally long periods.

Such overshadowing of a specific cause by conspicious predisposing causes is not rare in medical science. For example, "traumatic arthritis" as described by

2 SIMPLE WAYS

of Preparing Palatable High Concentrations of KNOX GELATINE

PHYSICIANS are constantly asking us for formulae for the preparation of Knox Gelatine in a concentrated palatable form, useful in the dietary treatment of such conditions as muscle fatigability and gastric ulcer. Research on such formulae has shown these to be excellent.

"The Knox Milk Stir"

Place the contents of 4 envelopes of Knox Gelatine in an ordinary drinking glass. Add 4 ounces of cold milk and allow to soak for five minutes. Add 2 more ounces of milk and stir until homogeneous. Then place glass in small cooking kettle of hot water until gelatine milk mixture liquefies. Add 2 more ounces of cold milk, which will bring the temperature to a satisfactory warm drink of about body heat. A tablespoonful of prune juice or a few drops of any bland flavor like vanilla may be added.

Total: 8 ounce liquid — 75 calories

"The Knox Fruit Stir"

Place the contents of 2 envelopes of Knox Gelatine in an ordinary saucer or cereal dish. Add 8 tablespoonfuls of any desired fresh or canned fruit juice, such as grape juice. Let soak for five minutes and eat with teaspoon.

Total: 4 ounce mixture — 50 calories

They are ideal when frequent feedings and extra calories must meet adequately the level of nutritive requirement. Indicated to allay the pain in the gastric ulcer patient when given hourly. An adequate food adjunct both from the standpoint of easy digestibility or "low residue" in gastro-enteric dysfunction or intestinal stasis. Also of value for their high amino-acetic acid (glycine) content in dystrophic muscular conditions.

Why You Should Insist on Knox Sparkling Gelatine

Because Knox Gelatine is 85% protein in an easily digestible form — because it contains absolutely no sugar or other substances to cause gas or fermentation, Knox Gelatine should not be confused with factory-flavored, sugar-laden dessert powders. Knox is 100% pure U.S.P. gelatine. Knox Gelatine has been successfully used in the dietary of convalescents, anorexic, tubercular, diabetic, colitic, and aged patients.

KNOX SPARKLING GELATINE

IS PURE GELATINE—NO SUGAR

KNOX GELATINE LABORATORIES
JOHNSTOWN, NEW YORK

Hilton in his "Rest and Pain," before the discovery of the tubercle bacillus quite adequately explained joint tuberculosis as the result of injury. The teaching survives to this day in the beliefs of most victims of Pott's Disease. How reluctantly even the medical profession of that day yielded to the bacterial "theory" of disease.

It is extraordinary that Sippy with his conviction upon the importance of the acid factor in ulcer did not devise a method of really continuous night and day neutralization. Ulcers apparently heal at a rate that is proportional to the constancy of neutralization. Some ulcers heal spontaneously, others heal by part time neutralization as by the Sippy routine, but the largest percentage of cures in chronic cases and in the shortest period of time is obtained by really continuous neutralization. This removes the immediate cause of ulcer and permits prompt healing. The predisposing factors should then be attended to as far as possible. This is a reversal of the process or of the sequence of events leading up to and causing ulcer. Secondary complications such as extensive cicatrization or obstruction really present a separate problem, usually surgical and play no role in the primary pathogenesis of peptic ulcer.

Meuhlengracht's remarkable reduction of mortality from hemorrhage by feeding the bleeding ulcer case liberally and by the use of alkalis is probably due to an approximately continuous neutralization and arrest of gastric motility.

Really continuous night and day aluminum hydroxide drip has been most effective in controlling persistent and recurrent bleeding. There is apparently a prompt cessation of the erosive process and of digestion of the newly formed clot in the bleeding vessel.

This conception of the etiology of ulcer has practical implications since there has been, even among gastroenterologists, a half-hearted conviction as to the importance of the acid factor and a half time use of antacids with half way results. Thorough use of continuous neutralization for prompt healing of the open lesion permits of a more rational follow-up leading to individualized treatment of the whole patient. Attention to the predisposing causes of disturbed gastric physiology is then of the first importance in the prevention of recurrences.

Vernon C. Rowland, Cleveland, Ohio.

SOME COMMENTS OF OSLER ON CIRRHOSIS

MEDICAL history has preserved for us the opinions of a small group of men who have had an instinctive knowledge of disease processes far in advance of the thought and teachings of their time. Of these men Sir William Osler stands closest to the recent generation; there are few investigators who are not in his debt, and who have not found in his writings an expression of some concept believed to be new. Some of his opinions on cirrhosis of the liver, written in editorial form in the Philadelphia Medical News a half-century ago, are in such accord with modern thought and practice that it seems worth while to call attention to them again after this long lapse of time.

Of ascites, which is still the symptom which first attracts attention to the disease, he has this to say, "The factor which determines the onset of dropsy in cirrhosis of the liver is not always clear. The highest possible grade of portal obstruction, even obliteration of the vena portae may exist without it. . . . . We must look beyond the liver for the explanation of these facts. . . . . The dropsy may be due to a transitory and remediable cause." It is still difficult to give a full and satisfactory explanation of the ascites due to hepatic damage, but it is increasingly clear that the answer is to be sought in a study of the factors which control the passage of fluids across living membranes. Hypoproteinemia and reduced osmotic pressure have recently been shown to be of great importance, and it now seems that there is a rough inverse relation between the latter factor and the rate of transudation. Inert substances, such as acacia, will raise the colloid osmotic pressure of serum and thereby tend to retain fluid within the capillaries; its use in the ascitic stage of cirrhosis is as yet in the experimental stage, but if nothing else is accomplished, studies on this point will afford a means of investigating the significant factors in the pathologic physiology of the formation of transudates.

The membranes involved have still to be studied; it is conceivable, but not altogether likely, that the solution to the problem will be found there. This possibility did not escape Osler's attention; he considered the possibility that, "owing to changes in the serous layer the capillaries are rendered more permeable and without any increase in the blood pressure permit of transudation." That anoxemia, now known to be a fairly constant finding in cirrhosis, may be partially responsible is suggested by the studies of Landis who showed that reduction in the oxygen content of the tissues greatly increased the rate of filtration through frog's mesentery.

Commenting on the prognosis in cirrhosis, Osler was convinced that "the disease may be arrested or even cured" and noted "the personal equation. . . . of the liver tissue" in respect to hepatotoxins. The observations of Bollman on animals with experimental cirrhosis have fully confirmed the possibilities of arrest or cure; he has demonstrated that the pathologic process in the liver can be carried to an almost fatal conclusion; the animals being thereafter restored to normal health and their livers regenerated to a very considerable degree by the use of high carbohydrate diets and glucose given intravenously. Similar clinical results are on record, as Chester Jones has recently shown. Osler feared that, "We probably have not any remedies at our command capable of curing a cirrhotic liver," a point with which all must agree, but it does seem possible to control the symptoms of the disease and induce some degree of repair of the liver itself in certain cases. So far as the variations in the resistance of some animals and individuals to hepatotoxic substances is concerned, this may depend upon dietary habits and the glycogen content of liver tissue; it has been clearly shown that experimental fatty degeneration of the liver requires for its production a diet low in carbohydrate and protein and high in fat and that a high carbohydrate diet will protect the organ against the most severe insults.

Osler's remarks on treatment emphasize some particularly important points; he disapproved of the practice of deferring paracentesis "until diuretics and

CANNED FOODS IN THE CONTROL OF LATENT AVITAMINOSIS B1

● Apparently mild vitamin B1 deficiency in humans is not characterized by very definite or entirely specific symptoms. While such a condition may be attended by anorexia, hypotonicity of the bowel, indigestion, vague pains and malaise, latent avitaminosis B1 hardly presents a picture which is favorable to its early clinical detection. However, there are two procedures which may be employed when this type of avitaminosis is suspected.

The first procedure (1a) depends upon the nature of the response to administration of pure vitamin B1. The second procedure, which has been more widely applied, makes use of the Cowgill formula for calculation of vitamin B1 requirement. By consideration of the actual vitamin B1 intake and the calculated vitamin B1 requirement in any specific instance, the probability of mild avitaminosis B1 may be evaluated (1b).

It is difficult to estimate the frequency of mild vitamin B1 deficiencies in the United States. However, until such information is at hand, it is not illogical to suggest that latent avitaminosis B1 must be regarded as an active possibility in some cases which may come to the attention of the medical practitioner. Fortunately, several factors are operative which give assurance that eventually the incidence of latent avitaminosis B1 will be reduced to a *minimum*.

First, those concerned with human nutrition have today more definite information concerning quantitative human vitamin requirements than ever before in history (2).

Second, every passing year brings marked progress in education of the layman to the necessity of a completely "protective" diet. The control of the latent avitaminoses is, in large part, dependent upon proper food selection and correct formulation of the diet by the layman consumer.

In the establishment of dietary regimes which will be protective against vitamin deficiencies, commercially canned foods may play an important part. Several hundred canned foods are available upon the American market at all seasons of the year. Nutritional research has shown (3) that modern canned foods retain in good degree the vitamin B1 contents of the raw materials from which they were prepared. This great class of foods—available to all consumers regardless of economic status—will contribute substantially to the alleviation and prevention of latent avitaminosis B1 in this country.

This is the thirty-second in a series of monthly articles, which will summarize, for your convenience, the conclusions about canned foods which authorities in nutritional research have reached. We want to make this series valuable to you, and so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

cathartics have been thoroughly tried." Purging of patients in this condition is now in general disfavor, and it is equally certain that diuretics have been used to the detriment of many patients. The best practice is now, as it was in Osler's time, to support the liver by all possible means, to correct so far as possible the abnormal composition of the blood, and to do paracentesis as it becomes necessary. In fact, preoccupation with the problem of dropsy as such, rather than attention to the factors responsible for it, is to be blamed for at least some of the difficulties which arise in the course of treatment. Much might be accomplished in the care of the patient if Osler's optimistic view were taken, "The practical point is this, that in certain cases of cirrhosis the effusion results from changes which are not necessarily permanent, and we should not regard the onset of dropsy in every case as the beginning of the end."

Albert M. Snell, Rochester, Minn.

ACETYLCHOLINE AND THE GENESIS OF PEPTIC ULCER

A NEW chapter in the physiology of the gastro-intestinal tract is being initiated by recent knowledge concerning the chemical mediation of nerve impulses involving the autonomic nervous system. Naturally, some speculation in regard to the effects of these chemical mediators on the normal digestive functions has been aroused and various hypotheses relating to the genesis of pathologic processes are being investigated in the light of these new conceptions.

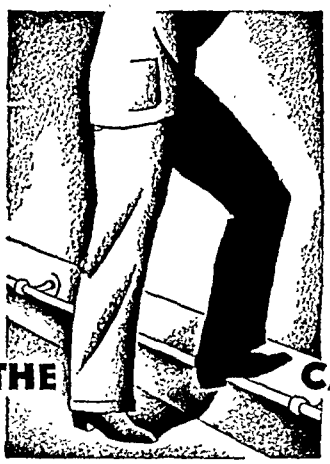
It is generally agreed that when parasympathetic nerves are stimulated a substance resembling acetylcholine can be recovered from the venous outflow of the stimulated region, and that sympathetic stimulation liberates a chemical substance, sympathin, which is closely related to epinephrine. Acetylcholine has been shown to have an extremely evanescent action and to be destroyed rapidly in the body by a specific enzyme, the choline esterase, which splits the ester into acetic acid and the relatively inactive substance choline. The action of acetylcholine can be prolonged and augmented by introducing drugs such as physostigmine and prostigmin* which inhibit the action of this destructive enzyme; these facts have been applied clinically in the use of acetylcholine or prostigmin, alone or in combination, to increase gastro-intestinal motility (1).

It has also been demonstrated that a substance, the action of which resembles that of acetylcholine, is the chemical mediator of those motor impulses arising in the parasympathetic nervous system which affect the stomach (2) and intestines (3). Sympathetic impulses passing to these regions liberate sympathin which inhibits intestinal contraction (4).

In addition to the known stimulating effect of acetylcholine on the gastro-intestinal musculature the drug usually is regarded as being a specific vasodilator of the peripheral vascular regions. The recent investigations of Necheles and his coworkers (5, 6, 7) indicate, however, that in the arteries of the perfused stomach of the rat and the dog and in the mesenteric and gastric arteries isolated from human beings small amounts of acetylcholine produce vasoconstriction. On the basis of this last observation these investigators concluded that, since the stomachs of patients with ulcer usually exhibit increased motor activity, it is conceivable that a larger or more continuous production of acetylcholine might also occur in these portions. They have assumed that certain parts of the duodenum and the lesser curvature of the stomach are supplied only by end arteries and, therefore, they have considered that a decreased blood flow produced by the action of a hypothetical excess of acetylcholine to these parts of the duodenum and stomach might be a factor in the genesis of ulcer.

There are other clinical and experimental studies which give some support to this assumption. Gastric and duodenal erosions and even ulcers have been produced repeatedly in animals by continuous stimulation of the vagus nerves or by the intraventricular administration of drugs which stimulate the parasympathetic nervous system. That such nerve stimulation, produced by lesions in the human central nervous system might result in the production of fatal ulceration of the stomach or esophagus has been demonstrated by Cushing (8) and others (9). Ulcerations produced in this manner are thought to be the result of hypermotility and hyperacidity, possibly supplemented by accompanying local spasm of the terminal arterioles.

In spite of these observations one must remember that considerable question still exists concerning the occurrence of an increase of free gastric acidity in animals (10) and in man (11) following the administration of acetylcholine. Furthermore, the anatomic studies of Atwood (12) demonstrate that the entire stomach and duodenum are well supplied with numerous arterial branches capable of forming anastomotic channels and that these regions are, therefore, in little danger of localized infarcation due to a decreased blood supply in the end-arteries.



While the possible relationship of the production of acetylcholine to ulcer is being investigated further, it must be remembered that the exact site of the formation, the mode of action and the normal disposition of this substance are still unknown. Likewise, the available evidence is insufficient to explain just what factor or factors control the integrity of the gastro-intestinal mucosa under normal conditions. Whether this control is exercised through maintenance of the proper blood supply or by changes in gastric or duodenal secretion is not known. Until these normal protective mechanisms are more clearly understood, any attempt to explain the probable etiology of ulcer on the basis of some abnormality relating to the chemical mediators of nerve impulses should be held sub judice.

Hugh R. Butt, Rochester, Minn.

AMONG THE CAUSES OF HYPERACIDITY

Certain disorders almost invariably, but certain "habits" not much less frequently, are the prolific source of gastric hyperacidity. The "last" drink of liquor, that additional cup of coffee, another pipeful of tobacco, rich food that pleases the palate but displeases the stomach, fear and worry—all must share the blame of mischief-making in the stomach.

Pointing out the error of the patient's mode of life and habits may be a preventive of excess acidity in the stomach, but for the prompt relief of the pain and discomfort attending it CAL-BIS-MA supplies the answer. Cal-Bis-Ma accomplishes gastric neutralization promptly and its effect is prolonged. Secondary acid rise and gaseous distention are prevented by its soothing, sedative, protective and adsorbent properties.

Why not ask us to send you literature and a trial quantity of Cal-Bis-Ma? It explains the composition, points out the uses, and lets you test the value of Cal-Bis-Ma by the best judge—yourself.

"ABERCROMBIE'S ACUTE ILEITIS AND COMBE-SAUNDERS-CROHN'S TERMINAL OR REGIONAL ILEITIS"—(OR, "CROHN-*GINZBURG-OPPENHEIMER'S* DISEASE")

IT is of interest to the gastro-enterologists, at this time, to be reminded of two very interesting studies and reports made more than a century ago concerning pathologic states of the ILEUM.

John Abercrombie (1780-1844) discussed ACUTE AND SUBACUTE FORMS OF ILEITIS in his book entitled "Pathological and Practical Researches on Diseases of the Stomach, the Intestinal Canal, the Liver, and Other Viscera of the Abdomen," Edinburgh, Waugh and Innes, (Glasgow and London), pp. 238-263, 1828.

At a Session of The College of Physicians in London, held on July 4, 1806, a report by Charles Combe and communicated by William Saunders, Fellow of the Royal College of Physicians, was read on: "A Singular Case of Stricture and Thickening of the ileum"—Medical Transactions, Published by the College of Physicians in London—London, Longman, Hurst, Rees, Orme and Brown, Paternoster-Row, Vol. IV, pp. 16-21, Report III, 1813.

This Report states that the patient, William Payne Georges, Esquire, of a very nervous and delicate habit. Died February 9, 1806. Body opened next day by Combe. The lower part of the ileum as far as the colon was contracted for the space of three feet, to the size of a turkey's quill, etc. An early report (1806) of REGIONAL ILEITIS"!

Included with these brief comments are photostatic reproductions of the original report of this very early (1806) case of REGIONAL ILEITIS or COMBE-SAUNDERS-CROHN'S DISEASE, and the report of Case C11, by Abercrombie (1828).

In Abercrombie's book (Edinburgh, 1828) appears Case C11, page 263, a girl aged 13, about a year before her death, began to be affected with pain of the abdomen and frequent vomiting.

Inspection (lines 22 to 27). "The lower end of the ileum, to the extent of about eighteen inches, was distended, thickened in its coats, externally of a reddish color and internally covered by numerous well-defined ulcers, varying in size from the diameter of a split pea to that of a sixpence. The lungs and all other viscera were healthy."

MEMPHIS DOCTOR DECLARES GREATEST STEP IN ARTIFICIAL INFANT FEEDING WAS CERTIFIED MILK'S INTRODUCTION

DALLAS, October 23—No step in the history of medicine did as much to simplify and make safe the artificial feeding of infants and children as did the production of certified milk, "the most idealistically pure milk the world has ever known," Dr. C. Barton Etter, M.D., a member of the Memphis & Shelby Certified Milk Commission, Memphis, Tenn., declared here today before the Certified Milk Section of the International Association of Milk Dealers convention at the Adolphus Hotel.

Certified milk enables the pediatrician to feed each baby as an individual with individual requirements, Dr. Etter asserted. "We are able to change any integral part of the milk to suit individual needs," he said, "without the necessity of changing the entire structure of the product, and always with the knowledge of the food value of the resultant mixture.

"Such freedom, to those of us who devote a large part of our time to the feeding of infants and children, is invaluable. In no other form of milk now available do we enjoy such freedom. Here we have a milk produced under the most sanitary conditions, hence a clean milk; a milk from tested cows eliminating the possibility of tuberculosis and undulant fever; a milk with the lowest possible bacterial count thus minimizing to the lowest degree the *possibility of intestinal infections*; and, finally, a milk of known chemical constituents standardized the world over, which would allow us to make those modifications necessary to fit the individual case without the necessity of a chemical analysis of the milk to be used.

"Given such a product upon which we can depend so freely, wherever it is produced, we have a basis for a very simplified method of infant feeding. Should an upset result we are familiar enough with our product to be able to recognize the probable cause of the upset and very easily make those changes that should shortly correct it."

Memphis Certified Sales Up

In Memphis, the use of certified milk has increased 20 or 30 gallons daily in the past year, Dr. Etter declared. "If the city of Memphis is to be taken as a fair example," he said, "we must assume that not only do the pedintricians recognize certified milk for its true value but that the public at large is *also recognizing this value*. Certified milk should continue to hold the place which it has so long and so rightfully held at the head of the list of available milks."

ST. LOUIS PHYSICIAN DECLARES CERTIFIED MILK "POTENT FORCE FOR PROGRESS" AT DALLAS MEET

DALLAS, October 23—Calling certified milk a "potent force for progress," Dr. Paul J. Zentay, M.D., Secretary of the St. Louis, Mo., Pure Milk Commission, today told the *Certified Milk Section* of the International Association of

As Pleasant to take As a Breakfast Food

MUCILOSE
(STEARNS)

Provides Bland, Non-Digestible, Lubricating Bulk in the Colon

Having once prescribed Mucilose you know how it corrects constipation and colitis by holding water in the feces, maintaining the normal fecal colloid*, and thereby producing a large, soft, pliable stool.

You will also have found that your patients favor the palatability, especially of the granular form, so that they are ready and willing to follow your prescribed regimen consistently—a vital consideration during protracted, corrective, restorative treatment.

Mucilose is a hemicellulose (vegetable gum) prepared by a special process from the Plantago loeflingii. You can prescribe it in one or other of the two palatable forms:

MUCILOSE GRANULES
MUCILOSE PLAIN

Milk Dealers convention at the Adolphus Hotel here why this "Honor Grade" is the milk of choice for the health officer, the milk sanitarian, the health educator, the physician, the pediatrician, the dairy scientist, the milk dealer, the general consuming public, the mother, and, finally, the child and baby.

"Certified milk is a factor that represents a continuous stimulation for a steady advancement in an extremely important phase of public health," Dr. Zentay said. "It leads the way toward the goal of what will be and must be reached sooner or later, i.e., the best possible milk for the largest number of people. Certified milk is small in quantity but like the leaven it acts like a ferment and thereby it is not only capable of unlimited growth but it activates growth unceasingly.

"The health officer necessarily will be interested in a well balanced public health program for his community. An essential part of such a program must be adequate milk control and sanitation. In developing this part of his program the up-to-date health officer may confidently turn to certified as a milk of choice. Why? Because certified has been during its entire existence the standard bearer of the milk industry.

"The milk sanitarian or dairy inspector must be primarily an educator. Where else but on the certified dairy farm can he find a cheerful and willing compliance with the most rigid regulations? For the educator in public health is there anywhere a more concise history of milk sanitation written than in the annually revised editions of 'Methods and Standards' for the production of certified milk?

"The physician must consider certified milk his first choice because he will demand that the cleanest and most nutritious milk should be available for his patients. Certified milk has always been the very own product of the medical profession, and has been a unique contribution of American medicine to the rest of the world of which it may be justly proud. The reason for the pediatrician's choice of certified is in the invaluable combination of original cleanliness and sanitation with scientific nutritional enhancement of food values.

"Is it not high time for us to educate mothers that in case of milk you inevitably will get only what you pay for? Every mother should be told that the higher price of certified milk is paid for superior value in every quality of milk."

New Orleans Physician Declares Babies Fed Certified Milk Have Greater Freedom From Disease

DALLAS, October 23 — Infants and children fed certified milk have more resistance to infections and greater freedom from disease, Dr. Roy E. de la Houssaye, M.D., President of the New Orleans, La., Pure Milk Society, asserted here today before the Certified Milk Section of the International Association of Milk Dealers convention at the Adolphus Hotel.

"The diet of the infant and child largely determines his well being," Dr. de la Houssaye said. "I have used *almost every kind of milk in my* practice. My observations lead me to say certified milk-fed infants and children have more resistance to infections and greater freedom from disease. I have noticed that infants and children fed on other than certified milk need three or four times the accepted dose of cod liver oil.

"What is certified milk? I must go back about 40 years. Statistics show there were 300 deaths, before the completion of the first year, to every 1,000 children born. Infants and children hardly had a chance. When you saw one sick with diarrhea, it nearly always meant death. What single factor did most to change this situation?

"Dr. Henry Coit of Newark, N. J., lost a child and, through the tragedy in his own home, realized this terrible condition. He found a dairyman who was willing to produce milk according to the rules Coit made at that time. Babies and children using this milk did much better than others. The rules and regulations were added to; more dairies wanted to produce this kind of milk; the same rules were adopted in other cities; this progress continued—hence the birth of certified milk.

"Certified milk is the purest form of raw milk obtainable. It is produced in accordance with the regulations prescribed by the American Association of Medical Milk Commissions. You must know that the men in the dairy industry who conform to these high standards are leaders. They are forever trying to raise the standards. They employ trained technical men whose business it is to see that better milk is produced. This necessarily induces careful feeding of the certified dairy herd.

"In working for better milk, which is—and always will be—certified milk, I am sure everyone knows that we receive, *as our only* compensation, healthier infants and children.

Human Nutrition Linked Closely to Diet of Cow, Dairy Bureau Man Says

DALLAS, October 22 — Improvement of human nutrition is linked closely to the diet of the cow, since there is much evidence of the value of milk as a supplementary or protective food and since in all known respects in which milk is particularly valuable its nutritive value is affected by the quality of the ration fed to the cow.

C. A. Cary, Acting Chief of the Division of Nutrition and Physiology of the Bureau of Dairy Industry of the United States Department of Agriculture, Washington, D. C., made this statement today in a paper read before the Certified Milk Section of the International Association of Milk Dealers convention at the Adolphus Hotel here. The paper was read by Dr. O. E. Reed, Chief of the Bureau of Dairy Industry, *in the absence of Mr. Cary.*

"Numerous nutritional surveys indicate that the dietaries of children and adolescents, and even of adults, may frequently be deficient in some respect," Mr. Cary wrote. "The more intimate our knowledge of the etiology of disease, the more evidence there seems to be that many human ills may be associated either directly or indirectly with such dietary deficiencies. And, as additional nutritive factors are found to be essential in the human diet, the evidence of the value of milk as a supplementary or protective food increases.

"The diet of a cow does decidedly affect the nutritive value of her milk in a number of important respects. The recent work at Wisconsin on the nutritive value of milk from cows on pasture and on winter rations indicates that we do not know all of the dietary essentials that are thus affected.

"As a supplementary food, milk is most highly esteemed as (1) a rich source of protein of high biological value, (2) as a source of vitamin A, (3) as a source of vitamin B, (or riboflavine), and (4) as a source of calcium and phosphorus in a form, or as a dietary combination, that renders these inorganic constituents readily assimilable. In all of these known respects in which milk is particularly valuable, its nutritive value is affected by the diet of the cow."

Dallas Physician Speaks Before Certified Section of Milk Meet; Urges Milk Use Throughout Life

DALLAS, October 23—Nutritional requirements from the cradle to ripe old age are met by certified milk, Dr. John G. Young, M.D., Chairman of the Dallas County Medical Milk Commission, declared here today before the Certified Milk Section of the International Association of Milk Dealers convention at the Adolphus Hotel. His subject was "The opinion was one prevalent, Diet."

"Throughout life, the diet requires the vital food, milk," Dr. Young said. "When milk is so essential, we should use and prescribe the best product obtainable. Certified milk, being the best obtainable, meets the requirements.

"The place of certified milk in the diet has been established and proved. Nothing is done to pure, clean milk, properly produced from well fed cows. It is protected from harm and given to the consumer in a state ready for the

THIAMIN CHLORIDE SQUIBB

AN ECONOMICAL MEANS OF ADMINISTERING VITAMIN B_1 IN LARGE DOSAGE

THIAMIN CHLORIDE SQUIBB is indicated in the treatment of all degrees of Vitamin B_1 deficiency, but it is especially useful in the more severe forms. It may be given orally or parenterally in the treatment of alcoholic polyneuritis, polyneuritis of pregnancy, gastro-intestinal hypotonicity, and cardiovascular disturbances due to Vitamin B_1 deficiency.

Thiamin Chloride Squibb (Crystalline Vitamin B_1 hydrochloride) permits accurate massive dosage in small volume. It is stable —convenient to use and palatable.

Thiamin Chloride Squibb is supplied in bottles of 50 tablets in 2 potencies, 300 (1 mg.) and 1500 (5 mg.) International units per tablet, and in boxes of 6 x 1-cc. ampuls—each ampul containing 3000 International units (10 mg.) of the crystals in solution. It is apparently equally effective whether given orally or parenterally. The latter method is suggested where quick results are desired and where gastro-intestinal disease may interfere with absorption from the alimentary canal.

For literature address Professional Service Department, 745 Fifth Avenue, New York.

E·R·SQUIBB & SONS, NEW YORK
MANUFACTURING CHEMISTS TO THE MEDICAL PROFESSION SINCE 1858.

best possible results we know milk can give. The nutritional requirements met by milk are met by certified milk from the cradle to ripe old age."

Dr. Young is an instructor in pediatrics at Baylor Medical School; attending pediatrician at Baylor Hospital and at Methodist Hospital; Chief of Staff of the Freeman Memorial Clinic; Fellow of the American Academy of Pediatrics; President of the Texas Pediatric Society; and President of the Dallas Pediatric Society.

"The growing child needs milk," Dr. Young continued. "It is possible to exist without it but not in a state of optimal nutrition, good health and well-being. As a pediatrician I realize this and so do most pediatricians. And as life through to old age is continual change, with repair, regrowth and modification occurring in the body, there is needed this vital food, milk, for the same 'sense of well being,' optimal nutrition and health.

"Those interested in certified milk still agree that mothers milk is the milk of first choice when available in quantities sufficient. When this supply is not provided, some other suitable food must be supplied. For ages, and through much research and clinical observation, this other suitable source has been found to be milk. With this there is no good argument.

"If milk, then the best milk, and so certified milk is the choice. A precious gift for a precious person. No other milk is 'just as good as certified milk.'"

UNPASTEURIZED MILK, CONSUMED BY MORE THAN HALF OF U. S., CAUSED 42 EPIDEMICS IN 1936, SCIENTIST SAYS

DALLAS, October 22—More than one-half of the 123,000,000 people in the United States are still consuming potentially dangerous raw, or unpasteurized, market milk even though the public health importance of milk pasteurization has long been established, Dr. James A. Tobey, prominent New York scientist and health expert, told the annual convention of the International Association of Milk Dealers here today.

Only about 47 per cent of the fluid milk produced in this country is pasteurized, it was declared by Dr. Tobey, until recently Director of Health Service of The Borden Company. The risk of epidemics due to contaminated raw milks of low grades is still very great, he asserted.

"In 1936 there were 42 epidemics of milk-borne diseases in the United States, involving 1547 cases of preventable diseases, and 28 unnecessary deaths, as reported by the United States Public Health Service," he said. "In every instance these unfortunate outbreaks of typhoid fever, septic sore throat, scarlet fever, and other communicable diseases were caused by infected raw milk of low grades. The only gratifying feature about these epidemics is the fact that the number is less than the country's average for the past ten years, indicating a gradual improvement in the small town and rural milk supplies in which most of these outbreaks occur.

Texas Cities Slow to Pasteurize

"In 1923 only about 70 per cent of the market milk in Dallas and Fort Worth was pasturized, and in 1931 only 80 per cent was accorded this important safeguard. Except for Galveston, where 80 per cent of the supply was pasteurized in 1931, other Texas cities have been unfortunately reticent in adopting this sensible safety measure, which ought to be universally applied for the best interests of the common health."

Dr. Tobey gave an analysis of statistics of pasteurization by sections of the country and by cities. Pasteurization has been much more widely adopted in the East North Central, Middle Atlantic and New England States than in the South Atlantic and South Central States, he declared, while the Pacific and Mountain States occupy a position between these other sections. While the southern states

IMMEDIATE FREEDOM FROM PAIN
AND REMARKABLY RAPID HEALING IN

PEPTIC ULCER

Creamalin—the distinctive colloidal cream of aluminum hydroxide—produces prompt subjective relief and objective improvement in gastric and duodenal ulcer. Pain and epigastric distress are relieved with the first dose, and are held in complete abeyance thereafter. Healing of the ulcer crater, as demonstrable roentgenologically, occurs in three to five weeks on oral administration, and in 7 to 10 days under continuous drip therapy.

Creamalin fixes 12 times its volume of N 10 HCl in less than 30 minutes (Toepfer's reagent). Its action is sustained, in contrast to the fleeting influence of the alkaline powders; it produces no secondary rise in HCl secretion, and even in large quantities cannot lead to alkalosis. • • The administration of Creamalin is free from undesirable side-actions. It is the safe and effective medication not only in peptic ulcer, but whenever profound acid neutralization is required.

For the Aristocracy of Thought*

> Your highly valued Journal is made to order for the aristocracy of thought of the Medical Profession of America . . . it has become a habit with me, and I would not care to miss a single issue.

The American Journal of Digestive Diseases and Nutrition

Was NOT established as a *vade mecum*, a news magazine, a humorous monthly nor a fictional alleviation for the jaded nerves of busy doctors . . Most readers by this time have divined this point of policy, and have come to know that, month by month, this periodical gives a cross section of current and modern gastro-enterological thought. It sees most of the manuscripts in this specialty: it prints all of them that are suitable . . . BETTER articles will be printed only when BETTER articles are written. The reader may confidently believe that at present the best work in gastro-enterology finds its way into these pages . . . Another way of saying that the management of this JOURNAL is seeking to perfect a really worth-while Archive in a most important field.

> *I am an admirer and reader of your excellent magazine.*

> *You cannot improve on the editorial content — it is and should be, an outlet for scientific thought.*

It is the firm intention of the Editorial Council that the pages of this Journal shall be kept FULL of important matter, and entirely EMPTY of all matter that is irrelevant . . .

> *Material and format are excellent. I enjoy it very much because the articles are scientific.*

> *It is certainly a well edited Journal and anyone who subscribes to it certainly gets his money's worth.*

Readers feel today that an important contribution to American Medicine is being, and will be, made through the agency of the American Journal of Digestive Diseases and Nutrition . . .

Quality brevity, educational value, scientific dignity, good typography and singleness of purpose are making friends in increasingly large numbers.

*These are excerpts from voluntary letters received from readers and the names of the writers are on file at the Office and may be had upon application.

No Other Special Medical Journal Ever Made the Subscription Showing in 3 Years That Has Been Accorded to the American Journal of Digestive Diseases and Nutrition

With only the numerically small American Gastro-enterological Association as a formal backer, this Journal has independently attracted a record group of constant readers.

WHY? . . . .

The reasons are obvious—

- One of the strongest Editorial groups in American Medical Journalism, realizing the void that existed in gastro-enterological literature, determined to make a special Journal that would meet very specific needs.
- The needs were for a journal that would collect and attract under one head the important contributions in this field, thus enabling the reader to learn what he wished without the inconvenience of looking through an extensive literature.
- This has been done . . . today our Editor receives countless manuscripts from the investigators of the U.S.A. . . . today numerous readers volunteer the fact that they have never made better investments than in the Volumes of the American Journal of Digestive Diseases and Nutrition.

Spend $6.00 per year or $10.00 for two years NOW.

Join the increasing Group of doctors, whose enthusiasm has made and is making history in American Medical Journalism.

The card below is attached for your use and is postage free.

To AMERICAN JOURNAL OF DIGESTIVE DISEASES & NUTRITION
435-455 Lincoln Bank Tower - - - Fort Wayne, Indiana

WHERE TO IN 1938?

Toward further advances in therapy, of course — acceleration of healing and higher percentage of successful treatment.

And to this end may we suggest in dietary procedure the use of Irradiated Pet Milk; a sterile, readily digestible milk of high caloric value — a milk incapable of introducing pathogenic organisms — free from the irritating physical characteristics of ordinary milk, and therefore conducive to early healing — a definite contribution of proved value to the advancement of diet therapy.

For complete protection against milk-borne infection, for quicker healing and fewer recurrences — for better dietary procedure, prescribe Irradiated Pet Milk.

SAMPLES AND LITERATURE WILL BE SENT ON REQUEST.

have recorded gratifying increases in the amount of milk pasteurized, the greatest percentage of urban sales of the hazardous raw milk is still in the southern and southwestern cities, he said.

"The percentage of milk pasteurized in American cities of 10,000 or more population increased from 81.8 per cent in 1927 to 87.5 per cent in 1931," the speaker continued. "There are in this population group something over 700 cities having a total population of more than 58,000,000 persons, according to the 1930 federal census.

"As the population of various communities decrease, however, the proportion of pasteurized milk also decreases, until in the rural sections it is close to zero. Thus, a recent survey by a committee of the International Association of Milk Sanitarians reveals that an average of only 38.6 per cent of the milk in communities of 1,000 to 10,000 population is now pasteurized. In this population group, there are more than 15,000,000 people, as shown by the census of 1930.

50,000,000 Live Where No Pasteurization

"Another 50,000,000 persons in the United States reside in villages having less than 1,000 population and in rural sections of the country, where pasteurization of milk, at least for human consumption, is seldom, if ever, practiced.

"The data in the Public Health Service report for 1931 shows that in this year there were only 35 American cities in which the entire milk supply was reported as pasteurized. There were, however, another 64 cities in which all milk except certified, the highest grade of milk and the only legitimate exception to the goal of universal pasteurization, was required to be pasteurized.

"Of the 99 municipalities on this honor roll, 16 were in Illinois, where incidentally 80 per cent of the state's milk supply is said now to be pasteurized. Thirteen of the honor cities were in Ohio, and there were 11 each in Massachusetts, New Jersey, and New York, these four states with Illinois accounting for two-thirds of the communities having from 99 to 100 per cent pasteurization."

Dr. Tobey declared that a current survey of the status of pasteurization, now being undertaken by officials of the United States Public Health Service, may divulge further improvements over the figures cited but, even so, the record is unquestionably not as creditable in many parts of the country as it should be. Pasteurization has made noteworthy progress, he asserted, and is making splendid advances, but there is still much to be accomplished.

Universal Pasteurization Can Be Achieved

"The goal of universal pasteurization in this country can be achieved by the cooperative and zealous efforts of competent health officials, comprehending physicians, a perceptive dairy industry, and an enlightened public, educated to demand the quality in its milk supplies that all progressive milk dealers are more than willing to give," the speaker continued.

"Although the organized medical profession, as represented by the American Medical Association, strongly advocates pasteurization, many individual physicians do not seem to realize the significance of this necessary process. In some parts of the country, education of the professional man in this respect is as much needed as is education of the presumably more ignorant layman.

"The Place of Certified Milk in the and is not yet wholly dispelled, that pasteurization is merely a corrective for an impure milk supply. Today that idea is a delusion, for pasteurization is

high-nutritive, low-bulk foods without sacrifice of minerals and vitamins

11 STRAINED FOODS, VEGETABLES, CEREALS, SOUPS, FRUITS

Concentrated nourishment, salt-poor, sugar-free, and low in fiber, perfected by ten years of authoritative research and experience, is provided by Gerber's Shaker-Cooked Strained Foods.

Gerber's own Department of Research and Nutrition, and the Gerber fellowship in a state university, with the continuous advice of leading medical authorities, have combined to produce strained foods raised to the physician's ideal standard.

Qualitative and quantitative analyses of any or all Gerber Foods will be furnished to a physician on request.

Gerber's superiority begins with the use of specially developed varieties of seeds. These are grown in chosen soils not more than an hour's transportation from Gerber kitchens, and harvested at the height of their nutritive value and flavor. Air is excluded throughout cooking processes and much additional effort made to conserve to the utmost all vitamin and mineral substances.

Gerber foods, in 11 varieties, are useful in various gastro-intestinal conditions because they supply vitamins and minerals ably in a restricted diet, which often is dangerously low in these two nutritive elements.

"NOW...WE HAVE THE MEANS FOR ACCOMPLISHING GENERAL GASTROINTESTINAL REACTIVATION"

HOW often doctors deplore the multiplicity of common complaints — from "indigestion" to chronic constipation — that follow in the train of dietary abuse, negligence, or irresponsible self-medication! They know how certainly the functional impairment of one organ reflects a broader disturbance of the delicate balance operating between the digestive, assimilative and eliminative processes as a whole. They emphasize the inadequacy of mere symptomatic relief.

In the absence of gross pathology, the physician today insists that the proper treatment of gastrointestinal dysfunction requires a due recognition of *all* contributing factors. In view of its multiple etiology, leading scientists have for years sought an adequately comprehensive therapeutic agent. Tri-Costivin is the brilliant culmination of their efforts.

* * *

In Tri-Costivin, for the first time, full regard is given to the requirements for *good digestion* — through the inclusion of high potencies of vitamin B_1 and $B_2(G)$ for the promotion of appetite, increase of hydrochloric acid secretion, and improvement of stomach tonicity. Bile extract is supplied to increase the contractile action of the gall-bladder, and duodenum gland extract (hormone cholecystokinin) to stimulate duodenal and gall-bladder function. The inclusion of gall-bladder tissue extract (hormone cholezysmon) serves to intensify the action of the pancreatic enzymes and to promote fat digestion.

Good assimilation usually follows on proper digestion — if the intestinal mucosa is in healthy condition. The vital dependence of intestinal health on a normal acid-base equilibrium ha led to the incorporation in Tri-Costivi of lacto-banana powder, and Trilactic (trade mark) with calcium lactate . . . effective agents for the re-establishment of the friendly aciduric type of flora. Absorption of fats is promoted also by the gall-bladder extract, bile salt, and vitamin B_1 and $B_2(G)$ content.

For *good elimination*, a healthy tonus of the intestinal musculature is indispensable. Here, the vitamins B_1 and $B_2(G)$, lacto-banana powder, and Trilactic ingredients of Tri-Costivin add a positive stimulus to peristaltic vigor. Agar karaya gum is included also to provide soft gelatinous bulk to the stool.

* * *

Tri-Costivin contains no cathartics or laxatives to cause irritation of the intestinal mucosa. Its striking success as a therapeutic weapon lies solely in the brilliant rationale of its physiologic approach to the underlying causes of dysfunction of the digestive tract as a whole.

Details of the research which led to the production of Tri-Costivin — and protocols of clinical investigations on this important new product — have been reprinted in the book, "The New Physiologic Approach." Write for it, and for samples of Tri-Costivin. They are available to the physician on request.

For sale on prescription in plain containers of 266 gm. with cellophane slip label—which the pharmacist is instructed to replace with a prescription label.

Dosage: 2-4 tsp. twice daily with morning and evening meals, followed by water.

PROFESSIONAL LABORATORIES, Inc.

not, and is not intended to be, a substitute for sanitation in milk production. The process renders a clean milk safe and helps to guarantee its purity, but it does not in any way obviate the necessity for an original milk supply of high quality.

"Another common delusion has been the erroneous idea that pasteurization exerts an adverse effect upon the nutritive properties of milk, long known as our most nearly perfect food. Actually, however, milk that has been pasteurized by modern methods is virtually equivalent in food value to raw milk. Not only does it furnish all of the vitamins, minerals, and other nutritional constituents that milk is depended upon to supply, but it is unimpaired in flavor, taste and digestive qualities.

"For many years, doctors, scientists and government officials have recommended a greater national consumption of pure milk and dairy products, since these are the foremost of our protective foods. The professors and pundits have properly urged the more widespread use of such nourishing and economical food combinations as bread and milk, bread and butter, and the like, but all such efforts would be intensified if the safety as well as the cleanliness and nutritional virtues of all market milk supplies could be guaranteed.

"Modern pasteurization of milk offers such a guarantee. It offers to the public a quality milk supply, the kind of a milk supply that merits and achieves public confidence, and thus enhances the dairyman's opportunities for quality sales."

FOR THE

Undernourished Child

The growing child, taxed by the heavy demands both of his school and his play, often shoots upward in height, but just does not seem able to "fill out"—frequently he is nervous and listless, as well.

In such cases, physicians have found through their own clinical experience, that the prescribing of a nourishing, easily digested food, such as HORLICK'S MALTED MILK often results in marked improvement. For this purpose HORLICK'S has a record of many years of success due to these outstanding qualities—

1. Tempting To The Appetite
2. Quickly Digested
3. Offers Valuable Nutrition

HORLICK'S MALTED MILK TABLETS are in an especially convenient form for use as a source of food-energy in midmorning or midafternoon—at home or at school.

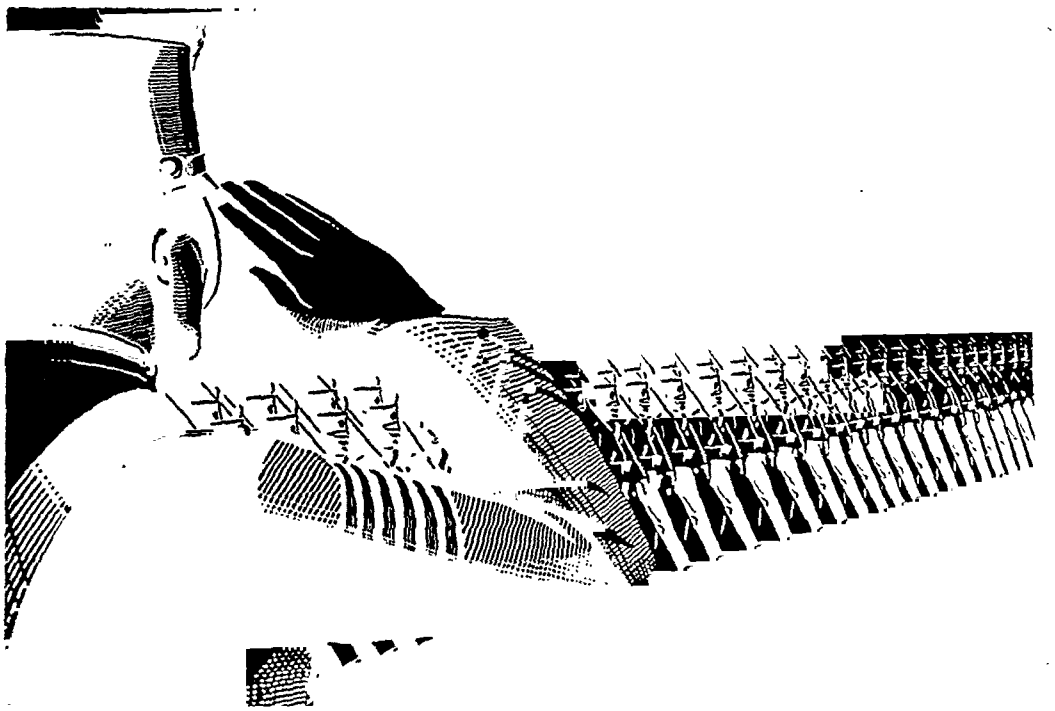
WEISS, SOMA AND WILKINS, ROBERT W.

Disturbance of the Cardiovascular System in Nutritional Deficiency. J. A. M. A., Vol. 109, pp. 786-793, Sept. 7, 1937.

Disease of the cardiovascular system is usually studied from the standpoint of infections and degenerative processes. Since it is the most important cause of death, the study of the relationship of nutritional deficiency to it is important. Severe dietary restrictions result in bradycardia, hypotension, and a decreased metabolism. The rate of blood flow is also considered to be decreased in these cases. If prolonged, fatty degeneration of the myocardium may result. It has been observed that cardiac standstill occurs more frequently in malnourished dogs and cats when operated upon, than in well nourished ones. It has also been observed during famines that malnourished patients are poor surgical risks.



A deficiency of protein results in nutritional edema, a lowering of the serum protein, and in the presence of heart disease the tendency for exudation into the pleural, pericardial, and peritoneal spaces and of pulmonary edema is increased.

Reduction of the blood sugar results in symptoms of hypoglycemia as occur in hyperinsulinism and diabetes with insulin shock.

Dehydration as occurs in diarrheal conditions, fevers, fistulae (biliary, etc.), prolonged vomiting, duodenal drainage, results in circulatory collapse and shock of dehydration. This is due to a reduction of blood volume, hemoconcentration and the accumulation of toxic waste products in the body.

Hypochromic or macrocytic anemias produce an increase in the cardiac output and velocity of blood flow, a hypotension and an increased pulse pressure. In pernicious anemia, fatty degeneration of the myocardium occurs producing the "tiger lily" appearance typical of far advanced stages of this disease. X-ray also shows some cardiac enlargement and physically there may be systolic and rarely diastolic murmurs heard.

Vitamin deficiency results first in biochemical changes, later functional

☆ DISCIPLINE ☆

"Discipline is the development of the faculties by instruction and exercise." When functions such as habit time of bowel movement are neglected through lack of discipline or intelligence, they require careful training to restore them to a normal state. Petrolagar has proved to be an agreeable and effective means of establishing bowel discipline . . . . Because Petrolagar mixes intimately with the bowel contents, it increases the bulk in the stool to a soft mass which is easily passed . . . . The Five Types of Petrolagar provide the doctor with a variation of treatment to suit the individual patient . . . . Petrolagar Laboratories, Inc., 8134 McCormick Boulevard, Chicago, Ill.

Petrolagar — Liquid petrolatum 65 cc. emulsified with 0.4 Gm. agar in a menstruum to make 100 cc.

Petrolagar

and finally structural. In the early stages, this may be a reversible process, but as time goes on these changes may proceed to a state of nonreversibility. Deficiency of vitamin B results in beriberi, which in its "dry" form is characterized by muscle wasting, and peripheral neuritis, while in its wet form, by cardiovascular disturbances and generalized edema. The cardiovascular symptoms of beriberi are dyspnoea on exertion, palpitation, tachycardia, embryocardia, gallop rhythm, prominent cardiac and epigastric pulsations and bounding peripheral pulses. The heart may be normal in size or enlarged, and systolic, rarely diastolic murmurs may be present. Cardiac asthma may occur. The arterial pressure is normal or the systolic may be moderately increased. Edema may be present. The electrocardiogram usually shows alteration in the T waves. Pathologically, there is no constant gross finding except slight dilatation of the right ventricle, but histologically, there is a degeneration of the myocardial fibers, swollen collagen, perivascular "edema," and separation of the myocardial bundles. It has also been noticed that infantile beriberi of the Orient occurs in breast fed babies. This may account for some of our cases of "idiopathic" cardiac hypertrophy.

Experimental evidence indicates that a deficiency of vitamin C predisposes to cardiac lesions. Once these occur, however, it does not cure them. Cardiac changes that occur in vitamin D deficiency can be ascribed to the simultaneous presence of vitamin B_1 deficiency.

Francis D. Murphy, Milwaukee.

An Improved
Antipyretic, Analgesic
ASPIR-VESS
(Aspirin, Buffered Alkali, Effervescence)
Alkali buffers aid by safely alkalinizing in respiratory infections, rheumatism, neuralgia, etc.
The CO_2 factor encourages gastric tolerance, rapid absorption, quick effectiveness.
For Safe Alkalinization
ALKA-VESS
(Alkali Buffers in Palatable Effervescent Solution)
Takes up acid in a safe, natural way with less danger of alkalosis. Pleasant to take—no objectionable, earthy, alkaline taste.
Both Aspir-Vess and Alka-Vess are supplied in convenient glass tubes of 25 tablets.

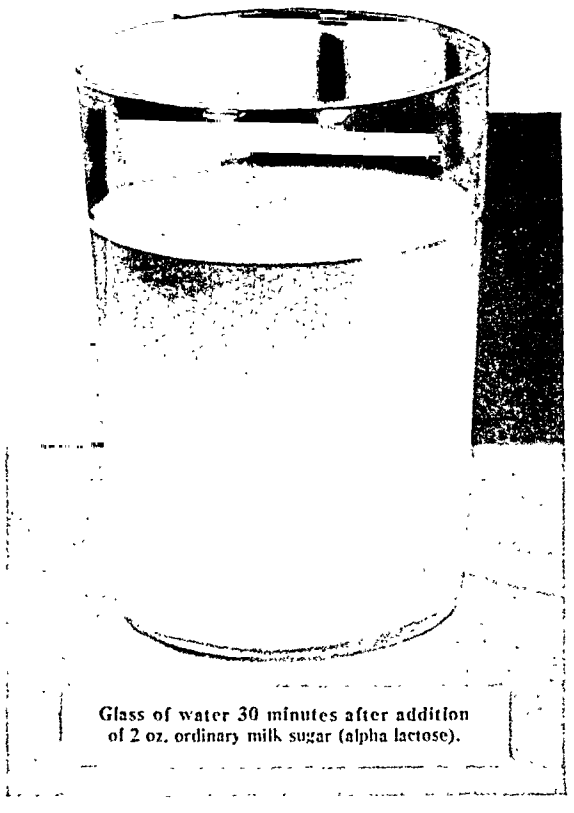
WHITAKER, LESTER R.



Congenital Adhesions of the Gall Bladder. Ann. Int. Med., XI, 379, Aug., 1937.

The material upon which this paper is based came from the Department of Anatomy of the Boston School of Medicine and Surgical Clinic of the Massachusetts Memorial Hospital and was an article contributed to an Anniversary volume in honor of Dr. Joseph Hersey Pratt.

The author states that abnormal peritoneal attachments to the gall bladder are more common than are inflammatory attachments. He calls attention to the nature of the sheets of tissue that run from the lesser omentum to the gall bladder, to the duodenum and the colon as being simple folds of peritoneum, with definite relation, definite structure and regular vessel arrangement. These, therefore, are concluded to be no evidence of past infection of a gall bladder. The author thinks that inflammation as a result of infection has been emphasized too greatly in pathological conditions of the gall bladder to the neglect of anatomical and metabolic factors. He thinks that cholesterosis is no more a manifestation of infection than is atherosclerosis in blood vessels. He looks upon both as evidences of degenerative changes as the result of toxic and metabolic disturbances rather than from inflammatory causes.

He offers two methods of determining whether or not a peritoneal attachment is a congenital one or an inflammatory one. The development of abnormal peritoneal attachments to the gall bladder are rather simple from an embryological viewpoint, the primary digestive tube having an anterior and a posterior mesentery and in the rotation of the stomach the posterior mesentery becomes the greater omentum, while the anterior becomes the lesser. From the anterior mesentery a bud grows out to form the liver, bile ducts and gall bladder. Usually the anterior mesentery is stopped at the common bile duct and portal vessel, but it occasionally becomes more extensive and runs from the common duct over to the gall bladder, down the duodenum and to the hepatic flexure of the colon, even as far as the right lobe of the liver and may, he thinks, close the foramen of Winslow. This bit of anterior mesentery may become a mere slight band of tissue running along the lesser omentum to the cystic duct or it

Two glasses show you one reason for specifying Beta Lactose

Glass of water 30 minutes after addition of 2 oz. ordinary milk sugar (alpha lactose).

Glass of water 3 minutes after addition of 2 oz. Borden's Beta Lactose.

● One excellent reason for specifying Borden's Beta Lactose is its greater solubility.

Actually, it is *five times* more soluble than ordinary milk sugar. So, it is decidedly easier to use.

And Borden's Beta Lactose also is much more palatable. So, it is much easier for your patient to take.

New, Improved Container — Borden's Beta Lactose now comes in a new, conveniently shaped container that permits easier measuring, easy access right down to the last grain. No directions appear on, or in, the container. Accepted, of course, by the Council on Pharmacy and Chemistry.

may be an extensive sheet of tissue. It may develop a mesentery and the gall bladder become enfolded, supported in these tissues. Sometimes it passes over the gall bladder without attachment to it. In some cases the tissue may be absent both above and below, leaving the band from the lesser omentum across the duodenum to the anterior surface of the gall bladder only.

The author emphasizes that in all these types general relations are the same except that different parts of the sheet tissue are missing. The opinion is expressed that such terms as "periduodenitis" and "peritholetystis" or "essential periduodenitis" only contribute to the general misunderstanding and false operative diagnoses.

A resume of the literature by Meyers and Bloom is quoted, in which those authors found 20 per cent of abnormal peritoneal attachments of the gall bladder and duodenum to be in apparently normal individuals. In their own assessment 54 per cent were found to be congenital membranes and only 5 per cent showed inflammatory adhesions. In the authors' material 51 subjects were studied and abnormal peritoneal attachments to the gall bladder were found in 45 per cent. The gall bladder in every one of these cases appeared to be normal. In a series of 100 patients in which a cholecystectomy was done by the author 18 per cent showed definite abnormal peritoneal attachments to the gall bladder.

The question is raised as to whether these congenital peritoneal attachments to the gall bladder, duodenum and colon may produce definite symptoms. The author thinks that perhaps the bare suggestion of the symptoms produced in this connection, such as vague discomfort in the right upper quadrant, loss of appetite, a sense of bloating, nausea, sour stomach, may be helpful indications of anatomical abnormalities which prevent a normal function. Abnormalities of duodenal outline are frequently shown in X-ray studies. The constancy of deformity of the duodenal bulb in ulcer as contrasted with shifting deformity of Duval is stressed. Duval's deformity is differentiated from an irritable cap by the fact that in the former the cap is filled but the deformity occupies a varying segment and remains as irregular atrophy. Constriction of the gall bladder or of its ducts by these abnormal sheets of peritoneal tissue running across the duodenum may result in discomfort and irregular pain in the right upper quadrant, even with nausea and vomiting. These symptoms are relieved by the removal of these congenital adhesions, usually with cholecystectomy. Since relief follows such operative procedures in cases where the gall bladder was restricted in its mobility by these congenital adhesions would seem to argue that the adhesions were the cause of the trouble.

The author concludes in his summary that congenital peritoneal adhesions to the gall bladder are much more common than ordinarily realized, being found in about one-fourth of the population, that while some of these adhesions may not produce symptoms some of them do. The symptomatology is not clear and is rather designated by the term *vague*. These patients are often neurotic. Preoperative diagnosis treatment consists of medical care with a view of relief to the alimentary lodes, psychological care and finally surgery for those cases where definite abnormalities obtain and where other measures have failed. The operative treatment consists usually in the removal of the gall bladder and the section of band or sheath of peritoneal tissue. It is urged that care be taken to prevent secondary adhesions, but no suggestions are offered as to how these be prevented.

SORICIN IN THE BOWEL

The physiological action of Soricin in the bowel has not yet been fully explained. This much *is* known: Soricin by mouth is non-toxic and harmless even in large doses. Soricin definitely aids in the treatment of such conditions as colitis, hypersensitivity of the intestinal tract and toxic absorption from the bowel as evidenced by symptoms of migraine, vertigo, and urticaria.

Soricin is effective because it is a detoxifying agent particularly adapted to internal administration. Its use is based on the clinical work of Dorst and Morris, Burger, Baker, MacQuiddy, Brown, Kline, Jackson, Mateer and others.*

Soricin (sodium ricinoleate) is available in two dosage forms:

Soricin Capsules (Enteric Coated):

10 grain size:
boxes of 20 and 100 capsules each
5 grain size:
boxes of 40 and 100 capsules each

Soricin Tablets (Enteric Coated):

5 grain size: bottles of 100 tablets

PRESENTING

DUOCHOL

(PLESSNER)

for Dependable Choleresis
and Cholagogue Action

Duochol (Plessner) presents a valuable addition to the physician's armamentarium in the management of hepatobiliary disease. Its rational formula offers a means of dependable, specific therapy in a number of biliary tract and liver derangements, especially when the undesirable irritant action of cathartics must be avoided.

Duochol exerts its influence upon the entire biliary apparatus. Secretion of bile is augmented appreciably. Because it contains the two most potent cholagogues known, Duochol intensifies gallbladder evacuation. Thus drainage of the entire biliary tree is stimulated. In consequence, food intolerance is corrected, epigastric and right upper abdominal discomfort is quickly relieved, and postprandial eructations and bloating are promptly overcome.

Duochol (Plessner) is indicated in chronic cholecystitis, toxic hepatitis, catarrhal jaundice, and stone-free cholangitis. Because it is free of irritant cathartics, it may be safely administered during pregnancy when latent gallbladder disease frequently becomes activated.

Composition

Each Duochol tablet contains highly purified bile salts, 2 gr.; sodium salicylate, 2 gr.; ext. cascara sagrada, ½ gr.; together with oleoresin capsicum and oil of peppermint.

Notable for Its Economy

The reasonable price of Duochol (Plessner) places it within the reach of all patients. This point is of importance when treating hepatobiliary disease, since therapy is usually protracted.

Samples on Request

Generous test quantities of Duochol (Plessner), together with appropriate literature, sent to physicians on request.

Availability

Duochol (Plessner) is supplied in bottles of 100 and 500 tablets. Available through all pharmacies upon prescription.

THE PAUL PLESSNER CO.

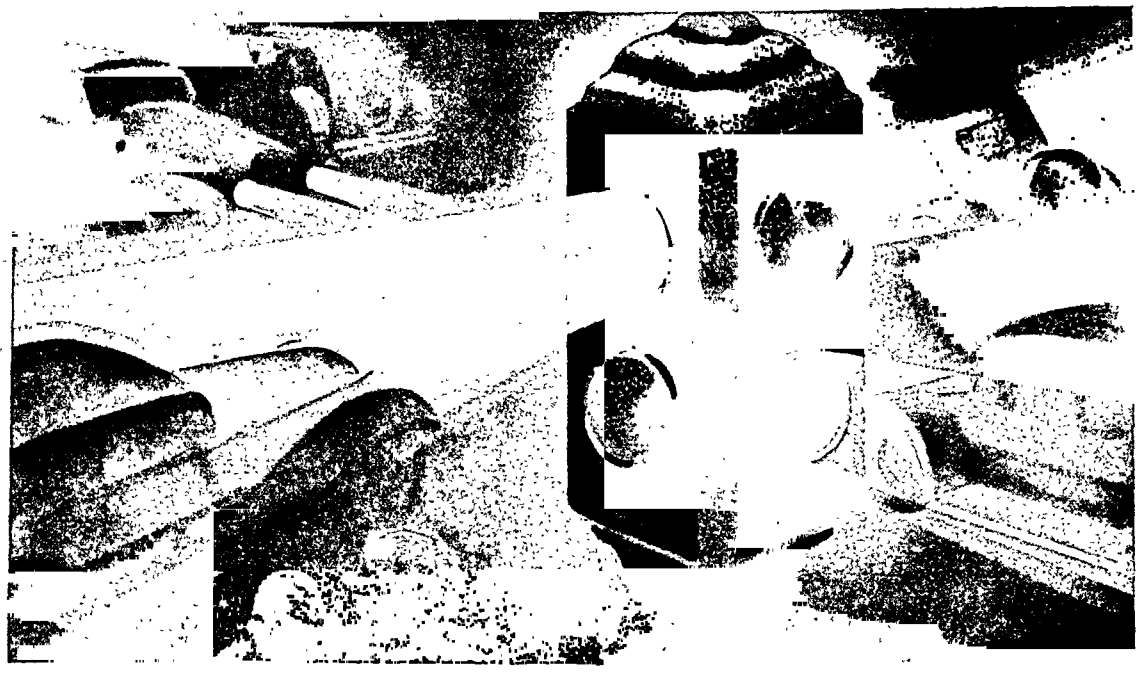
DETROIT, MICHIGAN

HURST, SIR ARTHUR.

Melanosis Coli. Guy's Hospital Reports, 87:332-342, July, 1937.

The author discusses melanosis coli from the historical standpoint, the nature of the pigment, morbid anatomy, histological appearances, and etiological relationship of carcinoma, constipation, purgatives and diarrhea.

Two cases are presented in which the melanosis coli cleared up while the patients were under observation.

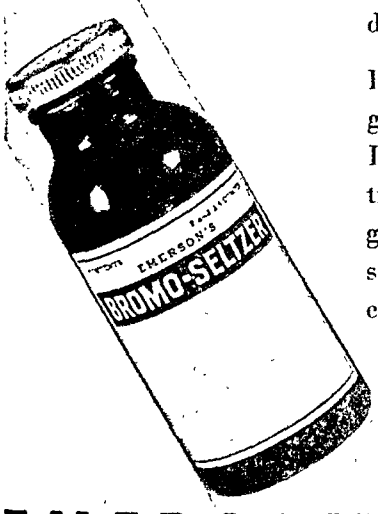


The following conclusions are presented from a review of the literature and a study of the author's own cases:

Some degree of melanosis coli was present in 11.2% of an unselected series of cases autopsied. The incidence is higher above the age of forty (17.7%), and still higher in carcinoma of the colon (50%), the melanosis in the latter being more intense above than below the growth. Melanosis coli is due to the deposition of a melanin-like pigment within large mononuclear cells in the mucous membrane of the large intestine and appendix. The chief causative factor is said to be artificial diarrhea produced by aperients which results in excessive putrefaction of proteins throughout the colon. The aromatic protein disintegration products are absorbed by the mucous membrane of the colon and converted into melanin by the action of a tyrosinase-like ferment. The pigmentation of the colon disappears with cessation of the diarrhea under treatment. Melanosis occurs four times as frequently in persons with carcinoma of the colon as in those without. It is usually confined to the part of the colon proximal to a carcinomatous obstruction in which stasis of semi-fluid faeces leads to excessive putrefaction and the production of precursors of melanin.

Hanes M. Fowler, Fort Wayne.

MISSISSIPPI VALLEY MEDICAL SOCIETY AWARD



The Mississippi Valley Medical Society offers a cash prize of $100.00, a gold medal and a certificate of award for the best unpublished essay on a subject of interest and practical value to the general practitioner of medicine. Entrants must be ethical licensed physicians, residents of the United States and graduates of approved medical schools. The winner will be invited to present his contribution before the next annual meeting of the Mississippi Valley Medical Society (September 28, 29, 30, 1938), the Society reserving the exclusive right to first publish the essay in its official publication—the Radiologic Review and Mississippi Valley Medical Journal. All contributions shall not exceed 5,000 words, be typewritten in English in manuscript form, submitted in five copies, and must be received not later than May 15, 1938. Further details may be secured from Harold Swanberg, M.D., Secretary, Mississippi Valley Medical Society, 203-224 W. C. T. Building, Quincy, Ill.

Green Light...RED LIGHT

FOOT on the brake, off the brake. Green light, red light, green light. Millions of cars on the roads requiring continuous watchfulness. Pedestrians leaping out of nowhere. You, as a physician, know how hard and nerve-racking a day's driving can be. Headaches are frequent—and often chronic.

Have you ever given Bromo-Seltzer a real trial as an analgesic? It has established itself as an effective pain conquerer. Its rapidity of action is a feature which merits your consideration. In scientific, synergistic proportions, Bromo-Seltzer ingredients are blended—for analgesia, sedation and gentle stimulation of mental activity. Citrates provide carbonic effervescence and combat hyperacidity.

Turn the green light on Bromo-Seltzer. You can prescribe it, with confidence, to your patients for relief of pain.

Samples and literature cheerfully furnished.

CONNOTATIONS. H. J. Sims, Denver, Colo.

Bone pathology dates to the time of Kolliker, who in 1873, propounded his osteoblastic and osteoclastic theory of bone production and bone absorption.

In 1835, Glenard published his thesis on visceroptosis. In addition to his description of the etiology, pathology and symptoms, he made the statement that "these subjects were unfortunate in that there was no treatment that had ever been devised which had done them any good and that," in his opinion, "they were consigned to a life of invalidism."

Meaker, in 1923, indisputably demonstrated tubal spasm actually existed.

Maisonneuve, in 1853, described gas gangrene under the name of gangrene foudroyante. In 1864, Pirogoff described the condition as acute gangrenous edema. Pasteur later described the causative organism as the vibrion septique.

Lister was almost deaf and blind during his last three years of life.

Errors are frequently the stepping stones to suffering humanity. Spencer Wells operated for an ovarian cyst and found a tuberculous abscess. He unknowingly established the surgical treatment for peritoneal tuberculosis. He, likewise, supposed an uterine fibroid was the cause of jaundice in an eighteen year-old girl. The spleen, and not a fibroid, was removed. Thus—inaugurating the surgical treatment of hemolytic jaundice.

Runge, in 1834, discovered carbolic acid. Its use was restricted to cleansing the sewage of the town.

In 1863, Jules Lemaire, a French pharmacist, wrote a book on carbolic acid and recommended its use for dressing wounds.

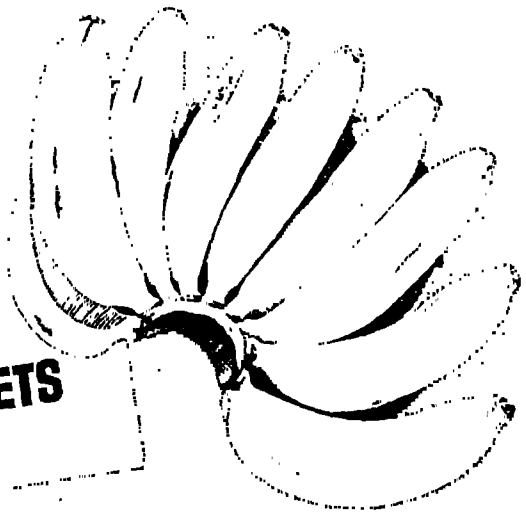
Von Bergmann, in 1886, was the first to use steam sterilization for instruments and dressings.

Partridge, in 1862, an English surgeon of great distinction, was called to Italy to locate a bullet in the ankle of Garibaldi. Not satisfied with his opinion, Nelaton from Paris was consulted. He made a steel probe with a porcelain tip. A metalic stain on the porcelain tip resulted when brought in contact with lead. As a result, he located and removed the bullet.

Joseph Jackson Lister, the association with Thomas Hodgkin, in 1827, determined the diameter of the red corpuscles and their rovleaux-formation.

Henry Gray, author of "Gray's Anatomy," did not live to see its publication. He died of small-pox at the early age of thirty-two.

Lister, in 1867, performed his first breast amputation on his sister.



VOLINI, I. F., WIDENBORN, H. L. AND FINDLAYSON, B.
Experimental Duodenal Ulcer. S. G. O., Vol. 65, No. 2, pp. 159-163, Aug., 1937.

In a series of 45 dog experiments in which the author successfully produced intestinal ulceration by the Exalto and Mann Williamson methods, the mucosa of the duodenum showed ulceration in 28 instances. The ulcers varied in size, depth and number. It seemed that the longer the animal survived after operation the smaller and less numerous the ulcers were. The cause of these ulcers is not clear; neither trauma nor interference with blood supply are likely causes, nor is food trauma a possible factor here. While the reaction of bile is frequently acid rather than alkaline it does not seem probable that it would be great enough to produce ulceration in the isolated duodenal loop.

The author reports these observations because no reference to such ulceration in the isolated duodenum has been seen by him, and in the hope that further study and research may be stimulated by this report.

N. M. Percy, Chicago.

USEFUL IN MANY INVALID AND CONVALESCENT DIETS

RIPE BANANAS are a natural, soft, bland food . . . with a delicate flavor . . . popular with most persons . . . nourishing . . . easily digested . . . non-irritating . . . do not readily ferment in the intestines . . . create intestinal conditions unfavorable to the growth of putrefactive bacteria . . . yield alkaline mineral residues in the body.

Because of these attributes, together with their soft fibre, pectins, high content of sugars, satiety value, low content of protein and fat, their vitamins (good source of A-B-C-G) and essential minerals, ripe bananas are prescribed by an increasing number of physicians in many invalid diets, including: ulcerative colitis; peptic ulcer; cardiac; diabetes; liver disorders; nephritis; tuberculosis; as well as in various post-operative and convalescent diets.

In the field of corrective diets, physicians are finding that ripe bananas help combat diarrhea and spastic constipation; also that in combination with milk they constitute a basis for planning a variety of effective, safe reducing diets for persons who are overweight.

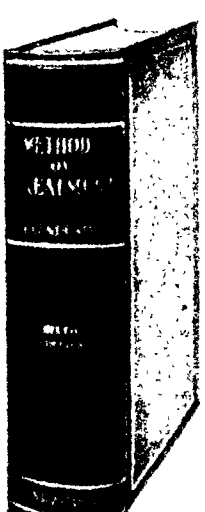
TRI-CALSATE

OLEUM PERCOMORPHUM CAPSULES

for diets deficient in

Vitamins A and D



Where there is an intolerance or an aversion to fats, such good sources of vitamin A as dairy products are studiously avoided by patients. Obesity, diabetic, pregnancy, and low-cholesterol diets especially tend to be deficient in vitamin A. Oleum Percomorphum Capsules offer a convenient and highly acceptable means of correcting this deficiency and also furnishing generous amounts of vitamin D. Each 10-drop capsule supplies not less than 13,300 A units and 1,850 D units (U.S.P.), the equivalent of more than 5 teaspoons of U.S.P. cod liver oil in natural vitamins.

METHODS of TREATMENT

There is no book on TREATMENT like CLENDENING "Methods of Treatment"

FIRST: It covers in ONE Volume ALL methods of treatment — Drugs, Diet, Physiotherapy, Hydrotherapy, Psychotherapy.
SECOND: It presents methods for treating patients step by step, and illustrates these methods. This is done so clearly, so accurately, and so logically that one can do them though he may never before have done them or seen them done.
THIRD: The book is so charmingly written that one is both instructed and inspired. This book is Clendening at his best—the master of words.
FOURTH: It is based on the last edition of the United States Pharmacopoeia.

by
LOGAN CLENDENING, M.D., Clinical Professor of Medicine, University of Kansas

New 6th Edition. 879 pages, 102 Illustrations. Price, $10.00

ROUNDER THAN MOST — "A textbook of internal medicine that is readable, sensible from start to finish, and rounder than most." THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

ALMOST PERFECT — "There is no greater need in the general practice of medicine than for a book which states in a clear, unambiguous way the principles of treatment and applies to the description of various procedures. This volume is almost perfect in all of these respects. . . . This is one of the rarest examples of a book that is both a reference work and a textbook. . . . This is one of the most valuable books that has been published in the field of internal medicine." THE NEW ENGLAND JOURNAL OF MEDICINE.

A VALUABLE REFERENCE — "This book, because it is a combination of materia medica and therapeutics of all is a valuable reference to any physician's library." SURGERY, GYNECOLOGY AND OBSTETRICS.

To

Blind Man's Buff Is No Fun In Medicine

Blind man's buff is a great game for children—groping about blindfolded, stumbling over things in search of the objective.

But in medicine only certainty and knowledge can lead to successful result. That is why physicians of experience have definitely decided upon Agarol in the relief of acute constipation and in the treatment of habitual constipation. They have found by enlightening experience that Agarol accomplishes well indeed the therapeutic objectives of intestinal lubrication, softening of the fecal contents, and stimulation of peristalsis. And Agarol does it without exacting penalties by accessory or after-effects. There is not even the after-taste of artificial flavoring to get used to.

AGAROL is available in 6, 10 and 16 ounce bottles. Average adult dose is one tablespoonful.

• Let a brief folder explain and a liberal trial supply demonstrate to you why Agarol is preferred by physicians and their patients. There are good reasons for it. Please write on your letterhead.

$C_{23}H_{33}O_3COOH$

Decholin has the above formula It is available in 3¼ gr tablets for oral administration, and in the form of its sodium salt for intravenous injection in ampules of 5% and 20% solution when intense and rapid choleresis is indicated

For Prompt, Intense Choleresis...

DECHOLIN-SODIUM

For Maintenance Thereafter...

DECHOLIN TABLETS

In hepatobiliary infections when especially rapid and intense increase of bile secretion is desired, the combined use of Decholin tablets (chemically pure dehydrocholic acid in crystalline form) and Decholin sodium is recommended. One or two intravenous injections of Decholin sodium soon promote the desired intensified bile secretion; thereafter, the oral administration of Decholin tablets helps to maintain it.

The increased flow of thin liver bile aids in the disposal of inspissated secretions within the bile ducts, and facilitates intrahepatic as well as extrahepatic drainage.

Decholin and Decholin sodium are of established value in chronic cholecystitis, noncalculous cholangitis, hepatitis of toxic origin, biliary insufficiency, biliary engorgement, and before and after biliary tract surgery. Contraindicated only in complete obstruction of the hepatic or the common bile duct.

Comprehensive literature, and the second edition of the brochure "Biliary Tract Disturbances" available to the profession on request.

The Dietary Problem of the Food Sensitive Patient

By

ALBERT H. ROWE, M.S., M.D.

SAN FRANCISCO, CALIFORNIA

IT is generally recognized that food allergy may affect practically any structure of the body and thereby produce mild to severe, acute, or chronic manifestations arising especially in the naso-bronchial, cutaneous, gastro-intestinal, uro-genital, and nervous tissues. Because of this, physicians are increasingly eliminating many foods from the diet either because of positive skin reactions, or because of the patient's history of possible idiosyncrasies. Too often such foods are eliminated, purely because of positive skin reactions, without the realization that many positive reactions to foods are non-specific, and that allergy frequently exists to foods not indicated by skin reactions. This has made the use of "elimination diets," modified, if desired, by positive skin reactions, of definite value in the diagnosis and control of food allergy. In the use of "elimination diets" emphasis must be given to the absolute necessity of providing the patient with menus, recipes, and instructions which will assure the possibility of adequate and reasonable meals obtainable at home or in restaurants or hotels—meals that meet caloric and metabolic requirements.

Thus the physician must assume the responsibility of placing the patient suffering with probable food allergy, on satisfying and appetizing meals from foods which are not productive of evident sensitization. Undesirable weight loss, protein, vitamin, and mineral deficiencies must not occur, especially because of the necessity of keeping patients on "elimination diets" often for prolonged periods of time if tissue changes from chronic allergic reactivity are to be finally eradicated. Patients must not be given a mere list of foods without explicit directions about menus which can be prepared in and away from home. The necessity for such menus has always been stressed in the use of my "elimination diets." In my work, moreover, many recipes have been developed for wheat, milk, egg, and cereal-free bakery products, desserts, and candies. Menus for restaurant, hotel, and home diets are published and should be made available to patients on "elimination diets" or other trial diets. The comparative frequency with which patients are sensitive to one or even to all cereals has emphasized the importance of a cereal, milk, and egg-free elimination diet, which is now the routine Elimination Diet III. For this diet, potato, lima bean, and soy bean flour have been used very successfully.

The ability to make such bread, cake, cookies, candy, or dessert requires care in following the published recipes, and varies with the personal skill and persistence of the cook or the baker. Many patients have excellent results from their efforts. The failure of others with the same recipes is at times difficult to explain.

Because of the time and care necessary to make these products without wheat, milk, or eggs, or any cereals, I have, for many years, enlisted the cooperation of local bakers. One, especially has been successful and is now distributing to patients according to their dietary requirements the following wheat, milk, and egg-free products, many of which are prepared fresh every day:

lima potato bread	corn and rice muffins
soy lima bread	corn muffins
rice bread	rye muffins
rye bread	soy lima snails
lima cookies	soy lima apricot cupcakes
lima molasses cookies	soy Danish snails (frosted)
corn and rice cookies	soy lima toast
rye cookies	cocoanut lima molasses squares
lima potato cup cakes	rye coffee cake
lima sugar cookies	lima soy cake
rice sugar cookies	fruit squares—lima crust
soy bean doughnuts	soy lima pineapple upside down cake
apricot pies—lima crust	
soy lima muffins	

Obviously some of these bakery products, as made by professional bakers, are difficult to reproduce in the ordinary kitchen, since their quality depends so much on special technique, and particularly on the ovens used in commercial work. Similar products will necesarily have to become available in most large cities throughout the world, so that the demands of the multitude of sufferers from food sensitizations can be met. It will also be desirable for certain national food companies to develop wheat, milk, egg, and cereal-free products, breads, probably in a sliced and toasted form, cookies, etc., which can be dispensed in air-tight packages to ensure fresh lasting qualities. It will be necessary that every ingredient of such products be printed on the package, a procedure that should also be enforced on all other food products sold to the public.

With such local and national distribution of products of varying composition, sufferers from food allergy, and physicians who are supervising their problems will be greatly aided in the satisfactory control of symptoms. As people become more aware of the frequency of symptoms arising from food sensitizations, hotels and restaurants will also necessarily take cognizance of the fact that all food is not tolerated by all individuals, and bakery products of varying content will be more generally available; and accurate information about the actual content of various foods on the menus will be more easily and cheerfully obtainable than it is today.

More definite discussion needs to be given to individual foods and allergens which cause sensitization. Milk allergy, especially, offers many difficulties. As stressed by Ratner (5) especially, evaporated milk is

denaturized to such an extent that some milk-sensitive infants can tolerate it without symptoms. In older children and adults, I have not found the use of such milk so successful in the control of symptoms due to milk allergy, and the complete elimination of all milk, usually with the exclusion of butter and other milk products, has been necessary for the eradication of symptoms. When sensitization exists to only the lactalbumin of cow's milk, fresh of preferably canned goat's milk, as prepared by the Myenberg Company of California, may be tried.

In infancy, a soy bean product like Sobee, can take the place of milk, and, as Clarke recently suggested, is taken more avidly by the infant if it is mixed with banana milk, either prepared from the banana flour or from the fresh fruit. If allergy to the bean or the banana exists, then almond milk prepared according to my former directions (1) may be used. Recently canned, homogenized beef or lamb has become available as excellent protein substitutes for milk. Such preparations can be diluted and served as a drink, in a bottle, or as a soup. Beef, and certain vegetables, minerals, and vitamins have been combined in a homogenized preparation called Cemac which can also be used in milk-sensitive patients. The use of pure beef or lamb, however, with the additional use of selected pureed or strained vegetables, minerals, and vitamins according to the patients demands, and evident or possible allergies thereto, would seem preferable.

When milk is excluded from the diet of older children and adults, other proteins such as meat or eggs to which sensitization does not exist, must be given in sufficient amounts to meet protein requirements. Homogenized beef and lamb and other meats will probably be of use in certain cases. Protein need may also be met in part by an extra intake of legumes, providing sensitization to them does not exist. When the use of butter must be forbidden, peanut, almond, or soy bean butters may be used, care being taken that an oil is not added in their manufacture which might give rise to allergy. When cottonseed allergy is not present, a butter substitute may be prepared from well-chilled Crisco, salted to taste. Such a product is now available on the market. A similar product could well be prepared from coconut oil or butter. A noncaloric butter substitute, made from a solid petroleum base, artificially colored. salted to taste, and flavored with a trace of butyric acid is also sold.

It is also helpful to advise the free use of jams and jellies made from fruits in the prescribed diet as a substitute for butter on bread, and chicken fat or bacon grease are at times also acceptable. In the patient who is markedly allergic to milk, as with all other foods to which definite sensitization exists, it is most important to stress over and over again the absolute necessity of eliminating every food product from the diet which contains a trace of milk or any of its products. Too often it is not realized that ordinary bread, cookies, and foods such as Ovaltine contain varying amounts of milk.

The difficulty in preparing a menu and nourishing infants or children without eggs is much less than without milk. Egg allergy, however, is extremely common, especially in children, and seems to be the initial allergy which gradually leads to the development of many others in certain cases. At times patients can tolerate the eggs of one bird and not of another, though usually allergy exists to several different eggs, probably due to proteins common to them. Such occurrence has been demonstrated experimentally. Occasionally patients may be allergic to the egg, meat, and even to feathers of chickens, probably due to the presence of a common allergen in them all.

A few patients are sensitive to several meats. Allergy to pork is probably most common, that to beef and to lamb occurring with decreasing frequency. Skin reactions may or may not occur to such proteins. An occasional patient, as in the case with chicken allergens, is allergic to milk, beef, and cattle hair in varying degrees. It must be appreciated that prepared meat products such as sausage, bologna, and frankfurters contain different kinds of meat, cereals, at times egg, and various spices, which make them entirely unsuitable for inclusion in an elimination diet, especially during the diagnostic period.

For several years, recognition of yeast allergy has made necessary the use of yeast-free baking products in sensitized patients. Such patients are also affected by the yeast used in beer, and the fungi and yeasts used in the manufacture of cheeses may also produce allergy in sensitized individuals. Baking powder may be used where yeast allergy is present, though it must be remembered that certain powders contain small amounts of egg and that some patients are sensitive to the bromates in such powders. In fact, when definite iodide or bromide sensitization exists, producing cutaneous lesions especially, it may be necessary to exclude all sources of them, such as baking powders and iodized salt from the diet. An unusual source of allergy is from dyes used in foods. When phenophthalein sensitization exists, productive as it is of many types of skin and mucous membrane lesions, all pink-colored foods and drinks should be excluded. Symptoms arising from other dyes in foods have been reported in the literature.

The reactions which arise in the same patient from biologically related foods were first reported by Vaughan. This is especially true of fruits, vegetables, fish and other sea food. Patients may be allergic to all pit fruits (Drupaceae), to all citrus fruits (Rutaceae), to apples and pears (Pomaceae), to potato and tomato (Solanaceae), or to carrots, parsnips, parsley, and celery (Umbelliferae). Such group sensitizations do not always exist. For instance, many patients sensitive to apples or oranges can take pears and grapefruit with no trouble at all. However, this tendency to group allergies must be remembered. The problem of patients sensitive to practically all fruits, or less frequently to all vegetables, offers a serious challenge. At times such foods are sufficiently denaturized by heat so that moderate amounts of enough of them, especially in the canned state, can be taken, and an adequate vitamin intake can be assured. At other times allergy does not exist to all biologically related foods, and a few can be taken to assure proper vitamins and minerals. In such patients, the challenge also arises to find some unusual vegetables or fruits as used by other nationalities to which our patients have not become allergic. Hawaiian taro, guava jelly, and arrowroot starch are examples. Increasingly, new foods of such types should be brought from Asia, Central and South America, and other lands, and made available for our people in America. The easy cultivation of avocados and dates here in America shows that

the growing of many other new foods will be possible. Reference to a compendium of edible plants, as published by Sturtevant, indicates the possibilities along this line, and has been discussed in my previous publications. Again considering the patient sensitive to most fruits and vegetables, the use of Vitamins A, B, C, D and G in pill or capsule form is distinctly indicated. It is usually imperative to insist on the taking of definite amounts of some of those foods to which the least apparent allergy is present. At the same time, an attempt to raise tolerance to the most important vegetables and fruits by the hypodermic administration of antigens containing the active allergens preferably from the fresh products themselves, prepared according to Coca's technique, is justifiable. The degree of success from such therapy is still uncertain in all cases.

A discussion of patients sensitive to many foods must also include the fact that *too frequently neurotic individuals acquire distastes and aversions and apparent idiosyncrasies to foods to such an extent that gradually such restricted diets are taken that severe nutritional damage develops.* The study of possible food sensitizations in patients must ever be made with this fact in mind. Moreover, certain patients who have several definite food allergies which have been uncontrolled for years, but which have directed their attention to the likelihood that diet in some way is responsible for their invalidism, develop odd habits of eating, or follow the suggestions of friends, quacks, or food faddists, with the final result that detrimental habits of eating are acquired which at times are hard to counteract. In such patients, it may be necessary to ignore the possible challenge of food sensitization until nutritional balance and an increase in weight are established. Later a study of the patient with trial diets or with the leukopenic index may be advisable.

At all times, undesirable weight loss and deficiencies in protein, mineral, and vitamin balance must absolutely be prevented. In the case of certain patients it may be better to suffer from the effects of actual or possible allergenic foods than to develop increasing invalidism through nutritional deficiencies. Not infrequently, moreover, patients must accept certain mild evidences arising from slight allergies to a few or many foods, particularly if the foods productive of major severe symptoms have been discovered. However, with a persistent endeavor to evolve a diet devoid of foods to which detrimental allergies exist, success is usually possible, and many severe or vague though invaliding manifestations and symptoms can fortunately be controlled.

A Rare Case of Primary Liver Carcinoma in Liver Fluke Disease (Clonorchis Sinensis)

By

WILLIAM A. SWALM, M.D., EDWIN S. GAULT, M.D.

and

LESTER MORRISON, M.D.

Temple University Medical School
PHILADELPHIA, PENNSYLVANIA

THIS case reported is presented (a) because of the rarity of clonorchiasis in the United States, particularly in the East; (b) non-surgical biliary drainage was the diagnostic means of discovering the liver fluke when the stools were negative on examination for parasites; (c) to reaffirm the observation that non-surgical drainage is at present the most valuable palliative measure in the treatment of the disease, as well as a promising means of introducing directly a chemotherapeutic agent to be yet discovered in combating clonorchiasis.

The liver fluke, clonorchis sinensis, is found in many Asiatic countries, mainly China, Japan, India and Korea. In Central Japan certain areas are estimated to have an infestation incidence of as high as 67% of the population, according to Katsurada (1). On the East coast of India, the eggs have been found in as high as 50% of the natives by Leger (2). However, in a statistical study, Uttley (3) reported the incidence of clonorchiasis to be 13.9% in 367 consecutive post-mortems in Hong-Kong and Faust (4) in a careful study in Southern Korea found the infestation in 20% of the population.

The fluke inhabits the human biliary tree, (as well as that of the dog, cat, rat, pig, mouse, camel and badger). It is from 10-20 mms. long and 2-5 mms. broad, has an oral and ventral sucker, is characterized by a spineless cuticle, a short oesophagus, simple intestinal ceca, branched testes situated posteriorly, a trilobate ovary and moderately developed vitelline glands. The eggs are from 28-30 mu long and 15-17 mu broad, operculated, very dark, and have a ciliated miracidium within. Development outside the body takes place in two different intermediary hosts—the primary, a mollusc, and the secondary, several species of the carp fish (fresh water variety). Human infestation then occurs on eating this latter fish raw—as is a custom in certain sectors of the already mentioned countries.

In lighter infestations the symptoms vary and in-

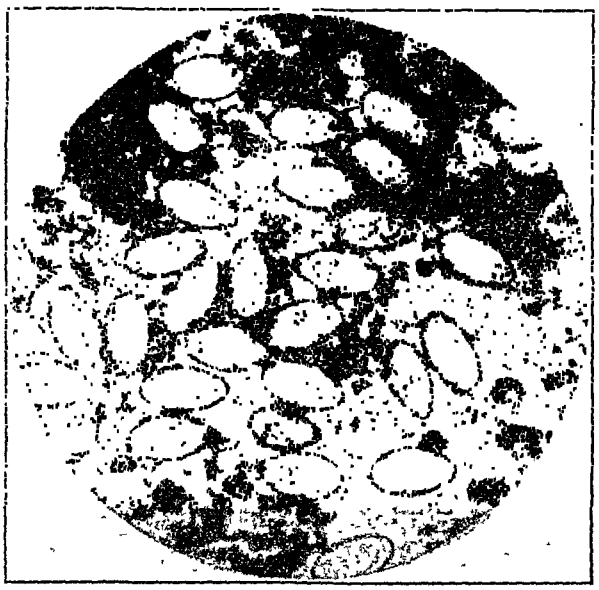

Fig. 1. Photomicrograph (approx. 400x) showing the eggs of the clonorchis sinensis as seen in the fluid obtained from biliary drainage. Note the operculum which is easily seen in several of the ova near the center; also the tiny spine at the opposite end. Within many of the ova the ciliated miracidium is plainly visible.

clude dyspepsia, epigastric and upper abdominal distress, unrelated to meals, and night blindness. When the disease becomes more advanced the liver descends below the right costal margin to varying size, recurring attacks of jaundice take place, and chronic diarrhea and vomiting are present. Late anasarca makes its appearance and a severe cachexia sets in which gradually terminates the disease fatally. Associated with this terminal picture, there is frequently a leukocytosis of over 30,000 and an eosinophilia of over 40%.

The underlying pathology of this infestation results from changes within the liver, brought about by the irritation of the adult fluke within the ducts. There results proliferation of the duct epithelium, with degeneration and necrosis of the periductile parenchyma.

If the infestation is heavy, small areas of necrosis of the liver 2 or 3 cm. in diameter may be seen which communicate with the ducts and contain many parasites. Later, marked periductile and interlobular cirrhosis occurs usually bringing about obstruction to the portal circulation. There follows enlargement of the spleen, chronic congestion of the gastro-intestinal tract with subsequent chronic gastro-enteritis. In some instances ascites may be present. Occasionally, biliary stasis results from obstruction of the ducts with transient jaundice. In a few cases, primary liver cell carcinoma (cholangioma) has been seen in association with the infestation. In rare instances, the pancreas may also be the site of the infestation with similar changes leading to fibrosis.

CASE HISTORY

A Chinese male adult, H. L., aged 47, was first admitted on 8/16/ 36 to the private service of Dr. John A. Kolmer at Temple University Hospital. The patient was formerly a resident of South China and had lived in this country for 21 years. His chief complaints were vomiting, pain in the upper right quadrant, loss of weight and general exhaustion, all of 6 weeks duration.

He was in good health prior to six weeks ago when he first experienced epigastric and upper right quadrant pain of variable duration after each meal. At this time, vomiting occasionally occurred on the ingestion of starchy foods, sour regurgitations and continuous belching were now present. Two weeks prior to admission vomiting occurred following each meal, associated with almost constant dull aching in the upper right quadrant. Scleral jaundice was simultaneously noted but was of transient nature. He had had mild diabetes 5 years previously which responded well to simple dietary management.

The only important physical feature during routine examination was the presence of an enlarged liver, extending approximately 5 cms. below the right costal margin; the abdomen was slightly distended. The patient appeared to be well nourished.

On admission his blood count revealed 6,750 leukocytes with 73% poly. neutrophils, 16% lymphocytes, 8% monocytes, 3% eosinophiles, 0% basophiles. The hemoglobin was 15 gms. or 89.55%; erythrocytes were 5,250,000 and of normal character, color index being 0.86. The urine was negative for sugar, but showed a very slight trace of albumin, and microscopically 2-5 hyaline casts per lower power field, occasional red blood cells and 0-7 leukocytes per high power field. The Icterus Index was 6 units, the van den Bergh gave a delayed—very weak direct reaction and the indirect van den Bergh estimation gave a reading of 0.25 mgms. The blood sugar value was 96 mgms. A stool study including culture made by an experienced bacteriologist showed no ova or cysts, no vegetative amoeba. A cholecystogram revealed insufficient gall bladder function but no evidence of gall stones. His T.P.R., except for the first day when a slight rise in temperature and pulse rate occurred, were essentially normal.

A non-surgical biliary drainage revealed a marked duodenitis and catarrhal cholecystodochitis. The eggs of the clonorchis sinensis (Fig. 1) were observed in the "B" and "C" fractions of the bile. Subsequently other biliary drainages were accomplished with essentially the same findings.

The clinical course continued with increasing enlargement of the liver, and persistent upper abdominal distress and weakness. The patient then left the hospital, sought treatment by Chinese herbalists, grew considerably worse and was readmitted two months later, with great exhaustion, persistent cough, great thirst and extreme dyspnea. At this time patchy rales throughout the lungs and marked

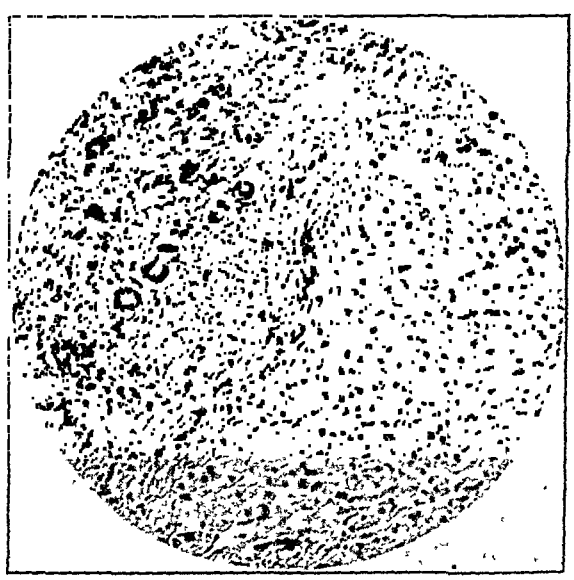

Fig. 2. Photomicrograph (approx. 100x) of a portion of the liver, showing marked interlobular and periductile fibrosis.

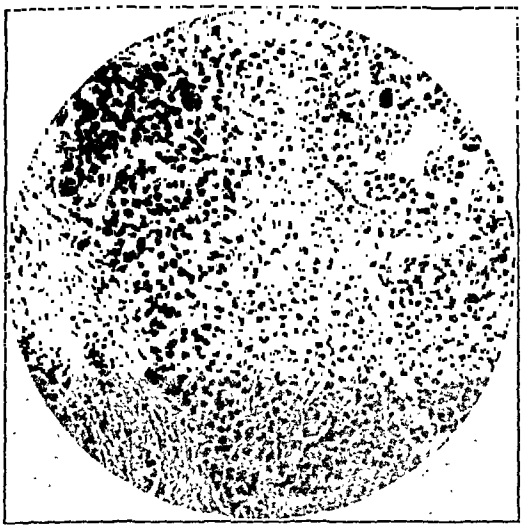

Fig. 3. Photomicrograph (approx. 100x) of an area in the liver showing the primary liver-cell carcinoma (cholangioma). No normal liver parenchyma is included in this photograph. Note the marked similarity of the arrangement of the tumor cells to the normal parenchyma. Observe the wide variation in size of the cells. The central portion shows degeneration and necrosis.

ankle and pre-tibial edema were present; the liver extended to the umbilicus, was tender to palpation and dehydration was considerable.

The blood sugar was 107 mgm., Plasma CO_2 26 volumes per cent; temperature was normal, pulse rate 108, respirations 30. The stools were now positive for the parasitic eggs, sputum examination was negative for the parasitic ova. His blood count revealed a leukocyte count of 9,300, of which 80% were poly. neutrophils, 10% lymphocytes, 7% monocytes, 2% eosinophiles and 1% basophiles. The hemoglobin was 12.5 gms. or 73.7%, erythrocytes 5,000,000, color index .73, the character of the erythrocytes were normal. The urine showed a slight trace of albumin, occasional red blood cells, but no casts. During the 6 days following admission, the temperature and pulse rate continued to rise, the sputum became bloody and coughing pronounced; marked weakness ensued, and the patient expired in the acute phase of the associated bronchopneumonia.

Complete necropsy was refused, but a stab biopsy of the liver was obtained. Histologically, this tissue showed (1) marked interlobular cirrhosis (Fig. 2); (2) areas of liver necrosis; (3) primary liver-cell carcinoma (cholangioma). (Fig. 3).

COMMENT

The importance and frequency of clonorchis infestation in certain sections of the Orient has been borne out. Following extensive histological studies in sixty-six livers infested with clonorchis sinensis, Hoeppli (5) corroborated the original work of the Dutch investigator Mebius (6) and showed that in many cases in which symptoms were light or non-existant, considerable histological changes were already present in the liver. He describes the increase in periportal tissue, fatty changes in the liver cells, extensive fibrosis, dilatation of bile ducts, with thickening of the walls and glandular proliferation. Typical Laennec's cirrhosis and parasitical portal cirrhosis is also reported.

In view of the two previous reports including a series of primary liver carcinomas in clonorchic livers (7, 8), it is possible that primary hepatic malignancy may be a sequel to the parasitic infestation, in addition to the parasitic cirrhosis and the hyperplastic cholangitis with chronic fibrous hepatitis which has already been described. The prolonged local physical irritation in addition to the toxic exudates may well be contributory factors in the production of the cancer.

It has been unfortunate that the work of various observers has tended to minimize the potential seriousness of clonorchiasis. This may be accounted for by (a) the long and drawn out course of the disease, and (b) the comparatively rare and scattered liver studies in clonorchiasis hepatis have been insufficient in impressing the significance of the terminal involvement of the clonorchic liver. It is because of these facts that the lack of therapeutic studies is to be greatly deplored in this not infrequent Oriental disease. To date there is not one drug which has shown any value in combating the parasite. The only therapeutic palliative measure has been the use of the non-surgical biliary drainage. To quote Bercovitz's (9) clinical studies in a large series of cases, "Biliary drainage yielded the most spectacular results in cases where the liver was enlarged and tense. Drainage continuously for a few days usually caused the liver to be reduced within the costal margin, and to all outward appearances the patient was "cured." However, in none of these cases did we ever finally rid the bile of ova." He then issues a warning against the use of the method of non-surgical biliary drainage by the untrained, because of the liability to shock and accidents. Filicene, benzol, emetine, oil of chenopodium, thymol, tetraiodophenolphthalein have been tried (10) but have proven failures. Calomel, urotropin and sodium salicylate have been attempted (11), as well as arsphenamine (12) and various other agents, unsuccessfully. Faust's use of gentian violet may prove of value but has not given definite results to date.

The importance of searching the bile in all cases of enlarged livers in patients coming from the Orient is emphasized by the fact that a careful stool examination by an experienced bacteriologist revealed no parasites or ova whereas on the following day, the ova were recovered from the biliary extractions. This is in agreement with Toullec and Riou (13) who were struck with the relatively infrequent finding of the eggs in the stools during life, as checked by post-mortem studies. They found that following duodenal intubation in all suspected cases of liver fluke infestation, the diagnostic incidence of clonorchis sinensis rose by leaps and bounds.

Since an attempt to halt the ingestion of improperly prepared fresh water fish or sea food by the natives of the Orient is obviously desirable but impractical, it would be a great service for Oriental research foundations and investigators to encourage therapeutic studies in this field.

Appreciation is herewith expressed to Dr. John A. Kolmer through whose courtesy this case is reported.

by the liver. From this, it seems that a reserve supply of concentrated bile, which may be discharged into the intestine in small amounts during the first 20 or 30 minutes after a meal, would have a favorable effect in initiating digestive processes in the intestine. In fact, the gall bladder bile is sometimes referred to by physiologists as "ignition bile."

If it can be established that the storage of bile for digestive purposes is a function of the gall bladder, it will be obvious that cholecystectomized patients, or patients with chronic disturbances of the biliary tract should be fed frequently with the idea of promoting the flow of bile by the liver, and thus keep it thin and moving as in animals where there is no gall bladder. That frequent feeding should be employed is an old clinical impression still held by some internists. But, such management will not generally be recognized as essential until its physiologic importance is proven. For example, formerly it was debated whether fats and acid fruits should be avoided by the patient with acute cholecystitis. Now, since it is known that fats and acids are potent excitants of gall bladder activity, doubt no longer exists.

In summary, the physiological evidence indicates that the chief function of the gall bladder is pressure regulation; but, the possibility that storage of bile for digestive purposes also occurs in those forms which concentrate bile, is one which cannot be easily dismissed. If the latter remains unproven, it may then be surmised that the gall bladder developed secondarily to the appearance of a sphincter at the junction of the common duct with the intestine to serve only the primary function of pressure regulation.

ANATOMICAL EVIDENCE

Bearing the physiology of the gall bladder well in mind, it should be interesting to examine various vertebrate phyla for this organ, ascertain its presence or absence, and correlate with this evidence, other facts pertaining to the economy of the animal. Thus, diet, other modifications of the digestive tract, and even taxonomical relationships, may bear on the existence of the organ in an individual species.

Little effort has been made to describe variations in the form or anatomical relationships of the organ. Suffice it to say that this hardly seems necessary, insofar as the organ is either present or absent, and no series between these extremes can be easily demonstrated.

In the lower chordates, the liver, for the most part, is represented by groups of "hepatic caeca," which are intimately associated with the digestive tract. The liver is not consolidated into an organ, separate from the gut, and the gall bladder is not seen.

In vertebrates, the liver first becomes a distinct organ and with its development the gall bladder is first seen. In the Cyclostomata, primitive jawless vertebrates, the organ is present either in the larval or adult form, or both.

Most fish possess a gall bladder, but it may be occasionally absent. Those species lacking the organ are true bony fish (Teleostii). In the simpler forms (sharks, chimaeras), it is apparently constantly present, as it is in the lung-fishes (Dipnoi). This later group resembles in some respects, the ancestor of the amphibians, and it is significant that the organ is constantly present.

Amphibians apparently all possess the gall cyst. From Carboniferous amphibians, reptiles arose. The reptiles flourished abundantly throughout the Mesozoic, and gave rise to the predominant forms of our present fauna, i.e., birds and mammals. Like the amphibians from which they arose, all existing reptiles possess the gall bladder. It is highly probable that the organ was never lost here, even in herbivorous types, because of the intermittent feeding habits of this group, and because the organ is not known to be absent from any existing reptile.

Birds are closely associated with reptiles, and unmistakably derived from them. They arose at about the same time as mammals, but their adaptability has led to both a greater diversity of structure and a broader ecologic range. Although reptilian ancestory may be equally remote from both birds and mammals, the earlier success of birds has possibly allowed a more complete manifestation of those tendencies to vary, which are visible in mammalian evolution. The gall cyst is frequently absent in birds, and correlation of this fact with knowledge of diet and morphology offers no explanation. In no order of birds yet examined, is the organ constantly absent.

In this investigation, mammals are the main [illegible] of interest, because our end is to explain its [illegible] invariable presence in man.

Among the *primitive mammalian orders,* Monotremata and Marsupialia, the gall bladder is constant

kilo of body weight, per day. Man, however, only secretes 20 c.c. of bile per kilo per day.

The Physiologic Capacity of the Gall Bladder: Since the size of the gall bladder, the bile output, and the ability of the gall bladder to concentrate, varies in different animals, the *physiologic capacity* will vary. By this term is meant that fraction of the daily output of bile which the gall bladder is capable of storing; and, if it were known with certainty that this bile was stored for digestive purposes, this phrase would be appended to the definition. A contrast of physiologic capacity is demonstrated by man who can store the bile secreted during 12 hours, and a guinea pig which can store only the bile secreted for 12 minutes.

An Additional Function of the Sphincter: It should be considered that this structure probably prevents the regurgitation of duodenal contents into the common bile duct. This prevents ascending infection of the liver. It suggests that animals devoid of a competent sphincter should have some compensatory mechanism. Several such mechanisms do occur. There may be a one-way valve; large quantities of bile may keep the ducts flushed out; the extra-hepatic ducts may show peristaltic activity. Investigations show that the horse which lacks both a competent sphincter and a gall bladder has both a valve and a liver which forms large quantities of bile. On the other hand, the adult pigeon*, which also lacks a gall bladder has very motile ducts, and a liver forming relatively large quantities of bile.

The Practical Significance of the Problem: It is not generally agreed that the gall bladder serves the function of the storage of bile for digestive purposes. This is because physiological studies have not as yet demonstrated detectable disturbances of digestion or nutrition after cholecystectomy. However, when a gall bladder which concentrates efficiently is removed, certain changes are known to occur. These are: (a) incompetence of the Sphincter of Oddi with a variable return of competence; (b) dilation of the extra-hepatic ducts; (c) small areas of local necrosis in the liver. These changes certainly indicate that the gall bladder has a function, even if its general role is not to store bile for digestive purposes. Unfortunately, it is not known why all these changes occur, but dilation of the ducts is generally attributed to the return of competence of the sphincter. If this interpretation is correct, and if no direct digestive disturbances result from cholecystectomy, then the chief function of the organ in man, the dog, and the cat, for example, is to regulate the pressure in the extra-hepatic ducts, and this regulation is rendered necessary by the Sphincter of Oddi. Hence, from an evolutionary viewpoint, a gall bladder was developed secondarily to the sphincter, and the sphincter served primarily to prevent regurgitation from the intestine. However, given an animal whose liver produces relatively small quantities of bile, it is then reasonable to assume that such an animal might possess a better digestive apparatus if a gall bladder and a sphincter were present to render possible the storage of bile for digestive purposes. The following facts force the consideration of such an hypothesis: (a) bile plays an important role in the digestion and absorption of fats; (b) it is essential for the absorption of vitamin D and carotene, the precursor of vitamin A; (c) it plays a role in the absorption of iron and calcium; (d) all domestic animals that form a small quantity of bile have a gall bladder of large physiologic capacity; (e) the absorption of bile salts from the intestine augments the secretion of bile

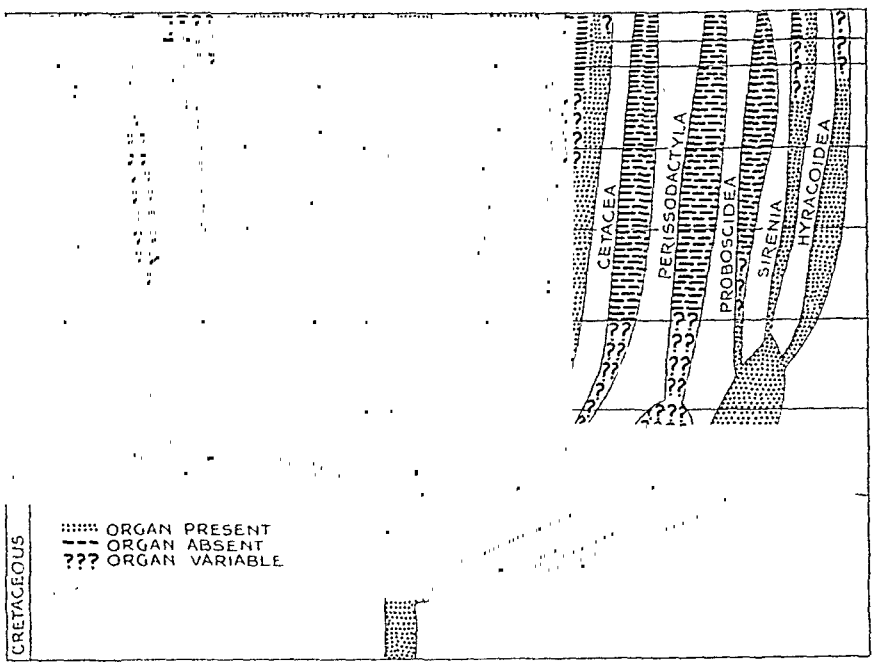

Fig. 1. Chronological distribution of existing placental mammals showing probable evolution of the gall bladder (after Romer).

*A gall bladder is seen in the embryo.

of a carnivorous animal of necessity offer only occasional meals, and these have generally a high fat content. From a physiological point of view, storage of concentrated bile should be of aid in the digestion of such meals, and it is significant that the organ is constantly present in these forms.

The absence or loss of the organ without harm or disturbance of survival value might be anticipated from the evidence of Schmidt and Ivy. They found species in which the organ had no apparent or demonstrable function. It may be said that the organ was "physiologically absent." Species possessing this type of a gall bladder are usually members of an order in which there are other species in which the organ is anatomically absent. *Further, the gall bladder is not absent from those species which have descended most directly, or with the least specialization in regard to body form, from the ancestor of mammals,* namely, insectivors.

Another factor which may influence the existence of the gall bladder in a given species is the proximity which this species has to the ancestral form. It will be noted* that those species, families, or orders which most closely resemble the ancestor of a given group tend constantly to retain the gall cyst, while those which vary most, tend to lose the organ. It is also very evident from our studies that the form and structure of the various portions of the gastro-intestinal tract are more readily changed in response to dietary habits than the gall bladder is lost.

The stable nature of the gall bladder suggests that it may be of value as a taxonomical characteristic. In only nine families was the organ found to be present in some members, and absent in others. In at least six of these the variation occurred between species or individuals. In the remaining three, it was possible to arrange sub-families, and here, for the most part, definite tendencies following the lines of arrangement were demonstrable. Individual variations in the organ are probably comparable to the anomalies occasionally seen in the human cadaver. The frequency with which these anomalies occur may be a measure of the declining "need" for the organ. Thus in the dissections of *Hyrax,* three observers found a gall bladder; five did not. With the giraffe on the other hand, the records show only two gall bladders out of about twenty dissections. From these records, it might be concluded that these animals will soon (in evolutionary time) lose the organ completely, and in all individuals.

It is interesting that closely related species particularly among the Muridae, may differ in the possession of the organ. *Besides this, the occurrence of anomalous absences in individuals of the same species suggest that it might be possible to study the mechanism of the inheritance of the organ and the physiological changes associated with its loss.*

CONCLUSIONS

1. The gall bladder is a typical vertebrate structure, found first in larval agnathostomes, and generally throughout the rest of the phyla.

2. All reptiles and amphibians have a gall bladder.

3. In birds the presence of the gall cyst is extremely variable, but carnivorous birds generally retain it.

4. The gall bladder is a primitive mammalian structure. It is not easily lost. It is not as readily lost as is the form and structure of the stomach, cecum and colon changed, i.e. a complex stomach may appear in a line of descent without the gall bladder being lost. It is usually retained in forms which most closely resemble the ancestral type; forms which vary most widely from the ancestral type may lose it.

5. Carnivorous mammals possess a gall bladder (except whales, *q.v.*), while mammals with other dietary habits may lose the organ. This apparently is related to the intermittent feeding habits of carnivorous types. Herbivorous forms with continuous feeding habits are most likely to lack the organ.

6. From the evidence of the dietary habits of cholecystous and acholecystous forms, one may conclude that if the gall bladder is removed from a given individual of any species, digestive efficiency will be diminished only if:

(a) the organ has a large physiologic capacity, and
(b) intermittent meals of a high fat content are given.

7. There is no anatomical evidence to indicate that the *Sphincter ductus choledochus* developed before a gall cyst. Yet the presence of such a sphincter renders a gall bladder essential as a pressure regulatory apparatus, unless the common bile duct manifests definite peristaltic activity as in the guinea pig, for example.

ADDENDUM

A point not referred to in our paper and which supports the concept that the gall bladder stores bile for digestive purposes should be mentioned.

If the sole function of the gall bladder is for the regulation of biliary tract pressure, why should the hormone, cholecystokinin, which is produced principally by the action of fats and acids, have been evolved. All hormones apparently manifest specific purposeful activities and the only purpose that cholecystokinin might serve is to evacuate the concentrated bile in the gall bladder when certain foods, particularly fats are eaten. The presence of the concentrated bile in the intestine would buffer acid, improve the digestion and absorption of fats and promote the formation of bile by the liver.

present. These two orders, although in some respects highly specialized, have for the most part many affinities for their reptilian predecessors. It may be recalled that the monotreme is a duck-billed animal, oviparous, but nourishing their young on milk. The marsupials have a pouch which shelters their premature young. A true placenta is not found. The invariable presence of the gall bladder in these forms is interesting. Many of them are as highly specialized as the placentals, but among the placentals where the herbivorous type of diet has been assumed, the organ is absent in certain species. Remembering that monotremes and marsupials are rather low in the scale of mammalian evolution, it would seem that the gall bladder is a primitive structure not easily lost.

Most living mammals are placentals, and the development of the placenta along with other marked advances, accounts for the success of this group.

Primitive placentals are known to have lived at the end of the Age of Reptiles, and these forms were insectivorous. From them arose our existing placental fauna, and members referable to the same order (Insectivora) as those early forms still exist.

Closely related are four existing mammalian orders, the insectivors, the bats, the flying lemur, and the primates. They show definite relationships particularly in dental pattern, but specializations make them superficially unlike. The parent stem of these is the order *Insectivora*; moles and shrews are the best known of this group. Bats are closely related to the insectivors, and an intermediate type gives some hint as to how these may have been evolved. The flying lemur, *Galeopithecus*, is this transitional form. It is assigned to the order Dermoptera (Fig. 1).

Forms which were unseparable from insectivors by early workers, have now been assigned to the primates. They illustrate stages in the evolution of the primate type. The lemurs are excellent examples. From these simple forms have been derived the monkeys, apes, and finally man. Monkeys, however, diversified into two distinct lines. One, the New World Apes, is more primitive, while the Old World forms have diversified more widely. From the Old World family, man arose rather late in geologic history.

All these allied forms possess a common simplicity of structure, and are traceable to those insectivors which were the first placental mammals. They all possess a gall bladder.

Early in the Age of Mammals, other stem types were formed, some of these have perished and are known only as fossils; others gave rise to existing phyla. One of these stem types, known as the condylarth, was probably distinct before the end of the Age of Reptiles. From it came an order (Perissodactyla) which has a long paleontological history. The horse is the typical member. Neither it nor any of its close relatives, the rhinoceros and the tapir, possess a gall cyst (Fig. 1).

The amblypods, like the condylarths, were fairly distinct forms by the end of the Paleocene. From them, later in geologic history arose three orders which are represented by a rather diverse number of forms, the elephants, the sea-cows, and the hyraces. These species show a tendency to lose the gall cyst. It is constantly absent in the elephants, and is variably absent among the sea-cows and the hyraces (Fig. 1).

Carnivors, and through them the even-toed ungulates (Artiodactyla), arose later in paleontologic history from insectivorous forms. The carnivors constantly possess the gall bladder.

The artiodactyls at the present time are all herbivorous types, and some of them have lost the organ. All of them may eventually lose it, but its retention by some existing forms may be because of the proximity which these animals have to their carnivorous ancestors. Among the artiodactyls, the deer, peccaries, and duikers, have lost the organ; in the other forms it is usually present. In the giraffe, its presence is recorded in two out of twenty dissections; in the hippopotamus, its absence is recorded in one of four dissections.

The whales are said to have arisen from carnivorous forms early in the Eocene. They are highly specialized and morphological relationships are not clear. They all lack the gall bladder, but Weissberg (1932) has pointed out that a compensatory dilatation of the common duct with a valvular mechanism may exist. It is also possible that despite their intermittent feeding habits, the complex nature of the stomach may provide the duodenum with a continuous trickle of chyme, making concentrated bile less necessary for digestive purposes. Were the whales of proven herbivorous ancestry, one might point out that the sac-like reservoir in the common duct is a compensatory mechanism developed in an animal which had lost its gall bladder, and then changed its habits so that a compensatory structure was again necessary.

The Edentates are a heterogeneous group of mammals including three orders.

The order Xenarthra (armadillos, anteaters, sloths) is a New World group of unknown ancestry. The present fauna is meager, but at one time these forms predominated in South America. They all possess a gall bladder with the exception of the three-toed sloth, a vegetarian. Its absence in this individual is difficult to explain, but it seems significant that variation first occurs in this order in an herbivorous form.

The Aard-vark *(Orycteropus)*, and the Scaly Anteater *(Manis)* represent two orders (Tubulidentata; Pholidota), also of unknown ancestry. They are insectivors and both have gall bladders.

Rodents are the most successful of recent mammals. They were distinct during Eocene times. Most of them retain the gall cyst, but it is absent in some forms. Outstanding examples of species which lack the organ are gophers, kangaroo rats, common rats, and some porcupines. There may be variation among families or even genera, within this order. The Muridae is particularly chaotic in this respect. Rodents are, for the most part, herbivors.

The foregoing statements are based on a study on the number of the families and species shown in Table I.*

Where it was possible, an attempt was made to select the most representative species of each family.

DISCUSSION

From the above evidence, several facts are forthcoming. In the first place, it will be seen that the gall bladder is present in all insectivors and carnivores (except whales), and that it may be lacking among omnivorous or herbivorous forms. The dietary habits

*The complete data collected in the course of this investigation will be issued in a Publication of the Field Museum of Natural History, Chicago. Zoological Series.

incidence of 80%. The clinical gastro-intestinal symptoms were definitely more pronounced in the patients with obstructive lesions than in the group where infection alone was demonstrated. No cases of acute urethritis as a rule do not warrant critical attention but in the light of these findings, they must be given adequate consideration since great relief of digestive symptoms was afforded a number of patients by eradicating these seemingly trivial infections.

EXPERIMENTAL PRESENTATION

Other investigators have demonstrated both fluoroscopically and kymographically that changes in the muscular activity of the digestive tube are reflexly excited by disease of the urinary tracts. It has been assumed that these changes in muscular activity are probably responsible for the production of the associated digestive symptoms.

Tixier and Clavel (1) in a series of acute experiments upon dogs by means of kymographic tracings showed that exteriorization of the kidney, stimulation

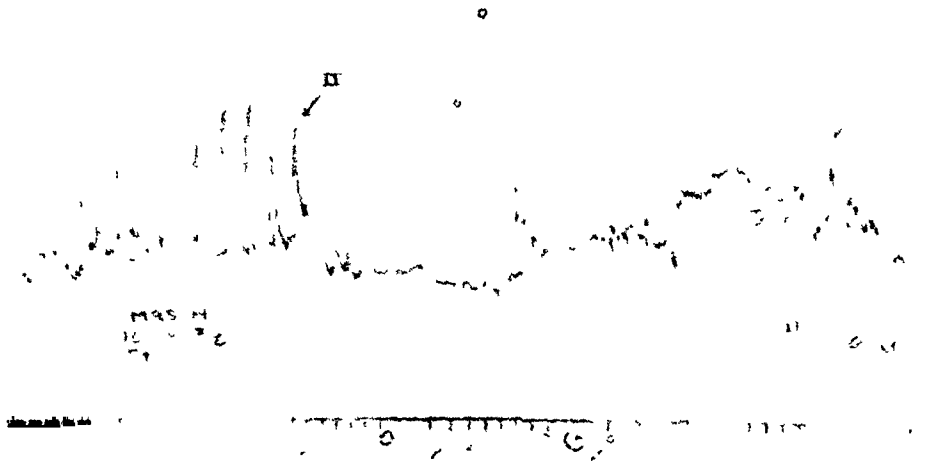

Fig. IA. Normal feeding reflex, human stomach. At point marked "2", patient was fed 4 oz. of milk and potato gruel. The tracing shows an immediate fall in tone and inhibition of peristalsis with a gradual restoration of tone occurring in about 25 minutes with a restoration of peristalsis. This constitutes the normal gastric appetite, or taste, reflex. It will be noted that the peristaltic rate is one complete contraction approximately every 2 minutes.

The Mechanism of Production of Digestive Symptoms Associated with Urologic Pathology

By

P. B. WELCH, M.D., MILTON M. COPLAN, M.D.

and

ROY J. HOLMES, M.D.

MIAMI, FLORIDA

DURING recent years, the authors, in common with many others, have observed the frequent occurrence of reflex digestive symptoms associated with and produced by urologic pathology.

While it has been generally assumed that these digestive symptoms were associated with disturbances of the muscular activity of the digestive tube, apparently the exact nature and location of some of these changes have not been reported. Accordingly, a clinical and experimental study was undertaken, (I) to show Clinically, that silent urologic pathology frequently is the exciting factor in the production of reflex digestive symptoms; (II) Experimentally, that these digestive symptoms are associated with and probably produced in part at least by certain changes in the muscular activity of the stomach, colon and probably duodenum and, (III) to postulate that the reflex changes observed in the muscular activity of the stomach and duodenum may be factors in the production of peptic ulcer.

CLINICAL PRESENTATION

The clinical aspects of the etiologic relationship of urologic pathology to reflex digestive disturbances have been exhaustively and competently presented by many observers. The probable nervous mechanism involved in the production of these viscero-visceral reflexes has been adequately recorded. This presentation is confined to an analysis of sixty cases consulting the gastro-enterologist because of digestive symptoms, subsequently referred to the urologists. Of this number, forty-eight patients were relieved by urologic diagnostic and treatment procedures.

The many and various symptoms presented by this group of patients have been abstracted and catalogued in Table I. Only ten of the forty-eight patients presented symptoms of urinary tract difficulties, unless pain in the flank might be considered as a specific urologic manifestation. There were four such cases.

In four cases no functional nor organic disease of the gastro-intestinal tract was demonstrated. Diagnoses of the gastro-enterologist are shown in Table II.

Of the forty-eight patients in whom definite urologic pathology was demonstrated, twelve patients had previously been subjected to abdominal surgery without relief of their symptoms.

Urologic investigation of these patients revealed that obstructive lesions along the urinary tracts predominated, being present in thirty-eight instances, an

*From Research Department of Jackson Memorial Hospital, Miami, Florida.

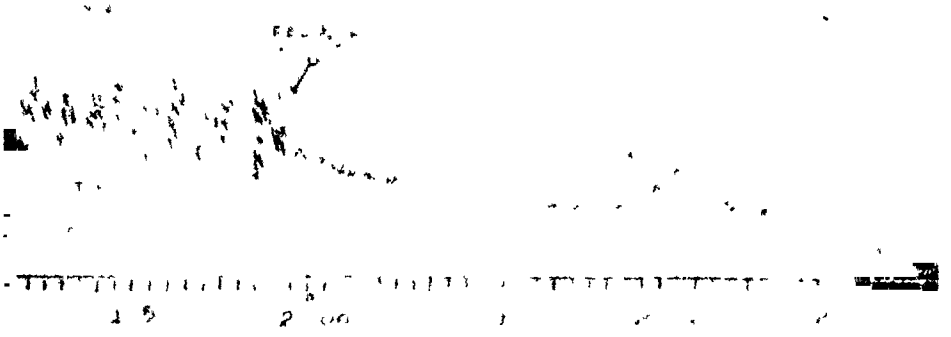

Fig. IIA. "Shows a normal gastric feeding reflex obtained by inserting a balloon through a permanent gastrostomy." At the point of feeding indicated by the arrow, there was an immediate inhibition of tone and peristalsis with reappearance of peristalsis in approximately 20 minutes. Note the close parallelism in the normal dog's stomach and the human stomach as shown in Fig. IA.

In another group of experiments, dogs were used. Gastrostomies were first performed. Later, we attempted to make a permanent ureteral fistula. In only one dog were we fortunate enough to have both a satisfactory gastrostomy and ureteral fistula.

In this dog, tracings were first made to show the normal gastric feeding reflex.

Later, a left-sided ureterostomy was made. This healed perfectly. There was no obstruction in the ureter and no apparent damage was done to the kidney.

Gastric tracings were made on a fasting stomach and the ureter was traumatized by twisting a catheter in the left ureter. The dog was then fed one ounce of ground cooked beef.

There was a momentary relaxation followed by an immediate and prolonged spasm of the gastric muscu-

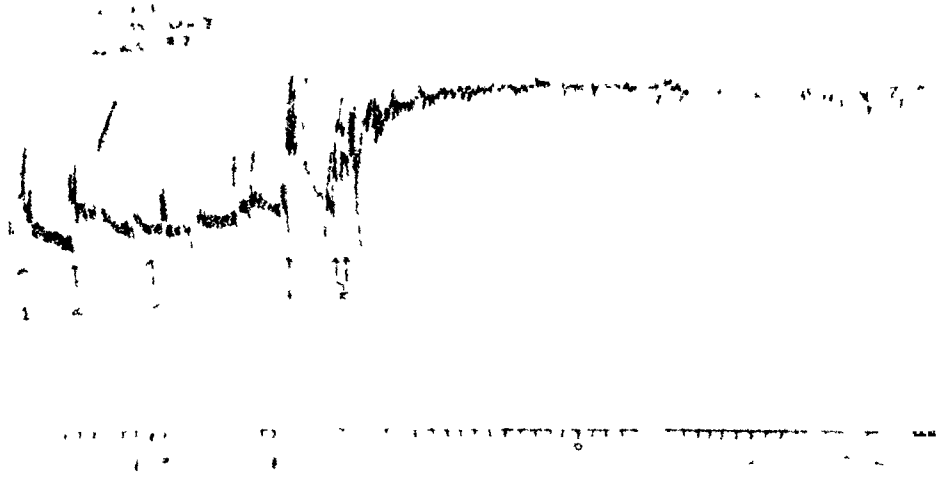

Fig. IIB. "Shows the inversion of the normal feeding reflex in the dog's stomach after ureteral trauma." At "1" catheter was inserted into the ureter. At "2", silver nitrate was injected and the catheter twisted. At "3", the catheter was withdrawn. At "4", the dog was permitted to smell food. The tracing shows an immediate increase in tonicity with superimposed peristalsis followed by relaxation. At "5", the dog was fed one-quarter pound of raw ground beef. Again, there was an immediate increase in tone with superimposed peristalsis. Thereafter, there was maintained a very high state of tonicity with small peristaltic waves. This tracing is almost exactly comparable to that of the human stomach, as shown in Fig. IB. The stomach was in complete spasm with almost complete obliteration of the lumen.

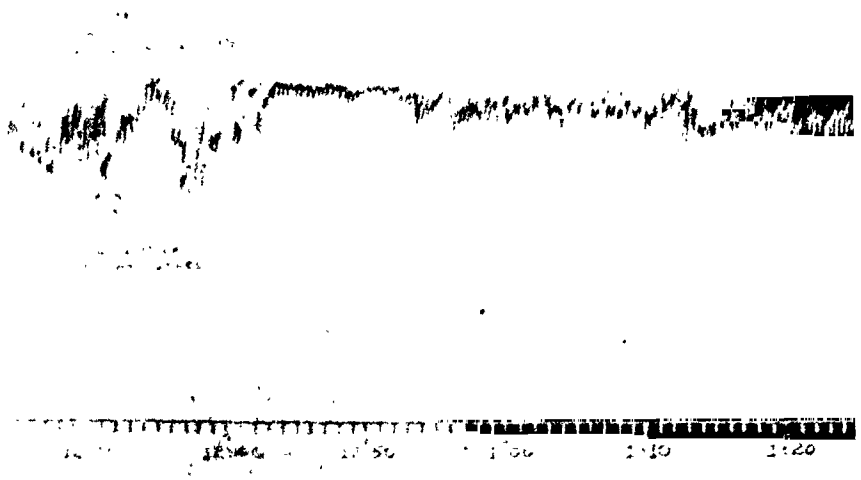

Fig. IB. "Showing inversion of the normal gastric feeding reflex in the human stomach associated with urethral and left ureteral stricture, symptomatically relieved by correction of the urologic pathology." It will be noted that before feeding and even after feeding the peristaltic beat is very rapid, as high as two peristaltic contractions occurring in one minute. At the point of feeding, an almost immediate increase in tone is noted followed by a temporary relaxation and again a continued very high tone. During the peaks of the contractions the lumen of the stomach was obliterated. It will be noted also in this tracing there was not an inhibition of peristalsis. This is the typical inversion of the normal gastric reflex.

of the kidney and stimulation of the kidney peritoneum caused an increase in frequency and amplitude of gastric peristalsis and produced tone changes in the colon. The latter consisted principally of immediate inhibition of tone and peristalsis. Unfortunately, these acute experiments did not simulate the conditions usually found clinically.

The conditions of the experimental work reported here were kept in as close an approximation as possible to the conditions usually encountered clinically. In this group of experiments, kymographic tracings were made upon the stomachs of dogs and humans and upon the colons of humans with preexisting or created urologic pathology.

CHANGES OBSERVED IN THE MUSCULAR ACTIVITY OF THE STOMACH REFLEXLY EXCITED BY UROLOGIC PATHOLOGY

It had previously been observed by one of us (2) that normally the gastric musculature relaxed immediately with the first taste of food—the normal feeding reflex (Fig. IA).

It was observed that in the presence of intra or extra gastric, abdominal pathology, this normal relaxation did not occur. Instead, with the first taste of food there occurred either a momentary relaxation followed by strong contraction, or an immediate increase in the tonicity of the gastric musculature with or without superimposed peristalsis. This contraction frequently amounted to violent and prolonged spasm which completely obliterated the lumen of the stomach. This constituted a complete reversal or inversion of the normal gastric feeding reflex. The degree of inversion or distortion was found to be approximately proportional to the severity of the symptoms encountered, and was not influenced by the character of the gastric secretions, establishing the changed muscular activity of the stomach as the probable source of symptoms.

This distortion of the gastric feeding reflex was usually associated with epigastric distress of varying degrees of intensity.

With this experience as a background, it was assumed that stimuli arising from lesions of the urologic tract probably produced similar changes in the muscular activity of the stomach. This was particularly indicated by the high incidence of the symptom of epigastris distress encountered with urologic disease as shown in Table I.

Kymographic tracings were made from the stomachs of two women with demonstrated urologic disease. A condom balloon was placed in the fasting stomach and connected by a duodenal tube to a recording device designed by one of us. This, in turn, recorded on a slow moving drum. The balloon was left in place long enough for the patient to become accommodated to its presence. The patient was then fed a cream of wheat and milk gruel and the changes in the feeding reflex were recorded. In both instances, there was found an increase in frequency and amplitude of gastric peristalsis and a marked inversion of the normal feeding reflex as shown in Fig. IB.

In this case, correction of urologic pathology resulted in complete subsidence of digestive symptoms. Unfortunately, with subsidence of symptoms, we were unable to obtain subsequent gastric tracings.

since three months after urologic treatment was instituted.

It is not assumed that disease of the urologic tract alone produces peptic ulcer but certainly the evidence indicates that it may in conjunction with other factors be an exciting cause in peptic ulcer production.

CHANGES OBSERVED IN THE MUSCULAR ACTIVITY OF THE COLON REFLEXLY EXCITED BY UROLOGIC PATHOLOGY

In this group, two women with permanent left-sided colostomies volunteered. Condom balloons were inserted into the proximal colostomy opening. The balloons were gently inflated with air and connected with the recording device in the usual way. The balloons were left in place for at least ninety minutes until the colon had accommodated itself to their presence. A cystoscope was then introduced without changing their supine position. A ureteral catheter was gently passed up the right ureter. The urethra, bladder and ureter were normal in each instance. ½ of 1% silver nitrate was injected into the ureter. The catheters were gently rotated and then withdrawn.

In both cases, introduction of the cystoscope and catheterization of the right ureter resulted in immediate inhibition of the muscular activity of the descending colon. Irregular tone changes followed until gentle trauma was supplied to the pelvis of the kidney and ureters. Trauma to the pelvis was accomplished by inserting the catheters up into the kidney pelvis. No reaction was noted in the colon. Introduction of ½% silver nitrate and/or twisting of the catheter in the ureter was immediately followed by a decrease in tone of the colon. Thereafter, for some time the tone changes were irregular until a late appearance (one-half hour) of increased muscular tone of the colon in both cases and increased tone and painful contractions at the site of the balloon in one case.

It is particularly interesting to note that in this one case, Fig. III, the patient had severe left-sided pain, occurring simultaneously with contractions in the colon, despite the fact that the right ureter was traumatized. It is probable that determination of the location of the painful contractions in the colon on the left side was due to the presence of the balloon, although the air pressure in the balloon did not equal one millimeter of mercury.

This experience suggests that the site of origin of symptoms arising in the colon are not associated with pathology in the ureter in the same side as suggested by Abeshouse (3) and Hartsock (4) and that possibly the local condition of the segment of the digestive tube is the determining factor in symptom production.

SUMMARY

A. An analysis is made of a series of forty-eight cases presenting digestive symptoms relieved by correction of preexisting urologic pathology.

B. Tabulations have been made of (1) The presenting digestive symptoms; (2) The gastro-enterologist's diagnoses; (3) Motor disturbances in various parts of the digestive tube which were found in 60% of the cases; (4) An analysis of twelve cases, or 27%, who had previous abdominal surgery without relief of digestive symptoms and who were subsequently relieved by correction of urologic pathology; (5) An analysis of forty-eight cases showing obstructive lesions of the urinary tracts in 80%; digestive symptoms were definitely more pronounced in this group.

C. Experimental studies of the muscular activity of the stomach and colon in humans and dogs showed that in the stomach, the rate of peristalsis was probably increased and that there was a marked inversion of the normal gastric feeding reflex associated with urologic pathology. In the colon, trauma of the urinary tracts produced a primary inhibition of tone and peristalsis followed by marked and irregular increases in tone and peristalsis. In one case, the colon contractions produced pain.

D. Evidence is produced which indicates that the side upon which the urologic pathology exists is not the sole determining factor as to the location of digestive dysfunction and pain, but that probably the local condition of the affected segment of the digestive tube is also a determining factor as to its location.

E. The marked changes in the muscular activity of the stomach and duodenum associated with urologic and other abdominal pathology may be factors in the production of peptic ulcer.

CONCLUSION

In view of the evidence presented in the voluminous literature and the clinical and experimental evidence presented here, it is obvious that it is incumbent upon the gastro-enterologist and internist to constantly keep in mind the high incidence of digestive symptoms excited by pathology outside the digestive tube, particularly in the urinary and genital tracts.

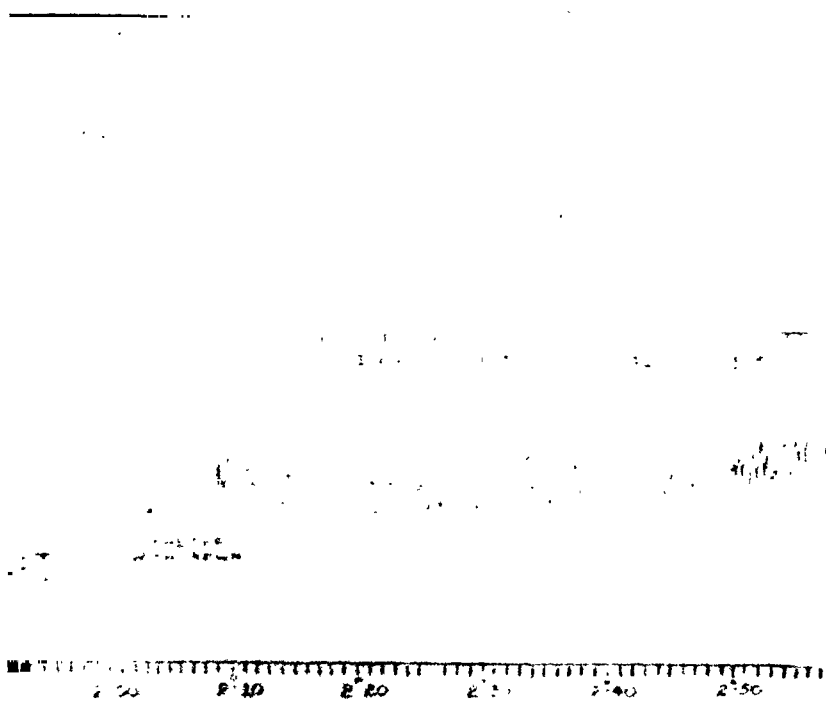

Fig. III. "Showing change in the muscular activity of the normal colon associated with trauma of the right ureter." The immediate effect of trauma to the right ureter was inhibition followed by a relatively late appearance of increased peristalsis and increased tone. The contractions in the colon shown from 2:20 on were accompanied by pain in the left side of the abdomen, with or without pain in the right flank.

lature. Apparently, the dog was distressed following the feeding as it became quite restless.

Comparisons of Figs. 1 and 2 show a striking similarity of reaction in the human and dog's stomachs.

Each tracing made of this dog's stomach after ureterostomy showed the same inversion of the gastric feeding reflex with a prolonged period of marked increase in tone following feedings. The balloon in the stomach was completely emptied upon removal during the period of high muscular tone, indicating a complete obliteration of the gastric lumen.

Fluoroscopic observations upon the duodenum and jejunum of many of the patients with urologic pathology has indicated that there is often a spasm of the duodenal cap and hyperperistalsis of the descending loop of duodenum, sometimes so marked as to cause regurgitation. No kymographic tracings have been made of the duodenum by the authors but clinical and X-ray observations have definitely demonstrated that there undoubtedly is an associated hypermotility and spasm of the upper small intestine reflexly associated with urologic pathology.

PROBABLE ETIOLOGIC RELATIONSHIP BETWEEN UROLOGIC PATHOLOGY AND PEPTIC ULCER

That urologic and other abdominal pathology excites intense and prolonged reflex spasm of the stomach certainly, and of the duodenum probably, cannot be doubted. That this spasm is complete enough to obliterate the lumen of the stomach has been demonstrated.

It is not unreasonable to assume that the severe squeezing of the mucosa of the stomach and probably that of the duodenum is sufficient to empty the blood vessels in the soft velvety mucous membranes and to produce a definite and prolonged local ischemia interfering with the nutrition and resistance of the affected mucosa and predisposing to ulcer formation, either secondary to infection or by direct digestion of the enfeebled, traumatized area.

It is difficult to understand why more ulcers do not occur when this type of trauma is present, as this distorted reflex is excited not once but at each regular meal, day after day, week after week and frequently month or even year after year.

Doubtless other conditions are necessary to be present for ulcer formation; remote infection, ulcer diathesis, allergy, faulty food habits, chemical or metabolic toxins, nerve lesions, absence of antipepsin, mental or emotional states, or other factors.

In this connection, it is not amiss to report one very theatrical case. Mr. A. B. had a duodenal ulcer more or less continuously for ten years. Finally, as a last resort, an investigation of his urologic tract was advised. Cystoscopy disclosed a congenital narrowing of both ureteral orifices. These were dilated and upon subsidence of his reaction to this measure, his digestive symptoms entirely disappeared. This particular individual was quite skeptical of his relief and endeavored by dietetic indiscretions and alcoholic excesses to reproduce his familiar digestive distress, without success. For three years, this man has been free from digestive disturbances. There is no X-ray evidence of duodenal ulcer now nor has there been

we have traced this mechanism through experimental hemorrhagic anemia in dogs. These animals were on a normal diet with no mineral restrictions or additions. Following hemorrhage, the dogs show a drop in blood iron and hemoglobin, the degree of which depends upon the amount of blood lost. In the course of a few hours after the blood loss, the copper content of whole blood is seen to rise rapidly to reach a peak two or three days later. Then as the iron and hemoglobin return to normal as a result of increased hematopoietic activity, the blood copper gradually is reduced again to its normal level. This inverse ratio between iron and copper is a very constant finding in induced hemorrhage in experimental animals.

TABLE I

Typical blood copper and iron curve for experimental hemorrhage in dogs

Sample No.	Date	Hemoglobin grams per 100 c.c.	Iron, mg. per 100 c.c.	Copper, mg. per 100 c.c.
1	11/6	14.11	46.28	0.115
	200 c.c. of blood removed from jugular vein			
2	11/7	12.27	41.13	0.158
3	11/9	12.02	39.31	0.170
4	11/12	13.25	44.40	0.162
5	11/13	13.42	44.99	0.155
6	11/18	13.56	47.46	0.150
7	11/24	13.28	46.52	0.125
8	11/25	14.15	47.48	0.122
9	12/5	14.81	49.64	0.122

In human subjects, hemorrhagic anemia as a result of massive bleeding from peptic ulcer affords an opportunity to compare the experimentally controlled mechanism in dogs with a similar clinical condition. It must be remembered, however, in interpreting the results that we are dealing with anemia superimposed on a pathological process and as a result the bodily intake of antianemic principles, iron, copper and other blood-building components may be delayed or altered through faulty assimilation and absorption. It must also be remembered that we are speaking here of acute, massive hemorrhage and not the chronic type which is often associated with peptic ulcers. The chronic bleeding type with loss of small amounts of blood over a long period shows a hypercupremia but it is not characterized by the sharp rise to a peak followed by the consistent descent which is seen in acute hemorrhage under adequate treatment.

In one human case of anemia following massive hemorrhage from an ulcer we were able to make analyses of blood samples at intervals from the time when the hemoglobin and iron were at their lowest until the normal values were again reached. This case with the exception of a few fluctuations compares very favorably with the response seen in the experimental anemias. The return to the normal iron and hemoglobin values was comparatively rapid under treatment. The behavior of the blood copper was the same as in the dogs, rising to a peak and gradually declining again to normal.

In three other cases it has not been possible to trace curves through to complete return to normal but in all cases the trend has been a reciprocal relationship between blood copper and iron, the copper dropping from a hypercupremia toward the normal at about the same rate that the iron content rose toward its normal.

The most likely conclusion to be drawn from the finding of a high blood copper content in almost all cases of anemia, is that the copper is brought into use from the body reservoirs to stimulate hematopoiesis.

CHART I

Blood copper and iron values after massive hemorrhage from ulcer in man

Sample No.	Date	Hemoglobin grams per 100 c.c.	Iron, mg. per 100 c.c.	Copper, mg. per 100 c.c.
1	12/10	10.74	34.12	0.164
2	1/3	12.57	42.14	0.156
3	1/5	12.46	41.77	0.145
4	1/15	12.66	42.43	0.156
5	2/6	13.20	46.23	0.143
6	2/20	15.12	50.69	0.140
7	4/16	16.32	54.75	0.145

Hemoglobin calculated from blood iron by the formula: Mg. of Fe divided by 3.35 equals grams of hemoglobin per 100 c.c. of blood (9).

The possibility of a copper anemia with an insufficient intake of copper and a depletion of the body stores has been suggested following some experimental work on rats and other animals (10). By maintaining these animals solely on a diet of milk collected in glass or earthenware containers and restricting the copper intake entirely over a considerable period of time, an anemia has been produced in which low blood iron and hemoglobin were accompanied by hypocupremia. This is theoretically and experimentally possible but our results with large numbers of anemias, as well as the work of others, indicate that the body storehouse supply of copper is exhausted only in very rare instances in human subjects.

Attempts to apply the results of experimentation on animals to man often lead to erroneous conclusions. The artificial conditions employed in making the diet copper-free for experimental animals cannot be practically applied to studies on human beings. Copper is present in ordinary drinking water. Any diet which approaches normal, including in it vegetables, fruits, meats, liver, pasteurized milk, and sea foods is comparatively rich in copper. The elevated blood copper in cases of massive bleeding from ulcers indicates that even with the restricted diet of the patient with gastric or duodenal ulcer, the body stores are not usually exhausted.

It seems, therefore, that hypercupremia represents a response to an emergency and that the mobilization of copper is effected to stimulate hematopoiesis and combat the anemia present.

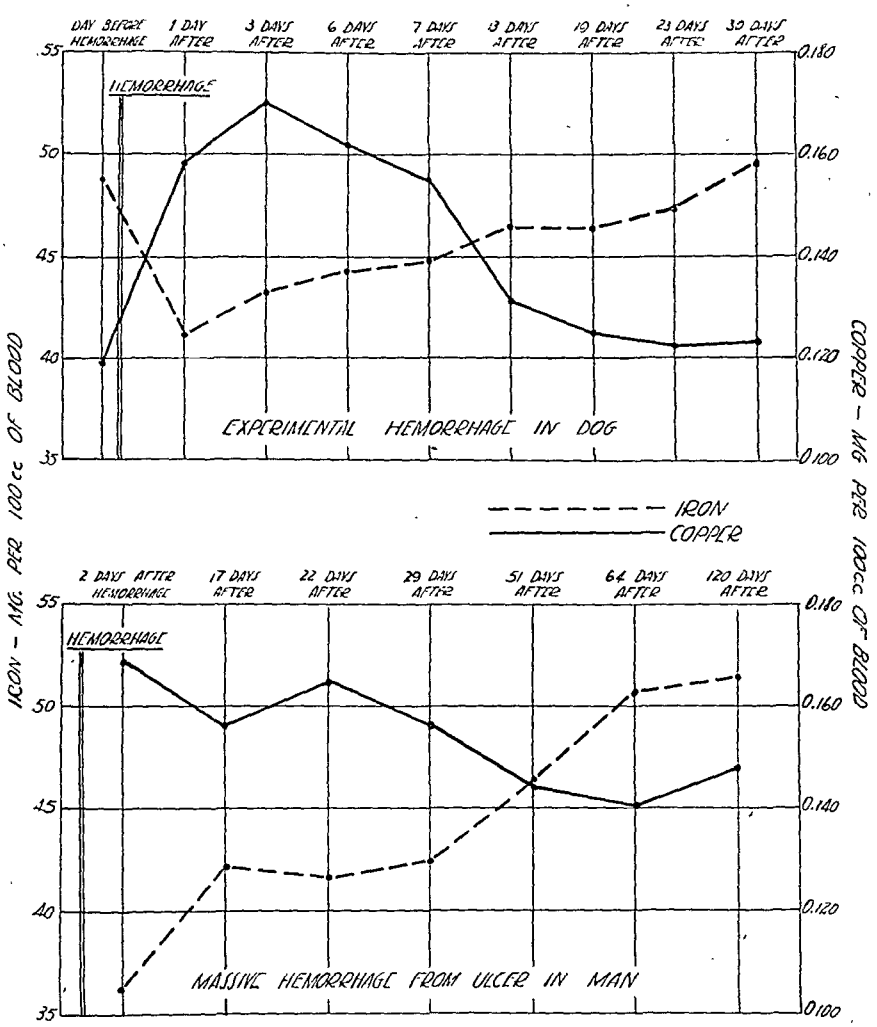
The Effect of Bleeding Ulcers and Hemorrhagic Anemia Upon Whole Blood Copper and Iron



By

ADOLPH SACHS, M.D.*

OMAHA, NEBRASKA

COPPER is now definitely known to play a part in the mechanism of hematopoiesis although its exact role is not clearly understood. Experimental work and observation, however, indicate that it acts as a catalyst. Its presence makes possible the utilization of the building materials, iron and protein, necessary for the manufacture of hemoglobin and erythrocytes. Copper plays a direct part in red cell production (1) and catalyzes the conversion of stored iron into the hemoglobinous form (2, 3, 4, 5, 6).

Under normal conditions the amount of copper in whole blood shows remarkably little fluctuation. The average amount in the blood of adults is 0.132 mg. of copper per 100 c.c. (7), which appears to be the optimum for its catalytic role in normal hematopoiesis. However, in the event that the iron or hemoglobin content of the blood is reduced, the copper usually rises quickly. Hypercupremia is the usual response to hypoferronemia.

We have had occasion to see such response many times in analyses of blood taken from patients suffering from various types of anemia (7, 8). More recently

chloride and ending at 0.38 per cent. (Normal is 0.44 per cent to 0.34 per cent). Other laboratory and X-ray work was negative.

Liver and iron were administered in large doses and eight blood transfusions were given, but the red count continued to drop. A month after admission the spleen became palpable and olive-green stools developed. The reticulocyte count at this time was 74 per cent.

In August, 1936, the blood examination showed the following: Red blood cells 580,000, reticulocytes 39 per cent, 15 normoblasts per 100 white cells, white blood cells 17,000 with 34 per cent stab forms, platelets 148,000. There were marked anisocytosis and hypochromia.

Following two blood transfusions a splenectomy was done under gas and ether anesthesia. Two more transfusions were given post-operatively. The jaundice began to disappear two days after the operation. and the red cell, hemoglobin, reticulocyte, and platelet counts began to rise. The patient felt much better and within a few weeks he was able to walk around the ward.

In October, 1936, the patient gradually became weaker, and the mild jaundice reappeared. The red cell count dropped to 1,200,000, the hemoglobin to 24 per cent, and the reticulocyte count to 28 per cent. Numerous transfusions were given, but he expired rather suddenly on October 18.

The spleen, removed at operation, weighed 560 grams. The capsule was thin and fairly smooth. The organ was doughy in consistency and on sectioning showed a dark red firm pulp, with fibrinous trabeculae and vessels which were retracted leaving a slightly puckered cut surface. The follicles were faintly visible and were grey in color. The microscopic section showed the malpighian bodies to be of normal size with well developed germinal centers. The arteries within the malpighian bodies were but slightly thickened and presented, occasionally, a slight hyalinization of the walls. The red pulp showed a marked congestion of the sinuses. The reticulum cells were scant. In many areas hemosiderin deposits were found. The trabeculae and splenic capsule were of normal appearance.

Post Mortem Examination: There was an enlargement of the liver due to infiltration by hematopoietic tissue. Smears of the bone marrow of the sternum, obtained by biopsy on August 14, 1936, and sections obtained from the bone marrow of the vertebrae, ribs, and sternum at autopsy on October 18, 1936, were examined by Dr. John Grill of the Department of Pathology. The morphological appearance of the bone marrow was very similar in all preparations. There were many closely packed, mature erythrocytes. Megakaryocytes were present, but not in an abundant amount. There were islands of closely packed normoblasts which contained dense, dark bluish stained, pyknotic appearing nuclei. Among the normoblasts there were megaloblasts with polychromatic cytoplasm, a reticular distinct chromatin network and in most instances without nucleoli. The cells of the leukopoietic series were found in normal proportions. Megaloblasts and myelocytes were scattered throughout sections and smears of the bone marrow. Eosinophilic myelocytes and metamyelocytes were quite outstanding in some places. There were also mature granulocytes.

The following tables show the important laboratory findings in these two cases:

DISCUSSION

The congenital form of hemolytic jaundice is usually much easier to recognize than the acquired type. The former pursues a long chronic course and usually no serious clinical manifestations arise. The acquired type may commence more abruptly and run a short stormy course leading to death within a period of a

Acquired Hemolytic Jaundice*

By

J. W. RASTETTER, M.D.†

and

FRANCIS D. MURPHY, M.D.‡

MILWAUKEE, WISCONSIN

HEMOLYTIC jaundice is a disease primarily due to increased fragility of the erythrocytes and characterized by anemia, increased destruction of red blood cells, acholuric icterus, splenomegaly, and a pronounced increase in the reticulocyte count. There are two forms of the disease, the congenital and the acquired, the first being the more common. The congenital type belongs to the inheritable diseases, occurring often in several successive generations, occasionally in several members of a family without cases among the ascendants, and also in a strictly congenital form, a single member of a family being affected from birth.

Imperfect accounts of the congenital form were given in 1885 by Murchison (1) and in 1890 by Wilson (2), but it was not until 1900 that the first accurate description was published by Minkowski (3). This was soon followed by articles in France by Gilbert, Castaigne and Lereboullet (4) and in England by Barlow and Shaw (5). Ten years later the condition was described in America by Tileston and Griffen (6) and shortly afterwards by Thayer and Morris (7). The true nature of the disease was little understood until 1907 when Chauffard (8) discovered the significant fact that the red cells showed a markedly diminished resistance to hypotonic salt solutions and reported (9) the presence of reticulated red cells in large numbers. Widal (10) was the first to describe the acquired type of the disease in detail and to recognize its hemolytic nature, although Hayem (11) had reported similar cases in 1898. The congenital form often is alluded to as the Minkowski-Chauffard type and the acquired form as the Hayem-Widal.

The following cases are presented because they demonstrate unusually severe grades of hemolytic jaundice and illustrate the pronounced contrast that may occur in response to splenectomy.

CASE REPORTS

Case 1. The patient was a white female, aged 41. She entered the hospital September 10, 1930, complaining of weakness, pain in the left upper quadrant and slight jaundice. The weakness started about six weeks before admission and became progressively worse. The week before admission she had three attacks of pain in the left upper quadrant which came on after eating and were relieved by vomiting. At this time she noticed that her skin and eyes were slightly yellow. There was no history of any food intolerance, hematemesis, or melena, but the stools were olive-green in color.

The family history was essentially negative.

The physical examination revealed a thin, white female, not acutely ill. She appeared anemic and was slightly jaundiced. The spleen was palpable and there was some tenderness in the left upper quadrant.

The blood examination on admission showed the red cell count to be 1,670,000, hemoglobin 35 per cent, color index 1.0, reticulocytes 19 per cent, white blood cells 4,000, polymorphonuclear cells 66 per cent, lymphocytes 34 per cent, platelets 130,000.

The icterus index was 50. The fragility of the red cells was increased, initial hemolysis beginning at 0.46 per cent of sodium chloride and ending at 0.32 per cent. (Normal is 0.44 per cent to 0.34 per cent). The urine was positive for urobilinogen. X-ray examination of the gastro-intestinal tract was negative. The van den Bergh reaction was indirect.

The patient was given liver and blood transfusions, but the red cell count rose only to 2,280,000 and the hemoglobin to 40 per cent.

A splenectomy was done. The spleen was found to be non-adherent and weighed 700 grams. It shrank to about one-half when removed. On pathological examination the malpighian bodies were distinctly visible. Microscopic examination showed that the follicles were not decreased. There was no fibrosis. There were relatively few lymphocytes, but an intense proliferation of endothelial leukocytes, many of them irregular in size and shape and some showing mitosis, were seen. The splenic pulp also showed a predominance of endothelial leukocytes. The liver was enlarged but smooth. The gall bladder was distended but no stones were felt.

A few days after operation a blood count showed the following: Red blood cells 2,120,000, hemoglobin 30 per cent, color index .71, reticulocytes 24 per cent, 7 normoblasts per 200 white blood cells, white blood cells 44,900, polymorphonuclear cells 83 per cent, lymphocytes 13 per cent, platelets 689,000. The jaundice began to decrease and finally disappeared. The patient felt much better and was discharged from the hospital October 30, 1930. The red cell count on discharge was 3,550,000, hemoglobin 47 per cent, white cell count 10,250, and reticulocyte count 21 per cent. This patient made an uneventful recovery and has remained well.

Case 2. The patient was a white male, aged 53, who entered the hospital June 3, 1936, complaining of progressively increasing dyspnea, mild jaundice, and generalized weakness. These symptoms began three months previously following a cold.

The family history was essentially negative.

Physical examination revealed nothing but a slight lemon-yellow tinge to the skin.

The examination of the blood on admission provided the following data: Red blood cells 2,700,000, hemoglobin 49 per cent, color index 0.9, marked anisocytyosis, reticulocytes 33 per cent, 4 normoblasts per 100 white cells, white blood cells 11,500, with 44 per cent stab forms, lymphocytes 26 per cent, monocytes 10 per cent.

The icterus index was 13 and the van den Bergh reaction was indirect. The urine showed urobilinogen but no bile. The fragility of the erythrocytes was increased, initial hemolysis beginning at 0.50 per cent of sodium

Submitted June 3, 1937.

few months. Failure to recognize and diagnose it is due in a large part to unfamiliarity of physicians with the disease. Although the clear cut text book type of case is distinctive, there are many cases presenting a clinical picture that may easily be confused with other types of blood dyscrasias and jaundice.

Acquired hemolytic jaundice may be secondary to some acute infection such as malaria, tuberculosis, or syphilis, but in most cases, as in those reported, the cause is not determined. The course of the disease may be acute, chronic, or chronic with periods of remission and relapse. Although the clinical picture of the acquired and congenital forms show striking similarity, there are some points of difference. Most outstanding are the episodes of pain and fever, the profound anemia, and the moderately intense jaundice which frequently accompany the acquired form, but are seldom noted when the disease is of the congenital type.

Acquired hemolytic jaundice is characterized by three major features, (1) splenomegaly, (2) anemia, (3) mild jaundice, and three minor features, (1) increased fragility of the red cells, (2) acholuria, (3) hyperreticulosis. The disease may begin with a sudden onset of violent pain, fever, and jaundice resembling that of a common bile duct obstruction, or it may begin insidiously with increasing weakness, anemia, mild icterus, and a sense of discomfort or pain in the left upper quadrant of the abdomen. Occasionally an enlarged spleen causing abdominal distress or a dragging sensation in the left side is the first symptom. During a crisis the spleen may enlarge considerably and then disappear under the costal margin when the exacerbation is over.

The jaundice of hemolytic icterus is usually mild. It deepens during a crisis, but never becomes dark brown as in a long standing obstructive jaundice. It is caused by an accumulation of the products of cell disintegration that the liver is unable to care for properly. A certain amount of altered pigment is absorbed into the blood stream.

The erythrocytes show increased fragility to hypotonic solutions of sodium chloride. Normal red cells show beginning hemolysis at about 0.44 per cent of sodium chloride and complete hemolysis at about 0.34 per cent. In hemolytic jaundice hemolysis may begin at 0.70 per cent of sodium chloride and be complete at 0.46 per cent or 0.50 per cent. Certain authors have looked upon the increased fragility of the red cells as being pathognomonic of the disease. In some cases, however, the fragility is normal especially where an extreme hyperreticulosis exists. Decreased resistance of erythrocytes is not confined necessarily to hemolytic jaundice.

The anemia varies greatly in different cases and at different times in the same case. Anisocytosis is usually quite marked, and there is a predominance of microcytes.

Reticulated red cells are greatly increased. Reynolds (12) reports a case in which the reticulocyte count reached 95 per cent. In his case the fragility of the erythrocytes was about normal, but he states that the large number of reticulocytes may have obscured the fact that the mature red cells were abnormally fragile. Some investigators believe that immature red blood cells, at least in certain disorders of the blood, are more resistant to hemolysis by hypotonic sodium chloride solution than the adult cells; others do not agree that this is true. Dreiling, Brody and Randall (13) reported a case in which the fragility test showed a beginning hemolysis at 0.5 per cent of sodium chloride and complete at 0.3 per cent on three occasions. At one time the reticulocyte count rose to 63 per cent.

Normoblasts are found occasionally, and polychromatophilia is often marked, but there is usually no granular degeneration. There are no characteristic changes in the leukocyte picture.

The stools are usually normal in color and consistency, but it is interesting to note that in the cases reported the patients developed olive-green stools at the same time that the spleen became palpable.

The absence of bile pigment from the urine (acholuria) in the presence of jaundice is usually found, but urobilin is often present. Giffen (14) reports a case of spontaneous hemoglobinuria in hemolytic jaundice. He found three other cases of this type in which the diagnosis of hemolytic jaundice was well established and an occasional case of questionable diagnosis that had been reported in German and French. He further states that from a study of both the clinical and the immunologic data, it seems justifiable to conclude that the hemoglobinuria of hemolytic jaundice is not due to syphilis, that it is not brought on by exposure to cold, and that the mechanism of hemolysis is not analogous to that in paroxysmal hemoglobinuria due to chilling.

Snelling and Brown (15) reported a case of a six year old child with hemolytic jaundice in which bone changes were found. The outer table of the skull was apparently gone and the diploe was in lines radiating out from the inner table with a very hazy appearance. The long bones were less dense than usual, and the growing ends, except the lower ends of the humerus, showed large spaces almost cystic in type between the trabeculae. The small bones of the hand showed this cyst-like arrangement to the fullest extent.

Bell (16) observed a case of a 15 year old male with acquired hemolytic icterus in which marked thickening of the skull occurred before splenectomy and the increase was about twice to three times normal thickness after splenectomy. This illustrates the marked activity and involvement of the bone marrow. No bones except the skull were involved in this process. Splenectomy brought about a permanent cure of the disease.

All of the symptoms of acquired hemolytic jaundice are subject to exacerbations sometimes accompanied by fever and always resulting in increased blood destruction. These exacerbations often follow dietary indiscretions, fatigue, or excitement. Occasionally one of the main symptoms of the disease, the increased fragility of the red cells, the splenomegaly, or even the jaundice may be absent.

DIFFERENTIAL DIAGNOSIS

In general these cases must be differentiated from other diseases accompanied by jaundice, splenomegaly, and anemia.

(1) *Diseases with jaundice:*

(a) Obstructive jaundice is excluded by the increased urobilin content, the absence of clay colored stools, and acholuria. Cholelithiasis is probably the most frequent source of error in the diagnosis of hemolytic jaundice because about 60 to 70 per cent of

other hemolytic agents, (4) a lessened tendency toward hemoglobinuria and jaundice after the administration of hemolytic agents, (5) a decrease in the volume of the portal blood, (6) the conversion of the bone marrow into red marrow and an actual increase in the volume of the marrow which can hardly be explained as merely compensatory to the anemia following splenectomy, and (7) the hypertrophy of the lymphatic tissues which seems to be due principally to hyperplasia of the endothelial cells.

The pathogenesis of the disease has been explained in two ways (25). One group of investigators (Widal, Vaquez and others) believe that it is essentially an increased fragility of the red cells, or, in other words, that the cause of the disease is to be found in a perversion of the function of the bone marrow so that it produces cells that are more easily fragmented than is normal. According to this theory, the splenomegaly is merely the reaction of the spleen to the presence in the blood of an increased number of cells that are ready for destruction. The other school (Minkowski, Chauffard and Banti) believe that the cause of the disease lies in the spleen. This organ for some reason becomes over-active and destroys more cells than it does under normal conditions. The latter view is strongly supported by the great improvement that follows splenectomy. The occurrence of occasional cases, typical in every respect except that the resistance of the red cells is normal, also points toward the splenic origin of the disease. However, neither of these theories is adequate to explain all of the findings.

Haden (26) gives a good explanation for the increased fragility of the red cells in congenital hemolytic jaundice, and since the process is somewhat similar in the acquired type it is worth while to give his conclusions. He finds that the diameter of the red cell in congenital hemolytic jaundice is decreased out of proportion to the change in volume, so it is apparent that the thickness of the cell must be increased and that the cell must tend to a spherical instead of biconcave shape. He made some experiments which indicate that the increased fragility is dependent on the spherocytosis or altered shape of the cells which affords a possible explanation for the increased hemolysis characteristic of the disease. He concludes that the red cells in congenital hemolytic jaundice constantly exhibit spherocytosis, best shown by the increased volume-thickness index. The diameter of the red cell in this condition is always less than normal, and the volume is variable. There is a direct relation between the volume-thickness index and the fragility. In congenital hemolytic jaundice the erythrocytes have at the beginning one of the shapes, through which a normal cell must pass when placed in successive dilutions of hypotonic salt solution, and so may be regarded as nearer the hemolysis point.

The pathogenesis of the jaundice seen in hemolytic icterus is best described by Rich (27). He classifies it as "retention jaundice" and states that it is recognized clinically by the following characteristics: (1) the bilirubin of the plasma which has never passed through the liver cells and is, therefore, unmixed with the constituents of the bile, gives the indirect van den Bergh reaction, (2) the stools contain an increased amount of urobilin because, in the face of the increased production of bilirubin, the liver is excreting more of the pigment than normally even though it cannot excrete enough of the excess to prevent jaundice, and (3) the urine contains an increased amount of urobilin but no bilirubin. It is free from bile salts which are formed in the liver and are absent from the urine unless they have been poured into the blood by the escape of whole bile from the canaliculi. Rich also states that jaundice resulting from over-production of bilirubin, in the absence of depressed liver function, rarely if ever occurs, because of the great reserve excretory power of the liver and because bilirubin is, as far as we know, formed only from the hemoglobin of destroyed red cells. Therefore an excessive formation of bilirubin is associated with an excessive destruction of red cells and an attendant depressing effect of anemia upon the liver. In hemolytic jaundice, in which there is an over-production of bilirubin, there is an anemia which depresses the excretory power of the liver. He also suggests that reticulocytes, which are present in high percentage, require more oxygen for their own metabolism than mature red cells, and may not be able to supply the tissues with oxygen as readily. This may be another factor in a depressed excretory function of the liver.

PATHOLOGY

Thompson (28) studied the spleens of thirty cases of typical hemolytic icterus and states that they all presented the same definite and characteristic changes. He describes the spleen of the typical hemolytic jaundice case as weighing 1000 to 1500 grams. It is usually easily removable at operation, being relatively free from adhesions. On section the fresh spleen presents a uniform and fairly characteristic appearance. The cut surface is relatively dry, dark purplish-red in color, and homogeneous in texture, bulging slightly above the capsule. The malpighian bodies are seen.

Thompson states that the microscopic appearance is uniform in all instances. The malpighian bodies are small and far apart. The venous sinuses are enlarged, widely separated, and frequently empty. The sinus endothelium is prominent, and the outline of these cells often bulges into the lumina of the sinuses. The pulp is a mass of closely packed red cells and this diffuse infiltration is the most striking feature of the microscopic appearance. There is no increase of connective tissue and no visible increase of iron pigment. The so-called iron incrustations are frequently encountered, usually within the trabeculae. There is no visible evidence of phagocytosis of the red cells, and, except for an occasional lymphocyte, one finds nothing but red cells distending, distorting, and dilating the pulp. He concludes that hemolytic jaundice is a definite clinical and pathological entity and that no difference exists between the congenital and acquired types.

PROGNOSIS

Since hemolytic jaundice is a disease of the reticuloendothelial system (25) it would be unreasonable to suppose that there would be no recurrences following splenectomy. A number of authors have called attention to this possibility and have seen cases where recurrence developed. Usually, however, the characteristic exacerbations do not return after splenectomy. The jaundice promptly disappears. In the absence of the spleen, red cell disintegration takes place in various remote areas of the body, probably in the bone marrow and possibly in the hemolymph nodes. Under

the cases are complicated by gall stones. Pemberton (17) reported on 118 cases of hemolytic jaundice, in which splenectomy was done, between 1908 and 1931, at the Mayo Clinic, and found conclusive evidence of disease of the gall bladder, with or without stones, occurring as a secondary complication in 68 per cent of the cases. Many patients have been operated upon for cholelithiasis, under the mistaken belief that the jaundice was of the obstructive type. The van den Bergh test is an aid in differentiating between hemolytic and obstructive jaundice.

(b) Acute infectious diseases with jaundice. In yellow fever and spirochetal jaundice, icterus is the outstanding feature. Jaundice is not uncommon in pneumonia and streptococcal septicemia. In these diseases it is probably hemolytic in origin.

(c) Familial icterus of the new-born is a very rare disease in which several children of a family are afflicted with deep jaundice shortly after birth. They usually die within a few days.

(2) *Diseases with splenomegaly:*

(a) Banti's disease or splenic anemia. Cirrhosis of the liver is usually present in the later stages of this disease and reticulated red cells are not abundant. Jaundice is not often present.

(b) In Gaucher's disease or large-celled splenomegaly there is a yellowish discoloration of the skin, but true jaundice is lacking. The spleen is enormously enlarged and the liver less so. A moderate anemia may be present.

(c) Syphilis of the liver may be accompanied by great enlargement of the spleen, but usually jaundice is absent. Syphilis may lead to true acquired hemolytic jaundice. The results of the fragility test and of anti-syphilitic treatment will lead to a correct diagnosis.

(d) Cirrhosis of the liver in the early stage does not show much enlargement of the spleen or jaundice except in the Hanot's type. Here the liver is much enlarged and jaundice is present. Portal cirrhosis is characterized in the late stages by ascites, hemorrhages and signs of collateral circulation.

(e) In chronic malaria the spleen may be considerably enlarged, but except in acute attacks, there is usually no jaundice.

(f) Tropical diseases with splenomegaly. Kala-azar is diagnosed correctly by finding the organism, Leishmania Donovani, in the material obtained by puncture of the liver or spleen.

(g) In leukemia the examination of the blood usually makes the diagnosis, but the occurrence of aleukemic leukemia must be remembered.

(h) In Hodgkin's disease the lymph nodes are enlarged and jaundice is absent.

(i) Polycythemia rarely is accompanied by jaundice, and the red cells are increased in number in contrast to the anemia that accompanies hemolytic jaundice.

(j) Diseases of infancy with splenomegaly. One must remember von Jaksch's anemia, rickets, tuberculosis, and hereditary syphilis. In congenital obliteration of the bile ducts the jaundice is of the obstructive type.

(3) *Diseases with anemia:*

(a) Pernicious anemia is characterized by macrocytosis, and there is no increased fragility of the erythrocytes.

(b) Acute hemolytic anemia, described by Lederer (18), is characterized by sudden onset, fever, leukocytosis and severe anemia.

(c) Idiopathic hypochromic anemia is characterized by microcytosis, low hemoglobin, and low color index. Usually there is no jaundice.

PATHOGENESIS

Despite the mystery that has surrounded the spleen in the past and the ignorance that still persists (19) regarding the exact nature of its physiologic functions, two important activities are now definitely established as centering in this organ. (1) the storage of red and white cells, (2) the phagocytic destructive activity of the reticulo-endothelial elements, the clasmatocytes of the splenic pulp, for the old or injured erythrocytes, granulocytes and blood platelets. Under physiologic conditions there is maintained a nice balance between bone marrow hematopoiesis and these splenic functions of cell storage and death. Krumbhaar (20), in 1923, proposed the term "hemolytopoietic equilibrium" for this balance. He states that bone marrow, spleen, liver, lymph nodes, and reticulo-endothelial apparatus combine to regulate the formation and destruction of blood cells in what may be termed the "hemolytopoietic system."

It has been the experience in medicine that, whenever any physiologic function is recognized for an organ, a disease entity due to a corresponding pathologic dysfunction, may be anticipated, and sooner or later will be encountered. Specific clinical entities involving disturbances in the functions of the spleen are known.

Another function attributed to the spleen (21) is the production of lymphocytes. It seems probable, that under some pathologic conditions, the endothelial cells and leukocytes may multiply and produce anti-toxins to counteract toxic substances brought to them. The most striking example of this is seen in typhoid fever.

During exercise (22), and in certain pathologic conditions, the spleen extrudes blood into the circulation to maintain circulatory balance. The ancients believed that the spleen had some relation to exercise and thought that the wind of runners was improved by splenectomy. The basis for this idea is not known. It may have been due to the prevalance of malarial splenomegaly, for this condition would obviously have an influence on exercise. The work of Barcroft (23) on the volume of the spleen indicated that the contents are expelled into the circulation during exercise.

The spleen seems to be the leading organ in the iron metabolism of the body (24); but just how this iron, derived from the breaking down of red cells, is carried from the spleen and formed into bile pigments has not been discovered since no free hemoglobin has been recognized in the splenic vein. It is probably tied in some way to the cells so that it is difficult to prove its presence. The spleen, like the rest of the reticulo-endothelial system, seems to be active in storing foreign coloring material as well as body-produced coloring matter. The endothelial cells of this system also have an intimate relationship to the metabolism of lipoids.

The important effects of experimental splenectomy (22) may be summarized as follows: (1) the occurrence of secondary anemia, (2) the production of leukocytosis, (3) the increased resistance of the erythrocytes to hypotonic sodium chloride solution and

Studies on the Control of Gastric Secretion*

I. Drugs Acting on the Autonomic-Sympathetic System. II. Drugs Acting as Central Emetics.

IF some relatively innocuous agent or procedure could be found that would abolish or greatly diminish the secretion of acid by the stomach, it should be of value in the treatment of peptic ulcer. In an attempt to understand more completely the control of the secretion of hydrochloric acid by the stomach, and with the idea in mind that some method might be obtained to produce temporary anacidity, the effect of a number of substances on gastric secretion in man and dog has been studied. These substances include:

I. Drugs acting on the autonomic-sympathetic system
   - A. Atropine
   - B. Bellafoline
   - C. Novatropin
   - D. Methatropin
   - E. Ergotamine

II. Emetics
   - A. Apomorphine
   - B. Apocodeine
   - C. Emetine
   - D. Quinine

METHOD OF EXPERIMENTATION

Experiments were performed on dogs with Pavlov pouches and on patients with chronic duodenal ulcer. Two types of gastric stimulants were used—food and histamine. Fractional test meals of crackers and water, and subcutaneous injections of 0.5 mgms. of histamine (ergamine acid phosphate, "Imido-Roche") were employed as the gastric secretory stimuli in fasting patients. The dogs were fed 200 grams of meat, 200 c.c. of milk, and 200 c.c. of water, or given 1 mgm. of histamine subcutaneously. Samples were withdrawn from the stomach of the patients every ten minutes for two hours before and after the test meal or histamine injection, and for seven hours from the pouches of the dogs after a meal, and for two hours before and after histamine. The acidity of the stomach contents was determined by titration with 0.1% Normal NaOH, Topfer's reagent and phenophthalein being used as indicators.

Drugs acting on autonomic-sympathetic system: Atropine, Bellafoline, Novatropin, Methatropin.

All who have observed the action of atropine (1) on gastric secretion in animals agree that the secretion is checked in all its normal phases. The literature has been reviewed recently by Gray (2) and an analysis of the mode of action of atropine on the parietal cell has been made. By using strictly controlled quantitative methods, it was shown that atropine decreases, but does not abolish, histamine stimulation of the parietal cell.

We find a difference of opinion as to the effect of atropine in man. Porter (3) found that the volume of gastric secretion was reduced after atropine, but that the free acidity was not changed. Others have found that the volume of secretion was reduced but that the free acid was higher (Klumpp and Bowie, Polland, Kalk and Siebert (4)). Keefer and Bloomfield (5) found that "not only was the total amount of secretion diminished, but the type of secretion curve was markedly altered." Rehfuss (6) found that the "psychic phase" was reduced, but that atropine did not abolish secretion. Winkelstein (7) found that atropine depressed the primary phase, and "also acts to suppress somewhat the chemical phase." Klein (8) says that in dogs all three phases of gastric secretion can be abolished by atropine, but in man the chemical phase cannot be suppressed. Roberts, Lockwood and Chamberlin (9) found that atropine reduced acidity and they thought that the regurgitation of bile caused by relaxation of the pyloric sphincter might neutralize the acid and cause the decrease. Others believing that atropine reduced gastric acidity clinically were Riegel, Bergmann, Mathieu, Schmidt, Chiari, Moore and Kilroe; Bennett, Loeper and Fau; Rall, Schiff and Kellerman; and Hernando (10). Bastedo (11) and Palmer (12) thought that it depressed gastric secretion only when untoward side actions were present, and Bastedo says that in the small doses which are used in man atropine is practically without effect on gastric secretion. Crohn (13) studied two patients with normal secretion periods. He found a slight rise of average total acidity when he gave one milligram atropine by hypodermic injection forty-five minutes after a meal. In two patients with continuous secretion he found that atropine stopped the secretion in an hour, and reduced the average total acidity. The same dose of atropine by mouth was ineffective. He also used belladonna until side actions were manifest. A test meal then showed an increase of average total acidity from 85.3% to 104.5%. The duration of secretion was decreased, however, to three hours. A careful study of the methods used in human subjects will reveal that most of the inconsistencies are due to differences in atropine dosage, differences in duration of the test period and the time of injection of the atropine, and differences in criteria used for determining inhibition of secretion. If doses adequate to dry the mouth are given, the total HCl output by the stomach is always decreased, the acidity may not change, or may increase or decrease.

Clinically both atropine and belladonna have been used extensively to reduce gastric secretion. In experimental work on gastric secretion in man and dogs, atropine has been generally used. We wondered if all of the belladonna principles supposedly present in proprietary products might prove more effective than the atropine derivative alone. We therefore attempted to compare the effects of atropine with one of the proprietary products of belladonna, namely *bellafoline*, in man and in the dog.

RESULTS

Table I shows the results of a comparison of the effect of subcutaneous injections of atropine or bellafoline on the gastric secretory response of the Pavlov pouch to histamine. Ten experiments were done with

other hemolytic agents, (4) a lessened tendency toward hemoglobinuria and jaundice after the administration of hemolytic agents, (5) a decrease in the volume of the portal blood, (6) the conversion of the bone marrow into red marrow and an actual increase in the volume of the marrow which can hardly be explained as merely compensatory to the anemia following splenectomy, and (7) the hypertrophy of the lymphatic tissues which seems to be due principally to hyperplasia of the endothelial cells.

The pathogenesis of the disease has been explained in two ways (25). One group of investigators (Widal, Vaquez and others) believe that it is essentially an increased fragility of the red cells, or, in other words, that the cause of the disease is to be found in a perversion of the function of the bone marrow so that it produces cells that are more easily fragmented than is normal. According to this theory, the splenomegaly is merely the reaction of the spleen to the presence in the blood of an increased number of cells that are ready for destruction. The other school (Minkowski, Chauffard and Banti) believe that the cause of the disease lies in the spleen. This organ for some reason becomes over-active and destroys more cells than it does under normal conditions. The latter view is strongly supported by the great improvement that follows splenectomy. The occurrence of occasional cases, typical in every respect except that the resistance of the red cells is normal, also points toward the splenic origin of the disease. However, neither of these theories is adequate to explain all of the findings.

Haden (26) gives a good explanation for the increased fragility of the red cells in congenital hemolytic jaundice, and since the process is somewhat similar in the acquired type it is worth while to give his conclusion. He finds that the diameter of the red cell in congenital hemolytic jaundice is decreased out of proportion to the change in volume, so it is apparent that the thickness of the cell must be increased and that the cell must tend to a spherical instead of biconcave shape. He made some experiments which indicate that the increased fragility is dependent on the spherocytosis or altered shape of the cells which affords a possible explanation for the increased hemolysis characteristic of the disease. He concludes that the red cells in congenital hemolytic jaundice constantly exhibit spherocytosis, best shown by the increased volume-thickness index. The diameter of the red cell in this condition is always less than normal, and the volume is variable. There is a direct relation between the volume-thickness index and the fragility. In congenital hemolytic jaundice the erythrocytes have at the beginning one of the shapes, through which a normal cell must pass when placed in successive dilutions of hypotonic salt solution, and so may be regarded as nearer the hemolysis point.

The pathogenesis of the jaundice seen in hemolytic icterus is best described by Rich (27). He classifies it as "retention jaundice" and states that it is recognized clinically by the following characteristics: (1) the bilirubin of the plasma which has never passed through the liver cells and is, therefore, unmixed with the constituents of the bile, gives the indirect van den Bergh reaction, (2) the stools contain an increased amount of urobilin because, in the face of the increased production of bilirubin, the liver is excreting more of the pigment than normally even though it cannot excrete enough of the excess to prevent jaundice, and (3) the urine contains an increased amount of urobilin but no bilirubin. It is free from bile salts which are formed in the liver and are absent from the urine unless they have been poured into the blood by the escape of whole bile from the canaliculi. Rich also states that jaundice resulting from over-production of bilirubin, in the absence of depressed liver function, rarely if ever occurs, because of the great reserve excretory power of the liver and because bilirubin is, as far as we know, formed only from the hemoglobin of destroyed red cells. Therefore an excessive formation of bilirubin is associated with an excessive destruction of red cells and an attendant depressing effect of anemia upon the liver. In hemolytic jaundice, in which there is an over-production of bilirubin, there is an anemia which depresses the excretory power of the liver. He also suggests that reticulocytes, which are present in high percentage, require more oxygen for their own metabolism than mature red cells, and may not be able to supply the tissues with oxygen as readily. This may be another factor in a depressed excretory function of the liver.

PATHOLOGY

Thompson (28) studied the spleens of thirty cases of typical hemolytic icterus and states that they all presented the same definite and characteristic changes. He describes the spleen of the typical hemolytic jaundice case as weighing 1000 to 1500 grams. It is usually easily removable at operation, being relatively free from adhesions. On section the fresh spleen presents a uniform and fairly characteristic appearance. The cut surface is relatively dry, dark purplish-red in color, and homogeneous in texture, bulging slightly above the capsule. The malpighian bodies are seen.

Thompson states that the microscopic appearance is uniform in all instances. The malpighian bodies are small and far apart. The venous sinuses are enlarged, widely separated, and frequently empty. The sinus endothelium is prominent, and the outline of these cells often bulges into the lumina of the sinuses. The pulp is a mass of closely packed red cells and this diffuse infiltration is the most striking feature of the microscopic appearance. There is no increase of connective tissue and no visible increase of iron pigment. The so-called iron incrustations are frequently encountered, usually within the trabeculae. There is no visible evidence of phagocytosis of the red cells, and, except for an occasional lymphocyte, one finds nothing but red cells distending, distorting, and dilating the pulp. He concludes that hemolytic jaundice is a definite clinical and pathological entity and that no difference exists between the congenital and acquired types.

PROGNOSIS

Since hemolytic jaundice is a disease of the reticuloendothelial system (25) it would be unreasonable to suppose that there would be no recurrences following splenectomy. A number of authors have called attention to this possibility and have seen cases where recurrence developed. Usually, however, the characteristic exacerbations do not return after splenectomy. The jaundice promptly disappears. In the absence of the spleen, red cell disintegration takes place in various remote areas of the body, probably in the bone marrow and possibly in the hemolymph nodes. Under

these circumstances, the products of red cell destruction reach the liver by a longer route and in a less concentrated form. The liver is better able to take care of the material, and jaundice results only when red cell destruction has reached a higher degree than is necessary to cause it when the spleen is present. The resistance of the red cells returns to normal in a large number of cases. Frequently, even though the patient is clinically cured, this resistance of the red cells remains unchanged. Lord Dawson (32) of England, reported a case of hemolytic jaundice in which Spencer Wells did a splenectomy in 1887. The patient was twenty-seven years of age at that time. She recovered and the jaundice permanently disappeared. In 1931 the patient was still in good health for her age. A few years previous to this, her blood was examined and the fragility of the red cells was found to be still increased. The reticulated red cell count returns to normal. There seems to be no change in the patient's resistance to bacterial infection following removal of the spleen.

Giffen (22) reports a total of 81 cases of hemolytic jaundice in which splenectomy was done with a hospital mortality of only 4.39 per cent.

The prognosis in the acquired type is less favorable than in the congenital form because death in many instances results directly from the anemia or from intercurrent infections.

TREATMENT

In spite of the fact that X-ray has been beneficial in the treatment of hemolytic jaundice, splenectomy is the only therapeutic measure worthy of consideration. Some men have questioned the advisability of such a serious procedure in mild cases, but splenectomy is to date the only curvature method of dealing with the disease. As Krumbhaar (20) said, "It is in hemolytic jaundice par excellence that splenectomy has had the greatest success." The operation, according to Hurxthal (29), is effective because it removes the organ of red cell destruction, even though it does not remove the real cause of the disorder, the fragility of the red corpuscles. It should not be done during an acute exacerbation.

Reifenstein and Allen (30) reported three cases of chronic hemolytic jaundice that showed definite clinical improvement with liver extract, but they believe that further observations are necessary before definite conclusions can be drawn. Martin (31), on the other hand, states that hemolytic jaundice responds to but one form of therapy—surgery. He has found that liver extract is unavailing and that whole blood transfusions are superfluous in view of the rapidity with which the blood count increases to normal after operation. Our experience with liver extract in the two cases reported shows it to be of little value.

SUMMARY

(1) The chief clinical manifestations of acquired hemolytic jaundice are outlined and discussed.

(2) Two typical cases of the disease are presented. The ineffectiveness of medical measures in the treatment of these cases is pointed out. One patient was cured by splenectomy. In the other case, amelioration of the symptoms occurred immediately after operation but within several weeks there was a relapse which resulted in the patient's death.

Studies on the Control of Gastric Secretion*

I. Drugs Acting on the Autonomic-Sympathetic System. II. Drugs Acting as Central Emetics.

By

A. J. ATKINSON, M.S., M.D.

and

A. C. IVY, Ph.D., M.D.

CHICAGO, ILLINOIS

IF some relatively inconsequent or procedure could be found that would abolish or greatly diminish the secretion of acid by the stomach, it should be of value in the treatment of peptic ulcer. In an attempt to understand more completely the control of the *secretion of hydrochloric acid by the stomach*, and with the idea in mind that some method might be obtained to produce temporary anacidity, the effect of a number of substances on gastric secretion in man and dog has been studied. These substances include:

I. Drugs acting on the autonomic-sympathetic system
   - A. Atropine
   - B. *Belladonna*
   - C. Novatropin
   - D. Methatropin
   - E. Eupentamine

II. Emetics
   - A. Apomorphine
   - B. Apocodeine
   - C. Emetine
   - D. Quinine

METHOD OF EXPERIMENTATION

Experiments were performed on dogs with Pavlov pouches and patients with chronic duodenal ulcer. Two types of gastric stimulants were used—food and histamine. Fractional test meals of crackers and water, and subcutaneous injections of 0.1 mg. of histamine hydrochloride acid phosphate, "Merck Reagent," were employed in the gastric secretory studies on factory patients. The dogs were fed 200 grams of meat, 250 c.c. of milk, and 200 c.c. of water, or given 1 c.c. of histamine subcutaneously. Samples were withdrawn from the stomach of the patients every ten minutes for two hours before and after the test meal or histamine injection, and for seven hours from the pouches of dogs after a meal, and for two hours before and after histamine. The acidity of the stomach contents was determined by titration with 0.1 N. Normal NaOH, Topfer's reagent and phenolphthalein being used as indicators.

Drugs acting on autonomic-sympathetic system. Atropine, Belladonna, Novatropan, Methatropin.

All who have observed the action of atropine (1) on gastric secretion in animals agree that the secretion is checked in all its normal phases. The literature has been reviewed recently by Gray (2) and an analysis of the mode of action of atropine on the parietal cell has been made. By using strictly controlled quantitative methods, it was shown that atropine decreases, but does not *abolish*, histamine stimulation, of the parietal cell.

We find a difference of opinion as to the effect of atropine in man. Porter (3) found that the volume of gastric secretion was reduced after atropine, but that the free acidity was not changed. Others have found that the volume of secretion was reduced but that the free acid was higher (Klumpp and Bowie, Polland, Kalk and Siebert (4)). Keefer and Bloomfield (5) found that "not only was the total amount of secretion diminished, but the type of secretion curve was markedly altered." Rehfuss (6) found that the "psychic phase" was reduced, but that atropine did not abolish secretion. Winkelstein (7) found that atropine depressed the primary phase, and "also acts to suppress somewhat the chemical phase." Klein (8) says that in dogs all three phases of gastric secretion can be abolished by atropine, but in man the chemical phase cannot be suppressed. Roberts, Lockwood and Chamberlin (9) found that atropine reduced acidity and they thought that the regurgitation of bile caused by relaxation of the pyloric sphincter might neutralize the acid and cause the decrease. Others believing that atropine reduced gastric acidity clinically were Riegel, Bergmann, Mathieu, Schmidt, Chiari, Moore and Kilroe; Bennett, Loeper and Pau; Ball, Schiff and Kellerman; and Hernando (10). Bastedo (11) and Palmer (12) thought that it depressed gastric secretion only when untoward side actions were present, and Bastedo says that in the small doses which are used in man atropine is practically without effect on gastric secretion. Crohn (13) studied two patients with *normal secretion periods. He found* a slight rise of average total acidity when he gave one milligram atropine by hypodermic injection forty-five minutes after a meal. In two patients with continuous secretion he found that atropine stopped the secretion in an hour, and reduced the average *total acidity. The same dose of atropine* by mouth was ineffective. He also used belladonna until side actions were manifest. A test meal then showed an increase of average total acidity from 85.5° to 104.5°. The duration of secretion was decreased, however, to three hours. A *careful study of the methods used in human subjects will reveal that most of the inconsistencies are due to differences* in atropine dosage, differences in duration of the test period and the time of injection of the atropine, and differences in criteria used for determining inhibition of secretion. If doses adequate to dry the mouth are given, the total HCl output by the stomach is always decreased, the acidity may not change, or may increase or decrease.

Clinically both atropine and belladonna have been used extensively to reduce gastric secretion. *In experimental* work on gastric secretion in man and dogs, atropine has been generally used. We wondered if all of the belladonna principles supposedly present in proprietary products might prove more effective than the atropine derivative alone. We therefore attempted to compare the effects of atropine with one of the proprietary products of belladonna, namely *bellafoline*, in man and in the dog.

RESULTS

Table I shows the results of a comparison of the effect of subcutaneous injections of atropine or bellafoline on the gastric secretory response of the Pavlov pouch to histamine. Ten experiments were done with

*From the Departments of Medicine and Physiology and Pharmacology, Northwestern University Medical School, Chicago.

Received July 20, 1927.

each dosage on two dogs. The pouch secretion over a two hour period was reduced by about 50% in each case. The height of titratable acidity was only slightly reduced and the total acid output in milligrams for

TABLE I

Showing effects of atropine and belladonna on the secretory response of the Pavlov Pouch to histamine (averages of 10 experiments with each dosage on 2 dogs)

	Total Vol. Output c.c.	Maximum Free Acid Clinical Units	Total Acid Output in mgms.
1 mgm. histamine (control)	21	119	97
2 c.c. bellafoline*	10.9	103	36
4 c.c. bellafoline	9.2	101	31
1 mgm. atropine	10	110	35
2 mgm. atropine	8	97	27

*2 c.c. of "bellafoline ampule solution" contains 1 mgm. of levorotatory belladonna alkaloids.

the two hour period was about thirty-three per cent of the usual histamine response. There was no essential difference in the effect of bellafoline or atropine. Because of the systemic effects of dryness of the mouth produced by atropine and the relatively large dosage necessary in the dog to reduce the gastric secretory response to histamine, we attempted a comparison of one of the more recent products, namely *novatropin*. Table II shows the effects of novatropin and of atropine on the gastric secretory response of a Pavlov pouch to histamine. There is a reduction in the volume secreted over a two hour period of about fifty per cent, but only a relatively slight decrease in the height of the titratable acidity. The decrease in volume, however, accounts for a considerable diminution in the total mgms. of acid secreted over a two hour period.

The effects of atropine and novatropin on the pouch secretion after a standard meal were also studied. Table III shows that the titratable free and total acidity were slightly diminished, but there was a considerable reduction in the volume over an eight hour period with consequent marked diminution of the total milligrams of hydrochloric acid secreted. Two milligrams of atropine were as effective as five milligrams of novatropin.

It should be pointed out that the drugs were injected just after the ingestion of the meal. The secretion during the first few hours is abolished or markedly depressed, the major portion of the secretion being collected in the later hours. In the dog atropine given at intervals markedly reduces the secretory response to a meal.

TABLE II

Showing effects of atropine and novatropin on the secretary response of the Pavlov Pouch to histamine

	Volume c.c.	Maximum Free Acid— Cl. Units	Maximum Total Acid— Cl. Units	Total mgm. HCl
1 mgm. histamine controls—Average of 20 experiments on 2 dogs	19	123	141	80
2.5 mgm. novatropin 1 mgm. histamine—Average of 14 experiments on 2 dogs	9	94	110	29
2 mgm. atropine 1 mgm histamine—Average of 10 experiments on 2 dogs	8	97	116	27

TABLE III

Showing effects of atropine and novatropin on the secretory response of the Pavlov Pouch to a meal (average of 10 experiments on 2 dogs)

	Volume c.c.	Maximum Free Acid— Cl. Units	Maximum Total Acid— Cl. Units	Total mgm. HCl
Controls with standard meals	127	142	165	685
2 mgm. atropine	57	134	146	271
5 mgm. novatropin	60	139	149	288

A comparison of the effect of atropine, bellafoline, novatropin and methatropin was made on eight patients with duodenal ulcer. The drugs were administered fifty minutes before giving 0.5 mgms. histamine as a gastric stimulus. The stomach contents were aspirated completely at ten minute intervals for two hours after the histamine injection. Table IV shows the average results. There was no effect on the height of titratable acidity reached, but the volume of secretion was diminished over the two hour period. Atropine reduced the volume and milligrams output of hydrochloric acid as effectively as any of the newer proprietary products in the dosages used. While it may be unfair to compare these drugs in the dosages used, systemic effects such as dryness of the mouth and skin, blurring of vision, or a sense of fullness in the head occurred with all drugs used in doses adequate to depress the HCl output.

We therefore do not believe that we can obtain satisfactory reduction of gastric acidity in man with any of the belladonna derivatives without producing untoward side reactions. In man the drugs of the bella-

Showing the effects of atropine, novatropin, methathopin and bellafoline on the gastric secretory response of patients with duodenal ulcer to histamine

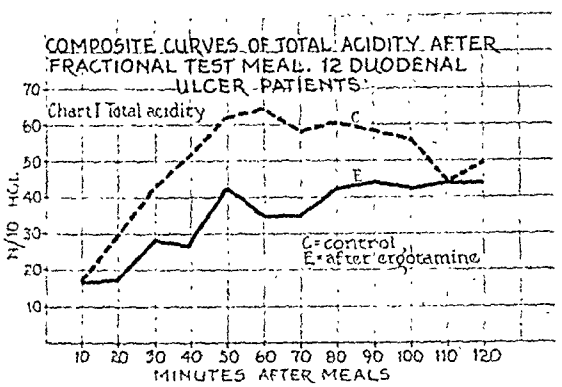
Composite averages of 8 patients	Volume c.c.	Maximum Free Acid Cl. Units	Maximum Total Acid Cl. Units	Total mgm. HCl
Histamine control	349	96	101	614
Atropine 1 mgm.	237	94	100	423
Novatropin 2.5 mgm.	263	98	104	534
Bellafoline 2 c.c. (1 mgm. levu-rotatory belladonna alkaloids)	300	96	102	585
Methatropin 10 mgm. (orally)	290	100	106	556

donna group used causes a diminution of the output of hydrochloric acid; but the concentration of the acid produced at the height of stimulation is not significantly diminished. In the dog the relatively larger doses, although producing dryness of the mouth, apparently do not produce toxic cerebral effects; the relatively larger dose of atropine given the dog depresses gastric secretion more.

It has been thought that histamine acted on the gastric cell, and atropine on the nerve ending. But since atropine does have some effect on the secretory response to histamine, it must act on the cell in addition to acting on the nerve ending. Brain and nervous tissue, however, are more susceptible to atropine poisoning than gastric tissue, and therefore we obtain toxic symptoms before we obtain achlorhydria in man.

CONCLUSION

Our findings with atropine are in accord with those of Keeton, Koch and Luckhardt (1) in the dog, and of Kiefer and Bloomfield (5) and Porter (3) in man. We noted a slight rise in the height of titratable acidity after atropine as did Polland (4), but the diminished volume of secretion always yielded a lower output of acid for the period of study. In order to obtain a depression of gastric secretion, the drug had to be given in amounts that caused dryness of the mouth. Atropine was as effective as any of the newer proprietary substitutes.



ERGOTAMINE

Volborth and Kudriawzeff (14) have claimed to have demonstrated the presence of excitatory secretory fibers in the splanchnic nerves to the fundus glands. Their data, however, are not very convincing. In Babkin's laboratory Baxter (15) proved, we believe, that the sympathetic nervous system has some relation to the secretion of mucoid fluid by the gastric mucosa. Section of the splanchnic nerves did not influence the volume of gastric secretion in response to sham feeding but the free and total acidities were lowered about eleven per cent. The output of pepsin and dissolved mucin reached its peak in the first twenty-five minutes and then abruptly fell in the splanchnotomized animals instead of gradually rising as in the normal animals. Ergotamine inhibited the "paralytic secretion" of mucoid fluid by the stomach after splanchnotomy. Bickel (16) believed that the sympathetic nerve supplies the fundic glands chiefly with inhibitory fibers. However, it has not been demonstrated definitely that the sympathetic nerves directly influence the peptic and parietal cells.

We desired to ascertain the effect of ergotamine, a sympathomimetic drug, on acid production, even though the influence of the sympathetic nervous system on the secretion of the gastric glands is not clear. Ergotamine has been found to depress and paralyze the sympathetics. It has been used clinically in migraine-like conditions, as a preliminary treatment before operations on the thyroid, and in the treatment of hyperthyroidism and "sympatheticotonia."

Fauley and Ivy (17) using Pavlov pouch dogs obtained results, showing that a definite decrease in the secretory response to a meal was obtained with a dose of ergotamine just less than the amount required to cause vomiting. Our problem was to determine the effect of ergotamine on gastric secretion in patients with duodenal ulcer. Two experiments were performed on each of 12 patients. On one day a control Ewald test-meal was given. And on another day 0.5 mgm. ergotamine tartrate (Sandoz) was injected subcutaneously twenty minutes before the Ewald meal. In most of the ergotamine experiments, the free and total acidities were moderately, but definitely lower than in the control experiments.

The average maximum free acidity in the control experiments was 55 free and 65 units of total acidity. The average maximum acidities after 0.5 mgm. ergotamine tartrate were 38 free and 45 units of total acidity. Composite curves of the acidity of twelve ulcer patients following ergotamine are compared with the control curve in Chart 1.

A moderate reduction in gastric secretion occurred with slight evidence of nausea. Six patients with duodenal ulcer were given a second dose of 0.5 mgm. ergotamine an hour after the meal. The composite curves obtained were approximately the same as though only the first dose had been given. The average values for maximum free and total acidity in the controls were 59 and 71, and after the second injection of ergotamine they were 36 and 48. When extreme nausea occurred the acidity was practically abolished.

In the histamine experiments, the patient swallowed the Rehfuss tube into the empty stomach, fasting samples were obtained, and 0.5 mgm. histamine was injected subcutaneously. Samples were withdrawn every ten minutes for two hours after the injection of histamine. A similar experiment was performed on a subsequent day except that 0.5 mgm. ergotamine tartrate was injected subcutaneously twenty minutes before the histamine injection. Table V summarizes the composite results in six patients with and without ergotamine. There is no change in the maximum free

TABLE V

Composite results in six patients using histamine as the gastric stimulus with and without ergotamine

and total acidity values, but there is a slight decrease in the volume of secretion over a two hour period with a consequent reduction in the total milligrams of acid secreted.

One patient exhibited more definite diminution in acidity than the others. In one patient slightly higher acid values were obtained after ergotamine than in the control histamine test. One milligram of ergotamine tartrate decreased the response to histamine more than 0.5 mgm. did (Table VI). The larger dose not only diminished the volume of acid secreted but also decreased the height of titratable acidity.

After 1 mgm. ergotamine (averages)	141	43	49	407

DISCUSSION

This investigation indicates that ergotamine tartrate in ordinary therapeutic doses definitely lowers the gastric secretory response to a meal in patients with duodenal ulcer, and in large doses diminishes the response to histamine. But, the margin between the significantly effective and harmful (nauseating) dose is too small for practical purposes. In some patients, giddiness, headache, sweating, rise of blood pressure, nausea, and vomiting may occur. In three of our patients unpleasant symptoms occurred even after 0.5 mgm. of ergotamine tartrate subcutaneously.

No evidence is presented to localize the action of ergotamine on either the nervous or humoral mechanisms of gastric secretion. The fact that one patient had higher secretion after ergotamine than in the control experiment seems to indicate that ergotamine acts only on part of the mechanism concerned in gastric secretion. The regulatory activity of the vagus nerve on gastric acid secretion is an established fact, but the influence of the splanchnics is still open to question. It is known that ergotamine, in adequate dosage, paralyzes the sympathetic. There is also some evidence (Rothlin (18)) that ergotamine may sensitize the vagus. At least it increases the susceptibility of the vagus action on the heart to electrical and chemical stimuli (acetyl choline). The vagus contains at least two kinds of excitatory secretory fibers (Vineberg (19)). One set causes a mucoid secretion and the other a juice containing acid and pepsin. Baxter (15) found both effects to be abolished by atropine, but after ergotamine there was a slight increase in the mucous secretion produced by weak rhythmic stimulation of the vagi in the neck. He attributed this slight increase to vasodilation. Could this be a sensitizing effect of ergotamine? If ergotamine sensitizes the vagus to inhibitory impulses (inhibitory nerves in the vagus for acid secretion are known to exist) transmitted to the gastric glands and thereby reduces the parietal cell secretion, atropine should abolish the ergotamine effect. Atropine and ergotamine were used in some further experiments for possible elucidation of the problem.

It has been claimed that ergotamine tartrate and atropine acted synergistically in patients with hyperacidity, and that atropine abolishes the nauseating effects of ergotamine. Experiments on dogs using histamine as the gastric stimulus show that atropine decreased the volume of secretion and ergotamine decreased the strength of the acid secreted (Table VII).

TABLE VII

Showing effect of atropine plus ergotamine on secretory response of Pavlov Pouch to histamine

	Volume	Maximum Free Acid	Maximum Total Acid	Total mgm. HCl
Average of 8 control experiments using histamine alone	23	119	133	98
Average of 8 experiments using 0.5 mgm. ergotamine and 2 mgm. atropine injected subcutaneously	6	76	95	15
Average of control experiments using 2 mgm. atropine	7	96	108	26

The atropine did not prevent vomiting, since in three experiments vomiting occurred. However, the acid secreted was no higher when vomiting did not occur.

Ergotamine 0.5 mgm. and atropine 1 mgm. were injected subcutaneously twenty minutes before 0.5 mgm. of histamine in 3 patients with duodenal ulcer. Lowering of the volume output gastric secretion, and of the total milligrams of acid secreted in a two hour period was observed, but there was no essential change in the maximum free or total acidity values (Table VIII).

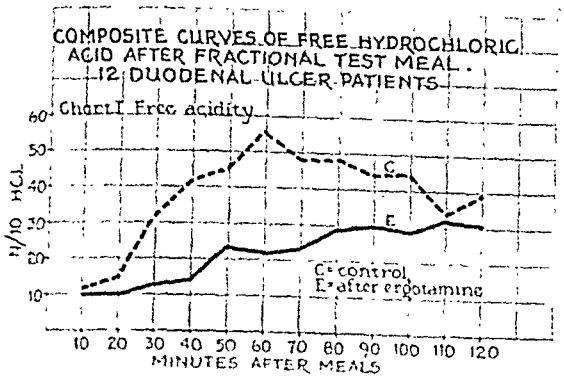

TABLE VIII

Showing combined effect of atropine and ergotamine on histamine response in three patients with duodenal ulcer

	Volume in 2 Hrs.	Maximum Free Acid	Maximum Total Acid	Total mgm. HCl
Control 0.5 mgm. histamine (averages)	254	65	70	518
Ergotamine 0.5 mgm. Atropine 1 mgm. Histamine 0.5 mgm.	132	68	70	214

Evidently atropine in the dosage used did not modify the ergotamine effect in man except to decrease further the volume and acid output.

The fact that large doses of ergotamine have some influence on the gastric response to histamine indicates that the humoral secretory regulatory mechanism may be involved, since histamine very probably acts directly on the peripheral mechanism concerned in the formation of acid. Animal experiments using Pavlov pouch dogs have been used with results more marked than those seen in our patients. More information regarding the mechanism of ergotamine action should

be obtainable by using extrinsically denervated pouch dogs and after vagotomy and splanchnotomy in dogs.

SUMMARY

1. Ergotamine tartrate in large doses diminishes the acid secretory response to histamine and to a meal.

2. The volume of secretion is usually decreased, but the peak of titratable acidity may be increased or unchanged. The summation effect is usually a diminution of the total HCl output.

3. The curve of acidity is generally depressed during the first hour after ergotamine and an Ewald meal, but may rise to normal in the second hour.

4. The margin of pharmacologic efficacy between acid inhibition and unpleasant symptoms is too narrow for this drug to be of clinical use in suppressing gastric secretion.

II.
EMETICS
APOMORPHINE

Since centrally acting emetics might influence gastric secretion either via the vagi or splanchnic nerves, we studied their effect on the gastric secretory response to histamine. Histamine was used because it is the strongest gastric stimulant known and its effects are the most difficult to diminish.

Sollman (20) states that apomorphine vomiting is prevented by very small non-narcotic doses of morphine and its esters. However, morphine alone will produce vomiting in the dog. We reasoned that if a small dose of codeine were given with apomorphine we might be able to prevent the vomiting.

One milligram of histamine, six milligrams of apomorphine hydrochloride and thirty milligrams of codeine sulphate were injected subcutaneously. The secretory response of the Pavlov pouch was diminished, but vomiting occurred (Table IX).

In man a combination of 15 mgm. of morphine sulphate and 6 mgm. apomorphine by subcutaneous injection was tried. Although the maximum free and total acidity values were unchanged the secretory curve after histamine fell much more rapidly than usual and the volume was lowered (Table X).

TABLE IX

Table showing effect of apomorphine and codeine on the secretory response of Pavlov Pouch to histamine

	Total Volume Output	Maximum Free Acid	Maximum Total Acid	Total Acid Output mgm.
Average of 6 control experiments on 2 dogs	20	119	134	98
Average of 6 experiments on 2 dogs with apomorphine and codeine	9.6	72	94	29

	Total Volume Output c.c.	Maximum Free Acid	Maximum Total Acid	Total HCl Output mgm.
Histamine control 2 hour response	320	64	74	520
Histamine plus 15 mgm. morphine and 6 mgm. apomorphine	134	60	72	146

APOCODEINE

Apocodeine is said to paralyze the sympathetic ganglia and to abolish the effect of splanchnic stimulation. Fifteen mgm. of apocodeine administered subcutaneously to Pavlov pouch dogs did not alter significantly the gastric secretory response to histamine.

TABLE XI

The effect of various dosages of quinine on the secretory response of the Pavlov Pouch for eight hours after a standard meal

	Total Volume Output c.c.	Maximum Free Acid	Maximum Total Acid	Total HCl Output mgm.

Average with 500 mgm. Quinine injected intravenously 20 min. after the meal	14	70	98	36
600 mgm. Quinine injected intravenously 20 min. after the meal caused vomiting	11	0	11	9
1 gm. Quinine in 200 c.c. N.S.S. injected intravenously at the rate of 1 mgm. per kilo body weight per min. caused vomiting	9	0	29	8

EMETINE HYDROCHLORIDE

Emetine hydrochloride was used as another example of a centrally acting emetic, and because it is used clinically to a small extent in the treatment of peptic ulcer. Sixty-five milligrams injected intravenously in Pavlov pouch dogs decreased the acid secreted by the stomach in response to histamine by thirty per cent. One hundred and twenty milligrams stopped secretion entirely and produced vomiting and diarrhea.

QUININE

Quinine while not classed as an emetic is an example of a protoplasmic poison which when given in large doses produces vomiting by stimulating the vomiting center.

Klocman (21) reported that quinine decreased the volume of gastric secretion in dogs to about 60% of normal. He stated that the effect persisted for several days. We extended his observations by attempting to produce a complete depression of the acid secretory response of the stomach in dogs.

In the attempt to find a dosage of quinine that would be effective in inhibiting gastric secretion, but would not produce vomiting, various amounts of quinine hydrochloride were given by stomach tube and intravenously in single doses twenty minutes after a meal, and by continuous intravenous injection over a period of fifty minutes. The doses used were 150 mgm., 300 mgm., 500 mgm., 600 mgm. and 1 gm. The volume of secretion of the Pavlov pouch following a standard meal was diminished, but in order to decrease the height of titratable acidity emetic doses of 600 mgm. intravenously had to be given (Table XI).

One gram of quinine hydrochloride in 200 c.c. normal salt solution was injected at the rate of 1 mgm. per kilo weight per minute, starting the injection 20 minutes after the dog had finished a meal. This injection stopped gastric secretion, but produced vomiting.

SUMMARY

In the attempt to diminish the acid gastric secretion by the use of centrally acting emetics, we studied apomorphine, apocodeine, emetine, and quinine. With subemetic doses we were able to decrease the total acid output over the period of observation. However, in order to decrease the height of titratable acidity emetic doses had to be used. These drugs, therefore, are of no practical value in clinical use for diminishing the concentration of the acid secreted by the stomach.

We wish to express our appreciation to Miss Vivian Bass for her technical assistance.

Part of the expense of this investigation was defrayed by contribution from the E. L. Dawes Fund.

Influencing Factors in Nutritional Deficiency Disease

By

RUSSELL L. HADEN, M.D.*
CLEVELAND, OHIO

NUTRITIONAL deficiency disease is due to an inadequate supply, absorption or utilization of vitamins, mineral salts or nutritional factors normally formed in the body from food elements. It has long been known that certain "deficiency diseases" such as scurvy and beri-beri result from an inadequate supply of certain vitamins. Only recently have we realized that a lack of necessary nutritional factors may play an important part in producing symptoms in many different diseases or may explain symptoms for which there has hitherto been no adequate explanation. Thus Mackie (1) has emphasized the great importance of nutritional deficiency disease in chronic ulcerative colitis, and Weiss (2) in the production of cardiac symptoms when the supply of vitamin B is inadequate.

Deficiency disease is due to the non-use of a specific nutritional factor at the site in the body where it is needed and normally utilized. The factor manifested cannot be used if it is not present, but it may be present, and yet not be utilized. The actual incorporation of a nutritional element necessitates an adequate supply, adequately absorbed and adequately utilized.

*Cleveland Clinic.
Submitted June 15, 1937.

For example, to prevent the development of pernicious anemia the bone marrow must constantly be supplied with the erythrocyte maturing factor formed normally in the stomach by the interaction of the intrinsic factor secreted by the gastric glands on the extrinsic factor taken in with the food. In idiopathic pernicious anemia there is a defect in supply since the stomach does not form the intrinsic factor; in sprue the factor is formed but lost on account of diarrhea; in myxedema, it may reach the marrow and not be used. In each of these three conditions the bone marrow may show the same response, namely the production of a macrocytic anemia.

In every patient with deficiency disease we must evaluate the factors influencing the supply, absorption and utilization of the specific nutritional elements. The more important factors to be considered are:

1. The normal reserve supply in the body.
2. The amount ingested or lost by vomiting or diarrhea.
3. The needs of the body especially as influenced by pregnancy, lactation and hypermetabolism.
4. Impairment of absorption from the gastro-intestinal tract by:
   a. achlorhydria
   b. hypometabolism
   c. toxemia
   d. circulatory insufficiency
   e. presence of certain substances such as mineral oil
5. Impairment of utilization in tissues by:
   a. toxemia as from chronic nephritis or infection
   b. metallic poisons as lead
   c. hypometabolism
   d. imbalance of food especially an excessive intake of carbohydrate
   e. imbalance of specific nutritional factors

It is apparent that the amount of any nutritional element available for use at any time is much influenced by the normal reserve level. The reserve of vitamins B, C and D and iron is very limited, while the body has the power of adequately storing vitamin A, most of the mineral salts, and the erythrocyte maturing factor protective against pernicious anemia. This fact partly explains the more frequent occurrence of some deficiencies than others.

All nutritional factors must be taken in as food or medication or formed in the body from food, hence the supply is directly related to the intake. Certain elements such as vitamin B and iron are normally present in most foods only in small amounts. Long continued vomiting or diarrhea will cause a deficiency even if the nutritional elements are ingested in abundance since absorption is interfered with. Patients who regularly take only small amounts of food not infrequently have a deficient quantitative intake although the diet may be qualitatively adequate. A combination of small intake and some vomiting, such as occurs in the early part of almost every pregnancy, is a potent factor in causing deficiency disease in pregnancy.

The amount of food which is adequate under normal conditions may be inadequate under conditions requiring larger amounts than normal. Pregnancy and lactation are the two physiological states requiring more nutritional elements. Hypermetabolism from any cause increases the need since the level of chemical activity is here much higher. The more important clinical causes are fever, leukemia, and hyperthyroidism.

Numerous factors may interfere with absorption after the nutritional elements are taken into the gastro-intestinal tract. The presence of achlorhydria has a definite effect on the efficiency of absorption, especially of the mineral elements. The iron deficiency anemias are much more common if free hydrochloric acid is absent from the gastric contents. This may be a chemical problem secondary to insufficient solution of iron in the absence of hydrochloric acid or may possibly be due to the lack of some factor necessary for the metabolism of iron whose absence is indicated by the achlorhydria, just as the achlorhydria of pernicious anemia is of importance only as indicating the absence of the intrinsic factor of Castle.

Hypometabolism necessarily interferes with absorption since here the level of vital activity is decreased. In most instances of hypometabolism, the metabolic level is probably not sufficiently lowered to make much difference alone but in myxedema where the basal metabolic rate is 30 to 40 per cent below normal, such a lowering of chemical activity is very important. A mild hypothyroidism may be important also when added to other factors.

A toxemia from any cause may interfere with absorption although this is probably much more important in affecting utilization than absorption. Circulatory insufficiency necessarily impairs absorption. The chronic and excessive use of mineral oil may impair the absorption of the vitamins. This has already been discussed in relation to vitamin A (3) and, from clinical observations, I am more and more impressed with the probability that mineral oil may also interfere with the absorption of vitamin B.

It is increasingly evident to students of nutritional disease that impaired utilization of specific factors in the tissues where they are necessary frequently precipitates the symptoms of deficiency disease. In such cases there is little therapeutic effect from giving more of the missing factors. A toxemia from chronic nephritis or an infection may act in such a manner. Metallic poisons, especially lead, produce a hypochromic or iron deficiency anemia which is not influenced by iron therapy. It is very probable that the neuritis of lead poisoning is due to a deficiency of vitamin B rather than a direct toxic effect of lead on the nerves. The lead here interferes with the utilization of both iron and vitamin B. This fact explains the ineffectiveness of iron or vitamin B in lead poisoning since the fault is in utilization and not in supply.

Hypometabolism will interfere with utilization just as it does with absorption due to a lowering of the level of chemical activity. It has long been observed clinically that iron may have no effect in an iron deficiency anemia unless given with thyroid extract. In such cases the utilization of iron is probably impaired by the hypometabolism.

A food imbalance may also influence the utilization of nutritional factors. An excess of carbohydrate especially will interfere with the use of vitamin B. This may be due to the fact that vitamin B is necessary for the oxidation of carbohydrates, so far unproved, or that some balance between carbohydrate and vitamin B is necessary as emphasized by Cowgill (4). Mc-

Carrison (5) showed long ago that a vitamin B deficiency will develop in a monkey in normal nutritional balance if carbohydrate alone is added to the diet. Little is known about the effect of an imbalance of other food elements on the utilization of specific nutritional factors.

It is quite probable that some balance between the specific nutritional elements may be necessary also. Certain types of nutritional deficiency constantly occur together. This is best illustrated by the frequent finding of an iron and vitamin B deficiency together. It seems probable here that iron influences the utilization of vitamin B or vice versa.

DISCUSSION

I have outlined the manner in which the development of nutritional deficiency disease may be influenced. Whenever deficiency disease is considered as a possible factor in a patient's symptoms the absorption and use of nutritional elements as well as the supply must be evaluated.

This discussion only emphasizes the many possible conditioning factors. These must be identified if possible since the treatment of deficiency disease, when due to deficient absorption or utilization, is a problem in treating the influencing factor rather than in supplying more of the missing element. Fortunately, at times providing an excessive supply of the factor needed may overcome a defect in absorption or utilization which cannot be treated or removed.

Every true deficiency disease is a chemical problem in which all possible influencing factors in the development of the disease must be considered. It is especially necessary to recognize the importance of the summation of several conditioning factors.

Clinical and Pathological Manifestations of Carcinoma of the Stomach

By

ABEL LEVITT, M.D., F.A.C.P.

and

JOHN F. ARGUE, M.D.

BUFFALO, NEW YORK

DURING the past seven years, one hundred thirty-two cases of carcinoma of the stomach have been studied on the gastro-intestinal service of the Buffalo City Hospital. We will review this series of cases and endeavor to evaluate and compare the important factors manifested, with some of the current medical literature on this subject.

AGE AND SEX INCIDENCE

Carcinoma of the stomach is usually considered a disease of middle age. In a series of five hundred forty-one cases, reported by Minnes and Geschicter, seventy-eight per cent occurred between the ages of forty-four and sixty-six years, ten per cent before the age of forty and two and six-tenths per cent after the age of seventy. The youngest in their series was twenty-five and the oldest eighty. In our series, the youngest was twenty years of age, while the oldest was eighty-one. The highest percentage, seventy-seven and three-tenths, occurred between the ages of forty and seventy.

Walton reviewed six hundred fifty cases and found that one hundred fifty occurred between the ages of fifty-one and sixty. Five of his cases occurred before the age of thirty, while in our series three cases or three and two-tenths per cent occurred before the age of thirty.

Minnes and Geschickter found gastric cancer to be three times as common in males as in females, while the Mayo Clinic shows the ratio to be slightly higher. In our group there were one hundred nine males, eighty-two and six-tenths per cent, and twenty-three females, seventeen and four-tenths per cent, approximately five times as common in the male as in the female.

The disease occurred in one hundred twenty-five members of the white race and seven members of the colored race. While our cases on the service are predominatingly white, still the incidence in the white race is much greater than in the colored race.

Age Incidence	No. of Cases	Percentage
20-30 years of age	3	2.2%
31-40 years of age	7	5.3%
41-50 years of age	26	19.7%
51-60 years of age	33	25.0%
61-70 years of age	43	32.6%
71-80 years of age	18	13.6%
Over 81 years of age	2	1.5%
	132	99.9%

SYMPTOMATOLOGY

In our series of one hundred thirty-two cases, the outstanding complaint was epigastric pain, present in more than seventy per cent of the cases. Flatulence and anorexia occurred in fifty-eight per cent of cases. Emesis was complained of in sixty-nine per cent. In only a small group of ten cases was hematemasis present. Enlargement of the abdomen occurred in five

From the Gastro-Intestinal Service, Buffalo City Hospital and Department of Medicine, University of Buffalo.

and three-tenths per cent. It is therefore evident that there are no pathognomonic symptoms which would permit the early recognition of the disease. Minnes and Geschickter in their series of over five hundred

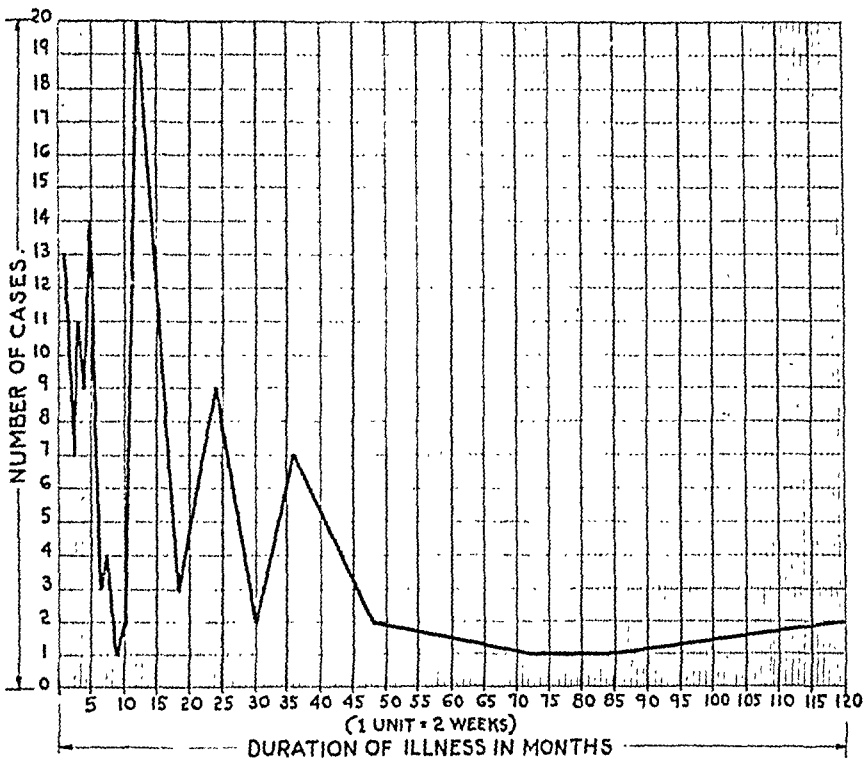
Incidence by age and sex of carcinoma of stomach

Observer	No. of Cases	Average Age	Percentage	
			Males	Females
Minnes and Geschickter	541	53.6		
Mason	1912	53.7	78.8%	21.2%
Balfour-Harris	1000	54.	79. %	21. %
Walton	650	57.2		
Levitt and Argue	132	57.5	82.6%	17.4%

cases found the most constant and conspicuous feature was the rapid loss of weight, observed in ninety-one per cent of their cases, and which corresponds closely with the findings in our group. Epigastric pain was present in seventy-four and eight-tenths per cent in their series.

PREVIOUS HISTORY

In one hundred twenty-one cases of the group studied, the duration of gastro-intestinal symptoms varied between one month and ten years. Thirteen patients had symptoms referable to the stomach less than one month before the diagnosis was established. The majority had complaints between five and twelve months. In fifteen cases, eleven and three-tenths per cent, a diagnosis of gastric ulcer had been made before it was established that carcinomatous changes were present.



PHYSICAL SIGNS

Physical examination in the early stages of the disease may reveal very little. The presence of a palpable mass in the epigastrium signifies the advanced stage of carcinoma. It was found in forty-three and six-tenths per cent of the cases studied by Minnes and in

Symptoms

Loss of weight	115 cases	87.1%
Epigastric pain	95 cases	71.9%
Emesis	92 cases	69.6%
Flatulance and anorexia	77 cases	58.3%
Constipation	48 cases	36.3%
Weakness	34 cases	25.7%
Tarry stools	25 cases	19. %
Lower abdominal pain	9 cases	6.8%
R.U.Q. pain	8 cases	6. %
Enlargement of abdomen	7 cases	5.3%
Diarrhea	3 cases	2. %
Dysphagia	3 cases	2. %
Jaundice	2 cases	1.5%
L.U.Q. pain	1 case	.7%

forty-four and six-tenths per cent in our series. Epigastric tenderness was observed in his group in thirty-two and three-tenths per cent, and in thirty-three and three-tenths per cent in our series. Emaciation was the outstanding clinical manifestation present in our series and was observed in sixty-two and eight-tenths per cent of the group. It is interesting to note that Virchow's node was present only four times in the

Physical signs

Emaciation	83 cases	62.8%
Epigastric mass	59 cases	44.6%
Epigastric tenderness	44 cases	33.3%
Enlargement of liver	36 cases	27.2%
Pallor	22 cases	16.6%
L.U.Q. mass	15 cases	11.3%
Abdominal distension	13 cases	9.8%
R.U.Q. mass	11 cases	8.3%
Jaundice	8 cases	6.0%
Ascites	5 cases	3.7%
Abdominal spasm	4 cases	3. %
Virchow's node	4 cases	3. %
Invisible peristalsis	3 cases	2. %
Prominent abdominal veins	2 cases	1.5%
R.L.Q. mass	2 cases	1.5%
L.L.Q. mass	2 cases	1.5%
Rectal mass	1 case	.7%
Large cervical glands	1 case	.7%
Smooth tongue	1 case	.7%

entire series. Hepatic enlargement was observed in thirty-six patients and ascites in only five of this group.

LABORATORY WORK

The absence of free hydrochloric acid in the gastric contents has long been regarded as a constant finding in carcinoma of the stomach. In a series of three hundred thirty-nine cases studied by Hartman, achlorhydria was observed in sixty-four and six-tenths per cent of the group, hypo-chlorhydria in twenty-five and nine-tenths per cent and normal values in six and seven-tenths per cent of cases. In our series, eighty-one per cent showed absence of free hydrochloric acid. The remainder showed varying degrees of hydrochloric acid present. Occult blood was present in both gastric contents and the stool of all cases. The blood Wasserman was positive in only seven cases of the entire group.

Roentgenographic studies of the gastro-intestinal tract were made in ninety-three cases. Of this group the diagnosis of carcinoma was made in eighty-one and seven-tenths per cent, ulcer of the stomach in five and three-tenths per cent, while the remainder of the group were reported as negative. Obstruction as evidenced by retention of the barium meal was observed in thirty cases. Since the entire group had carcinoma of the stomach, the X-ray diagnosis was conclusive in the majority of cases.

Blood examinations were made in ninety cases of the group. The hemoglobin was under sixty per cent in thirty-eight cases and eighty per cent or less in seventy-four cases. The red cell count was under three million in twenty cases and under four million in sixty-three cases, suggesting that a hypochromic anemia was predominant. In seventy cases a leukocytosis above eight thousand was present.

LOCATION OF CARCINOMA

In tabulating the location of the cancer in the stomach we include the findings of X-ray, autopsy and surgery. This gives us one hundred forty-two lesions observed in our series of one hundred thirty-two cases.

Location of carcinoma

Pylorus	79 cases	55.6%
Lesser curvature	13 cases	9.1%
Pars cardia	11 cases	7.7%
Pars media	7 cases	4.9%
Entire stomach	1 cases	2.8%
Greater curvature	4 cases	2.8%
Duodenum	1 case	.7%
Pre-pylorus	1 case	.7%
Undetermined	22 cases	15.5%

RESULTS

Forty-four cases of our entire series were submitted to surgery. In sixteen of this group, a laparotomy was performed, and the lesion was considered far advanced. In twenty-two cases a gastro-enterostomy was performed. A gastric resection was done in six cases. Of the total group operated upon, four cases lived for one year following the operation, the remaining number died within a period of less than one year.

Thirty-six cases of our series were autopsied and the diagnosis of carcinoma of the stomach was confirmed. In the autopsied group twelve cases showed metastases to the regional lymph nodes, and a similar number showed metastases to the liver. Five cases showed involvement of the omentum, four of the peritoneum, and two each in the pleura and spleen. The esophagus, mediastinum, brain, pancreas and renal vein were each found to be involved once in separate cases. Ten cases showed no metastatic involvement. Associated findings in the autopsied group were cholelithiasis, cirrhosis of the liver, diverticulosis of the colon and gastric ulcer once each in separate cases.

COMMENTS

Dr. Allen A. Jones. The examination of gastric contents for the presence of lactic acid, macroscopic, microscopic or occult blood and Oppler-Beas bacilli is of great importance in gastric carcinoma. Usually, in the presence of lactic acid, hypochlorhydria or achlorhydria is found but, in some instances, free hydrochloric acid is present with a definite positive chemical test for lactic acid. It is best to examine the morning fasting stomach contents using the fractional method.

Even gastroscopy or X-ray may fail to reveal a malignant process in the stomach.

In the presence of more or less epigastric pain, anorexia, steady and rather rapid loss of weight and a markedly increased sedimentation rate of the red blood cells, malignancy should be suspected.

The authors wish to express their appreciation to Dr. George B. Pantera for assistance in compiling the statistics.

The Value of Diagnostic Non-Surgical Biliary Drainage as Compared with Cholecystography*

(An Analysis of Biliary Drainage Findings in 64 Operated Cases Compared with Findings by Cholecystography in 60 of These Cases)

By

WILLIAM T. DORAN, M.D., JOHN WILFRID FORSTER, M.D.

and

LESTER C. B. SPIER, M.D.

NON-SURGICAL biliary drainage has now been in use for nearly two decades. However, it has not received as universal an acceptance as has cholecystography. In the hands of many workers, the value of biliary drainage compares favorably with that of cholecystography in the diagnosis of biliary tract pathology, particularly cholelithiasis. Bockus (1) showed that the cholecystogram demonstrated stones in 29.2% while biliary drainage suggested the presence of stones in 83.2% of 148 proved stone cases. In 79 stone cases where the gall bladder was still functioning, 97% showed crystals in the preoperative bile. Cholecystography demonstrated pathology in 88.4%, while drainage showed pathology in 98% of 143 proved stone cases. From this clinic four years ago Doran, Lewis, Denneen and Hanssen (2) published a paper enthusiastically endorsing biliary drainage as a diagnostic procedure. We are still employing it routinely in all cases attending the gall bladder clinic.

Rousselot (3) in 1933, described a technique of drainage which was invariably successful. By using a tube with a metal stilet, he was able with the assistance of a fluoroscope to pass the tube into the duodenum in a very short time. He found biliary drainage valuable in the diagnosis of cholelithiasis.

In our clinic we have found that with a Twiss (4) duodenal tube, unsuccessful drainages are much less common than with other types. If a drainage is unsuccessful, it is repeated the following week, the patient in the meantime taking 10 minims of Tincture of Belladonna three times daily following meals. This usually succeeds in overcoming the pylorospasm. Twenty-five per cent magnesium sulphate and olive oil are used as stimulants. Very often we obtain concentrated bile after stimulation with olive oil when the magnesium sulphate stimulation has failed. Rarely do we fail to obtain concentrated bile from a gall bladder which functions normally by cholecystography.

The bile is examined macroscopically for color. A dark olive-green or molasses color usually denotes good gall bladder function. If no concentrated bile is obtained we conclude that the gall bladder is not functioning. The sediment is inspected. The presence of brick-red particles is usually due to the presence of calcium bilirubinate pigment. The bile sediment is examined microscopically for cholesterol crystals, calcium bilirubinate pigment, and bile-stained pus cells. Cholesterol crystals are easily recognized as colorless, rectangular crystals with a corner punched out. Calcium bilirubinate pigment appears as lustrous orange or gold-colored granules; less often it appears as brick-red particles.

Preoperative non-surgical biliary drainages were done in 64 operated cases (See Table). Crystals were found in the bile in 27 cases or 43.5%. At operation stones were present in 22 of the 27, or 81%. Of these 27 cases, calcium bilirubinate pigment without cholesterol crystals was present in 10. At operation stones were present in 9 of the 10 cases, or 90%. Cholesterol crystals alone were present in 11. In 10 of these, stones were present at operation, or 91%. Both cholesterol crystals and calcium bilirubinate pigment were present in 6 cases. Stones were found at operation in 3, or 50%.

Of the 62 cases studied, 48 had stones at operation. Of these 48 cases, 21 had crystals in the preoperative bile, or 43.7%; 19 showed neither crystals nor concentrated bile. Pathological drainage findings, that is, the presence of crystals or the absence of concentrated bile, were found in 40 of the 48 stone cases, or 83.3%. The remaining 8 patients with stones, or 16.6%, had a normal biliary drainage.

In 5 of the 14 patients, 35.7%, with a pathological gall bladder without stones at operation, crystals were present in the preoperative bile obtained by biliary drainage.

SUMMARY

1. An analysis of biliary drainage findings in 62 operated cases is presented.

2. In 83.3% of cases showing cholelithiasis at operation the preoperative biliary drainage findings were suggestive of gall bladder pathology.

3. In 43.7% of cases showing cholelithiasis at operation, the diagnosis was suggested by the presence of crystals in the bile obtained by biliary drainage prior to operation.

4. 81% of the patients suspected of having gall bladder disease and showing crystals in the bile had stones at operation.

5. Approximately one-third of the patients who at operation had a diseased gall bladder without stones had crystals in the preoperative bile.

CHOLECYSTOGRAPHY

Cholecystograms were done in 60 of the above mentioned operated cases. 31 showed failure of visualization, 15 showed shadows suggestive of calculi, 6 were reported as faint visualization, 1 showed normal visualization with delayed emptying, and 7 revealed normal visualization and normal emptying.

*From the Gall Bladder Clinic—Fourth Surgical Division, Bellevue Hospital.

63. M. L.	0	Cholesterol Bilirubin Ca	OV	—			Chronic cholecystitis
64. J. R.	0	Negative	OV	—	—		Dilated thickened gall bladder

OV—No visualization of gall bladder.
NV—Normal visualization of gall bladder.
FV—Faint visualization.

DE—Delayed emptying
Calculi—Shadows resembling calculi seen in roentgenogram.

Of the 31 cases showing failure of visualization, stones were present in 23, or 74.2%. The 8 remaining cases showed various types of gall bladder pathology such as fibrosis or atrophy, chronic cholecystitis, and empyema. Of the 15 cases in which shadows suggestive of calculi were reported, stones were present at operation in 13, or 93.3%. In the 6 cases showing faint visualization by cholecystography, stones were found at operation in every case (100%). Of the 7 cases showing a normal cholecystogram, 3 showed stones at operation (43%). In the one case showing normal visualization and delayed emptying, stones were present at operation.

In 46 proved stone cases, the cholecystographic findings were as follows: 14, or 30%, shadows suggestive of calculi; 50%, no visualization; 13%, faint visualization; and 6.7% normal visualization and normal emptying.

SUMMARY OF CHOLECYSTOGRAPHIC FINDINGS

1. An analysis of cholecystographic findings in 60 operated cases is presented.

2. While only 30% of gall stone cases coming to operation showed stones by cholecystography, over 93% showed a pathological cholecystogram, viz. calculi, no visualization, faint visualization or normal visualization with delayed emptying.

3. In patients suspected of having gall bladder disease a pathological cholecystogram almost invariably indicates a pathological gall bladder. If the cholecystogram is reported normal there is a larger error; 6.7% of stone cases and 20% of other types of gall bladder pathology failed to show a pathological cholecystogram.

COMPARISON OF DIAGNOSTIC VALUE OF CHOLECYSTOGRAPHY WITH THAT OF BILIARY DRAINAGE

In patients with cholelithiasis, cholecystography was superior in revealing pathology — 93% as compared with 83.6% for biliary drainage. Actual calculi were demonstrated in cholecystograms in 30% of cases while the presence of calculi was suggested by biliary drainage in 43.7%. When findings by biliary drainage and by cholecystography are both considered, pathology was indicated in 95.9%.

CONCLUSIONS

1. Non-surgical biliary drainage is a useful diagnostic procedure.

2. It compares favorably with X-ray in the diagnosis of biliary tract pathology.

3. Finding crystals in the bile is not pathonomonic of stones, but is evidence of pathology in the biliary tract.

Abstracts

HENRY KENDALL MULFORD

America lost one of its foremost exponents of preventive medicine in the passing of Henry Kendall Mulford, in his 71st year, on October 15, 1937.

The company which bore Mr. Mulford's name was the first in this country to commercially distribute antitoxins. Small Pox Vaccine and curative serums used in the prevention and cure of infectious and contagious diseases were soon added. Through the distribution of these biologicals, he was probably responsible for the saving of more lives than any other man in the history of medicine and pharmacy. These alone stand as a fitting monument to his life of service to humanity, and thanks to his stimulating influence on the younger men whom he drew around him, the good work that he accomplished and new work started will continue to grow on and on.

The story of the life of Mr. Mulford, as unfolded by men who have known him since his embarkation into the field of pharmacy, is of interest. Born in Bridgeton, New Jersey, October 10, 1866, of old New England stock, H. K. (Henry Kendall) Mulford came from a family of sea captains, and his forebears played an important part in local history. He attended the Bridgeton elementary school, later the South Jersey Institute, a military prep school having a curriculum comparable with present college work.

A Fitting Background

Starting his drug career at the age of 18 in the employ of Dodge & Olcott, New York, appreciating at this early period the need for a sound basis on which to begin his life's work, he returned to Philadelphia. He secured a job (not a position) in the drug store at 18th and Market Streets, Philadelphia, operated by the later world-wide known teachers, Dr. Joseph P. Remington and Dr. L. E. Sayre. Everyone in medicine and pharmacy knows the history of Drs. Remington and Sayre, and this first employment in a retail drug store furnished a fitting background for the future that Mr. Mulford made for himself.

When Dr. Remington decided to devote his full time to the Philadelphia College of Pharmacy, and U.S.P. work, he disposed of his interest in the retail store to Dr. Sayre. Within a few months Dr. Sayre was elected as Dean of the College of Pharmacy of the University of Kansas, and he sold one-half interest to Mr. Mulford, who having previously qualified as proprietor by passing the state board, was in charge of the business.

In the interim, Mr. Mulford took the pharmacy course at the Philadelphia College of Pharmacy, and after waiting a year on account of age requirements, for his sheep-skin, at the age of 21 he became a full-fledged pharmacist, and the complete owner of this drug store.

It is significant that Mr. Mulford's predecessors were leaders in pharmacy.

In the Pharmacy (now nearly 160 years old) in which Mr. Mulford started his actual pharmaceutical experience, Henry Bowers made glycerine; Samuel Eastbrook perfected medicated lozenges; Drs. Remington and Sayre developed their background and Mr. Mulford started his work on the standardizing of drugs and later began his research in the biological field. Mr. Mulford was the first in this country to supply Diphtheria Antitoxin for use by the medical profession distributed through the pharmacist.

As an ethical pharmacist, besides making his own U.S.P. and N.F. prep-

ations, being of an originative type, Mr. Mulford began perfecting and manufacturing various pharmaceutical specialties, and in 1890 he formed the firm bearing his name, The H. K. Mulford Company, and manufactured for distribution through the wholesale and retail drug trade, a line of pharmaceuticals, featuring compressed tablets, for the manufacture of which he perfected and patented the well-known Crown Tablet machine.

Associated with Mr. Mulford at the outset of this company was Dr. E. V. Pechin, a graduate of the Philadelphia College of Pharmacy, and now retired.

His Biological Work

In 1893, Mr. Mulford began studies in the production of Diphtheria Antitoxin, and always associated with him the leaders in bacteriologic, immunological and bio-chemical research work.

The progress in biological history during the period from 1893 to the time of his death is emblematical of the foresight of Mr. Mulford. Success was largely due to his dynamic energy combined with his dominant characteristics of ethics in pharmaceutical manufacturing, perserverance, and his love of fellowman, which not only influenced the direction of his associates, but secured active cooperation of his coworkers; he believed in giving authority with responsibility.

A Leader in Colloid Therapy

Realizing the principle that life itself is the application of the colloidal equation, in 1921 Mr. Mulford directed his study to Colloid Chemistry and later established the Mulford Colloid Laboratories. His work in this field has been successful in the production of medicinal colloids (Sulphur, Manganese, Iron and Iodine, etc.) and in developing antigens for the treatment of poison ivy.

In 1926, he accepted the Directorship of Research and Biological Laboratories of The National Drug Company at 5109 Germantown Avenue, Philadelphia, and at the biological laboratories at Swiftwater, Pa., Mr. Mulford actively worked in developing biological products for the interests of humanity, and in striving to protect and save human lives.

Ethical to the nth degree, Mr. Mulford believed in the highest standards of manufacture of biological products, and in their distribution through the ethical pharmacist by selective distribution. He was a leader in biological and galenical standardization. In addition to having established the first biological laboratory in the U. S. for the production of Diphtheria Antitoxin, Mr. Mulford was one of the first advocates of the development of the standardization of biologicals and galenicals. In work, he had the active cooperation of Dr. Edgar Fahs Smith, late Dean of the University of Pennsylvania, Dr. George H. Meeker, now Dean of the Post-Graduate School of Medicine of the University of Pennsylvania, the late Dr. A. C. Abbott, Prof. of Bacteriology and Director of Hygiene, University of Pennsylvania Medical School, and his assistant, the late Dr. David H. Bergey, who succeeded Dr. Abbott as professor and director. Dr. Bergey was the first scientist of this country to test antitoxins for potency according to the Ehrlich standards. It was significant that after a 40 year friendship, Dr. Bergey became an associate with Mr. Mulford as the Director of Research in Biology for The National Drug Company, up to the time of Dr. Bergey's death.

Widely Honored

The degree of Master of Science was conferred upon Mr. Mulford by Lafayette College in 1918, and the highest honor in pharmacy, Master of Pharmacy, was conferred upon him by his Alma Mater, the Philadelphia College of Pharmacy and Science, in 1933. He was a member of the American Pharmaceutical Association, American Drug Manufacturers Association, American Pharmaceutical Manufacturers Association, American Chemical Society, the Franklin Institute and the Union League.

Mr. Mulford was active right up to the last. A week before his death, he attended the American Public Health Association meeting in New York, and the Pennsylvania State Medical Society meeting in Philadelphia.

The drug world, educators and publishers deeply mourn the death of H. K. Mulford, an inspirational leader; an indefatigable worker; a man among men; unimpeachable in character and integrity, a loving husband, father and grandfather, a man loved and beloved by all who knew him, and his friends were legion.

Our sympathy is sincerely extended to his widow, Mrs. Lillian Ware Mulford; a daughter, Mrs. H. H. Fehr; a son, H. K. Mulford, Jr. and a brother, Lewis J. Mulford of New York, who survive him.

*Jeghers, H.

The Degree and Prevalence of Vitamin A Deficiency in Adults. J. A. M. A., 109:756, Sept. 4, 1937.

Out of 162 students tested on the biophotometer for evidences of vitamin A deficiency, 50 were selected as showing the best dark adaptation, another 50 were chosen as subnormal, and nutritional, clinical, and other data were compiled for both groups. Of the entire 162, 35 per cent had low photometer readings, and 12 per cent had clinical manifestations of the deficiency.

Although the incidence of colds was about the same in both groups, the duration and severity of colds was less in the normal group than in the subnormal. About half of the latter group had definite night blindness, and 15 had dryness of the skin.

The vitamin A deficiency was treated by giving 70,000 units of vitamin A in the form of carotene orally for two weeks, followed by 25,000 units daily until dark adaptation became normal. Therapeutic results were striking, 36 cases having regained normalcy, and 9 being improved.

Estimates of the necessary minimum vitamin A intake vary from 1000 to 8700 units daily, but the author found that all persons who consumed over 4000 international units daily were normal. He suggests, however, that 50 per cent over this figure be allowed for optimal benefits. Individuals vary in capacity to absorb, store, convert, and destroy vitamin A.

Among foods yielding liberal amounts of vitamin A are milk, butter, cheese, cream, eggs, liver, spinach, carrots and most green and yellow vegetables, fish roe, prunes and kidneys. Poor choice of foods was mainly responsible for the vitamin deficiencies found.

Jeans, P. C. and Stearns, G.

The Vitamin D Requirement of the Child. Am. J. Dis. Childr., 54:189, July, 1937.

In the first year of life, retention of calcium increases with calcium intake if vitamin D is given, but not without vitamin D. When milk with 135 units of vitamin D to the quart is fed at the level of 1.8 ounces (53 c.c.) to the pound (0.45 Kg.) of body weight, most infants show more than the calculated minimum retention, but with smaller amounts of the milk, many infants show retention below this minimum. The retention with 400 unit milk is greater than with that of 135 unit milk and is above the calculated minimum for most babies at less than 1.8 ounces of milk to the pound.

In children over 1 year of age, retention of calcium increases with the intake, whether or not vitamin D is given, but the retention is greater with vitamin D. Between 1 and 6 years of age the retention without vitamin D in half of the cases is below the minimum requirement with 750 c.c. of milk, and in the majority of cases is not above it until 1000 c.c. of milk is given. With 340 units of vitamin D daily, the retention in the majority of cases is above the minimum when 750 c.c. of milk is taken, and always when 1000 c.c. is given.

Vitamin D is, therefore, necessary for many children between 1 and 6 years of age. The child over 6 requires

*This and the following abstracts are taken, by permission, from The Borden Digest for October, 1937.

vitamin D to a slightly less extent than the child under 6. With 340 units of vitamin D daily, from 750 to 1000 c.c. of milk is adequate for most subjects, but 500 c.c. is insufficient for most children even when a teaspoonful of cod liver oil is added daily.

ELLIS, L. N. AND ZMACHINSKY, A.

The Sparing Action of Lactoflavin on Vitamin B_1. Science, 86:245, Sept. 10, 1937.

Experiments with laboratory animals showed that the addition of lactoflavin to diets deficient in vitamin B_1 exerted a sparing effect upon this vitamin, since the growth and length of survival of the animals during the period of vitamin B_1 deficiency was directly dependent upon the lactoflavin content of the maternal diet. These results are in agreement with those of other investigators. The sparing action has been found so far to be specific only for vitamin B_1.

The lactoflavin used in the reported experiment was Borden's 1E grade, which is tested free of vitamin B_1 and other water-soluble vitamins. Lactoflavin is now considered to be vitamin B_2 or G.

RAFSKY, H. A.

Non-Surgical Treatment of Pyloric Obstruction Resulting from Peptic Ulcer. N. Y. St. J. M., 37:1539, Sept. 15, 1937.

A series of 26 cases was successfully treated by non-surgical means for the inflammatory type of pyloric obstruction. The methods employed consisted of a gastric lavage of warm water given every day, then every other day, and subsequently less frequently as the patient improved. For five days eight ounces of sweet milk, one-half ounce of sweet cream, and one dram of sugar were given every two hours, and one-half an ounce of olive oil, twice daily. Then two raw eggs or egg-nogs were added. On the sixth day, two ounces of cooked cereal and three eggs were allowed; on the eighth day, four ounces of cereal and two ounces of pureed vegetables; on the tenth day, four eggs; toast was permitted on the twelfth day. Some alkalis, but not in excessive amounts, were also used.

After from 3 to 10 years, twenty patients are still comparatively symptom free.

Pasteurization in England and America. Edit. Am. J. Pub. Health, 27:920, Sept., 1937.

Pasteurization of *all* market milk, says this editorial, is now generally recognized by health and medical authorities, by most of the dairy industry, and by a substantial proportion of the people of this country as an *essential* public health measure. Today, about 88 per cent of the milk supplies in all cities over 10,000 population in this country is pasteurized, although the amount varies in different parts of the country, and the average is brought up by the many larger cities where nearly 100 per cent pasteurization has been attained. In our communities in the 1000 to 10,000 population group, on the other hand, only about 39 per cent of the milk is now pasteurized. These figures indicate that market milk in our large cities is much safer than in the rural sections of the country.

This editorial also expresses the opinion that more certified milk should be pasteurized.

In England, pasteurization has not received as wide recognition as in the United States, although the British public health and medical professions are strongly advocating this desirable process, which they believe should precede much-needed attempts to increase milk consumption in Great Britain. Recent investigations have shown that pasteurization does not appreciably affect the excellent nutritive properties of milk.

"Raw milk, whether in England or America," concludes this editorial, "should no longer be permitted to impede public health progress."

HOY, W. A. AND NEAVE, F. K.

The Phosphatase Test for Efficient Pasteurization. Lancet, 233:595, Sept. 4, 1937.

Since 1935 the phosphatase test has been used to detect the efficiency of pasteurization, the efficacy of the test depending upon the fact that the tuberculosis bacillus is destroyed more quickly than the phosphatase when milk is heated.

The test is valuable in indicating faulty operation of or defects in pasteurizing machinery, and it can also be applied in the case of the high-temperature short-time method of pasteurization.

The survey reported showed that the efficiency of pasteurization in London had been greatly improved during the past two years, especially in the larger firms having their own control laboratories. The test is particularly useful in advisory work in tracking down faults in the functioning of pasteurization.

GRAHAM, S. AND MORRIS, N.

Effect of Boiling on Nutritive Value of Milk. Arch. Dis. in Childr., 12:169, June, 1937.

Metabolism tests on two boys, aged 10½ and 7½, showed that when 50 per cent of the caloric value of the diet and 70 per cent of the protein were supplied by milk, there were no significant differences in the retentions of calcium, phosphorus, and nitrogen when raw milk and boiled milk were given. The results indicate that there is no evidence that over short periods the boiling of milk impairs either its absorption or utilization, when there is an ample supply of proximate principles and minerals, and the caloric intake is adequate.

KOBER, L. R.

Undulant Fever Therapy: Excellent Results From Typhoid Vaccine Intravenously. S. W. Med., 21:817, Sept., 1937.

Successful treatment of 7 cases of undulant fever with foreign protein shock therapy, in this instance typhoid vaccine administered intravenously, is reported by the author. This method was used for strong and healthy patients, but in those who are seriously debilitated or suffering from complications, less severe reactions are obtained with intramuscular or subcutaneous injections of melitensis vaccine.

MCLESTER, J. S.

Nutrition Problems in Education. J. A. M. A., 109:838, Sept. 11, 1937.

Since good nutrition is a prerequisite to health, and the healthy child can make the best use of the education offered him, every effort must be made to see that all school children are properly nourished.

Nutritional failure is seldom simple or complete, but is generally multiple, incomplete, and correspondingly complex. The vague borderline case of nutritive failure of mild degree is the most interesting, and such cases are the most frequent. The prime duty of the school physician is to recognize disorders of this type and to correct them.

The school must endeavor not only to correct these defects, but to enhance the development of the normal child by having him reach optimum instead of merely adequate nutrition. To do this requires education of the pupil, the parent, and the teacher. The greatest energy should be expended not on individual, selected children, but upon the student body as a whole.

Emphasizing the essential nature of any one food factor or group of factors is dangerous, except in the case of milk. "Because of its importance to the child," declares the author, "I think it proper to emphasize time and again the great value of milk.

The nutrition class is of great educational value, not only because of its help to the undernourished pupil, but for its influence on the dietary habits of all students. The example set by the lunch room is likewise of great help to teachers who are giving broad instruction in nutrition.

COWELL, S. J.

The Physiological Bases of Nutrition. Brit. M. J., p. 406, Aug. 28, 1937.

The British Medical Association has

a Section of Nutrition. Its scope, said the author in an address at the last annual meeting, should be wide enough to cover a large part of the field of medicine, and indeed it is already capable of so doing.

In discussing the practical aspects of nutrition, it is pointed out that milk-feeding tests on children have demonstrated that the mean rate of growth can be accelerated with this valuable food. Dental caries can also be prevented by dietary means, and infections reduced by proper nutrition.

Optimal nutrition can be secured by increasing the intake of such protective elements as safe milk and other dairy products, all kinds of vegetables, especially green vegetables, eggs, fat fish and liver. Such protective foods are essential for pregnant and lactating mothers and for growing children, all of whom must have a liberal allowance of milk.

COKE, E. C.

Plans of the Chilean Government for Improving the Nutrition of the People. U. S. Pub. Health Reps., 52:1150, Aug. 20, 1937.

In outlining the problem of nutrition in Chile, and the Government's plans for its improvement, the Minister of Health states in this article that the most serious and immediate problem is that of overcoming a gradual decrease in milk production, already below the minimum needed. Milk, he says, is the principal material for the building of a race, irreplaceable in nearly all cases by any other food, and the most important of the protective foods.

Milk has, furthermore, "an inhibitory action on precocious sexual development," according to studies of the author and his co-workers.

The Government is stimulating milk production and consumption by purchasing milk for school lunches, and by lending capital at low interest to the dairy industry.

GODBOLE, N. N.

Milk. The Most Perfect Food. Chemical Publishing Co. of N. Y., Inc., p. 138, $2.50, 1936.

The professor of industrial chemistry of Benares Hindu University in India has prepared this text in English for the purpose of disseminating correct knowledge of milk as "the most perfect food." As a factor in promoting necessary consumption of milk and dairy products in India, this creditable treatise should serve a useful purpose, and it should also be of interest to those in this country who are directly concerned with the production and distribution of milk, generally known in the United States as "our most nearly perfect food."

The book begins with some interesting references to milk from ancient Vedic and Ayurvedic literature; then presents statistics on milk imports, production, and use in India and elsewhere; discusses the composition and nutritive properties of milk and dairy products, and their influence on health; presents arguments in favor of a vegetarian diet; discusses tea, coffee, cocoa, tobacco and alcoholic drinks; and concludes with some comments on the medicinal properties of milk, and on breeding and feeding.

There is a vigorous foreword by Pandit Madan Mohan Malaviya, an extensive table of food analyses, and a good index. The book is an interesting contribution to the international literature on milk.

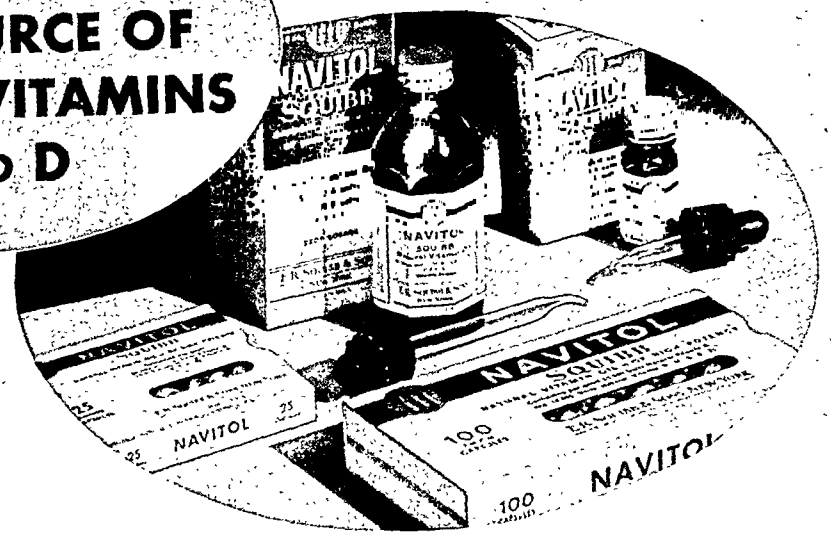
MEANS, J. H., HERTZ, S. AND LERMAN, J.

Nutritional Factors in Graves Disease. Ann. Int. Med., XI, 429, Sept., 1937.

The thesis of this presentation is that malnutrition may cause or at least precipitate thyrotoxicosis. The material that forms the basis of their observations came from the Thyroid Clinic of the Massachusetts General Hospital and covered a total of 35 cases. Fourteen of these presented a thyrotoxic loss of weight following in the course of attempts at reduction in overweight cases. The remainder of the series presented malnutrition as the result of a variety of conditions other than deliberate efforts at reduction of obesity. In presenting their thought on malnutrition the authors have endeavored to distinguish between what they call general malnutrition, the result of a total negative unit balance, and specific types of malnutrition.

Myasthenia is listed as a common manifestation in Graves Disease. Among other manifestations of general muscle weakness they offer the rather interesting thought that exophthalmus may be merely a local expression of a general muscle weakness. The degenerative changes in the striated recti muscles contrasted with the normal appearance of the smooth muscle of the eye is offered as a suggestion that a muscle imbalance obtains which results in exophthalmus. Decalcification of the bones is listed also as a specific form of malnutrition. They suggest that while thyroid secretion causes a definite increase in the rate of removal of calcium and phosphorus from the bones, it differs definitely from the influence of the parathyroid hormone in that there is no significant increase in the blood calcium and blood phosphorus in the latter condition. They believe that the marked withdrawal of these chemicals is a specific influence of hyperthyroidism and not the result of an accelerated metabolism. They observed in a few cases of long standing thyrotoxicosis a rather marked osteoporosis of both the spinal vertebrae and of the long bones and call attention to one case particularly in which there was found a compression fracture of a lumbar vertebra the result of osteoporosis. This patient recovered symptomatically, though without much evidence of recalcification from an X-ray standpoint, on a high calcium diet and Viosterol. They found a subnormal hemoglobin value in a rather large per cent of their cases. These patients presented the tongue and low hydrochloric acid content, with the characteristic male changes of a hypochromic anemia. A satisfactory restoration of the blood iron was obtained under a regime of iodine and iron. Whether there is avitaminosis in these cases of Graves disease is discussed. They noted an improvement in appetite and a gain in weight in some of their cases of thyrotoxicosis when fed Vitamin B but no change was noted in the basal metabolic rate. The role of Vitamin B in thyrotoxicosis is suggested, but an evaluation of its real influence was fogged by the simultaneous administration of iodine. They urged that in the preparation of a thyrotoxic patient for operation that saturation with iodine is not sufficient, but that the general nutrition should be improved with reference to specific deficiencies.

In their conclusions they warn against a too vigorous reduction of the gland in obese patients and suggest that thyrotoxicosis may be induced thereby. They believe that a high protein diet is undesirable in the preparation of the thyrotoxic patient for operation on the ground that the specific action of protein is to increase metabolism. They prefer to rely more exclusively upon carbohydrates. Their attitude toward fat content of the diet is a neutral one. While recognizing that unnecessary delay in the thyrotoxic patient in securing operative relief should be avoided, yet they hold that there is a tendency of the surgeon to operate before the evidences of malnutrition, as well as the cardiac insufficiently, have been adequately cared for.



Virgil E. Simpson, Louisville.

ALVAREZ, W. C.

New Light On Intestinal Peristalsis in Health and Disease. Proc. Staff Meetings Mayo Clinic, 12:657-660, Oct. 20, 1937.

The author reports on some work which has been in progress over a period of several years. He concludes that there are two separate systems of nerves regulating the small bowel activity, one consisting of long nerves uninterrupted by synapses, very resistant to anoxemia and nicotine, and believed to mediate the impulses that are

most economical
AS A SOURCE OF NATURAL VITAMINS A AND D

IN NAVITOL, the physician has available a product with a Vitamin A content slightly higher than halibut liver oil with viosterol and the same high Vitamin D potency—yet costing less than half as much. The advantage of economy without sacrifice of quality or efficacy is particularly important in a Vitamin A and D dietary supplement that is taken routinely. Navitol is a blend of specially selected, highly refined fish liver oils supplying, per gram, 55,000 units of natural Vitamin A and 10,000 units of natural Vitamin D (U. S. P. XI). Ten drops (or one 3-minim capsule) supply 9400 units of Vitamin A and 1700 units of Vitamin D (U. S. P. XI). Navitol is available in 5-cc. and 50-cc. dropper bottles and in boxes of 25, 100, and 250 soluble gelatin capsules.

NAVITOL MALT COMPOUND

An economical dietary supplement which presents in a palatable syrup an abundance of Vitamins A, B, D, and G in natural form; also calcium, phosphorus and liver extract in therapeutically beneficial quantities. Distributed in 1-lb. and 2-lb. wide-mouth jars.

For literature address Professional Service Department, 745 Fifth Avenue, New York

E·R·SQUIBB & SONS, NEW YORK
MANUFACTURING CHEMISTS TO THE MEDICAL PROFESSION SINCE 1858.

NAVITOL SQUIBB NATURAL VITAMIN OIL

responsible for so-called systolic contraction of the small bowel, the other a system of short nerves interrupted by synapses, sensitive to nicotine and anoxemia, and believed to preside over the coordinated peristaltic rushes. He feels that during life and health the synaptic nervous system of the bowel and the extrinsic nerves are constantly supplying the muscle with some sedative which keeps the fibers from responding strongly to every stimulus that arrives by way of the long unbroken nerves.

A possible explanation for gas pains and failures of peristalsis in persons subjected to adverse influences is offered on the basis of loss of the normal quieting nervous mechanism thus leaving the bowel at the mercy of the stream of stimuli arriving by way of the hardy long tracts. At present there is no known specific remedy for such conditions.

LINDSAY, J. W., RICE, E. CLARENCE, SELINGER, MAURICE A. AND MISH, K. HAMMOND.

Protamine Insulin as a Contributing Factor in the Death of a Diabetic Patient with Cerebral Arteriosclerosis. Ann. Int. Med., Vol. 10, June, 1937.

The authors present a case of fatality of a diabetic patient treated with protamine insulin.

Here the difficulties in the control of the patient's diabetes were reduced, however reactions attributed to insulin hypoglycemia were accentuated, with death resulting from a severe hypoglycemia from the cumulated effects of the insulin.

The patient, an unmarried white female, developed diabetes mellitus in 1931 at the age of 44. Up to August, 1933, when she came under observation, she had lost 71 pounds.

Treatment with varying doses of ordinary insulin and varying diets during and after hospitalization never satisfactorily controlled the diabetes. Occasional insulin reactions were experienced with an attack of coma in October, 1934.

Protamine insulin was started on April 1, 1936, with immediate improvement. Because of economic circumstances the patient was unable to maintain proper contact with the clinic.

On September 3, 1936, she was found unconscious in bed and removed to the hospital with a tentative diagnosis of coma due to hypoglycemia. She remained comatose and died eight days later. At necropsy most striking changes were found in the brain, exhibiting marked arteriosclerosis.

The history obtained from the patient's relatives and friends indicates she probably experienced the effects of a low blood sugar on a number of occasions over a period of 2 months preceding death.

Because of the possible dangers incident to the use of any insulin preparation with prolonged action and cumulative effects, the authors feel that their use should be restricted to those who can be kept under constant control.

The medical treatment with accompanying tables of diet and insulin before and during hospitalization is discussed.

NICHOLS, BERNARD H.

Roentgenology as an Aid to the Diagnosis of Lesions in the Upper Right Abdomen. Jour. Ind. State Med. Assoc., 30:565-567, Nov., 1937.

In cases where there is uncertainty as to the exact type and location of lesions in the upper right abdominal quadrant the radiologist should be approached as a consultant and he should determine the type and method of examinations necessary to obtain the most satisfactory explanation of the patient's symptoms. Too often the radiological examination is useless because some specific procedure was ordered which was entirely inadequate to establish the correct diagnosis.

The frequency of need for exploratory operations has lessened with advance in radiology.

A 14 x 17 film of the abdomen permits examination of the spine, pelvis and abdominal organs which includes the kidneys, ureters, bladder, liver and spleen. This examination should be carried out before any opaque media is introduced into the circulation or abdominal organs.

Lesions of the spine include, arthritis, postural defect, neoplasm of the bony spine or spinal cord, fracture, dislocation, or ruptured nucleus pulposus. Calcific deposits in the abdomen may be due to kidney stones, ureteral stones, calcified tumor or cyst, calcified gall bladder, gall stones, mesenteric glands, or calcific deposits in the outline of the kidney pelves and calices due usually to old tuberculosis of the kidney. The location of suspicious calsific deposits should be determined immediately. Abnormalities of the kidney as regards size, shape, position and presence of tumors can be determined.

If the foregoing examination reveals no abnormalities then a plain film of the gall bladder region should be made and cholecystographic dye administered to determine the function and presence or absence of non-opaque stones. If the gall bladder is not visualized the dye should be repeated the following night. The administration of barium should then follow with complete study of the stomach and duodenum by fluoroscopy and such films as are necessary and a 24 hour observation to determine the intestinal motility. This is followed by a barium enema and then by air enema if a suspicious lesion is present.

One should not overlook the possibility of gastric crises, angina, or pancreatic disease in cases of upper abdominal lesions. Of course, the radiological examination would not help here.

The author closes with the plea that the roentgenologist be considered a consultant just as any other consultant in medicine and that many satisfactory results will be obtained thereby.

ROSENAK, BERNARD D.

Inflammatory Diseases of the Small Intestines (So-Called Regional Ileitis). Jour. Ind. State Med. Assoc., 30:568-572, Nov., 1937.

The earliest cases reported of regional ileitis described the condition affecting the terminal portion of the ileum. Subsequent reports have described the lesions occurring in separate parts of the ileum, the jejunum, the cecum and even the duodenum in a recent case. The pathology of the lesions is that of a non-specific inflammation, involving all layers of the intestinal wall and characterized by early infiltration of the fibroblasts, thus leading to thickening, induration, and stenosis with marked mucosal destruction.

The etiology of the disease is unknown. There is no evidence to substantiate a possible causal relationship to appendicitis or tuberculosis. Bacillary dysentery and long standing functional disorders have been mentioned as possible causative factors but further study is needed for confirmation of such views.

Clinically, the disease is found in young adults in more than half the cases. The outstanding symptom is abdominal pain, usually of a distinctly colicky nature and tending to be present intermittently over long periods of time. Fever is usually present, the type and degree depending upon the condition of the lesion. In the average case it varies between 101 and 103 and is usually constant. Some change in the bowel habits is usually seen and diarrhea is almost the rule. The stools usually number 3 to 6 per day, are semisolid or mushy, and do not contain much mucus or gross pus or blood. Constipation may ensue with the development of the obstructive stage of the disease. Nausea and vomiting are seen occasionally in early cases and more often in later stenotic phases of the disease. Leukocytosis is never extreme in uncomplicated cases, and there is usually a microcytic anemia. Generally the patients present weakness, emaciation, and weight loss in proportion to the duration and severity of the

"The day will come... when all milk will be packed in cans"

Whether or not this prophecy will come true remains to be seen. It is, however, interesting to note that it has been made time and again by prominent physicians.

The basis for the prediction is not, of course, the relative merits of containers—but rather the comparative values of two forms of milk, evaporated milk and ordinary "fresh" milk.

Since milk is an important part of the dietary employed in the treatment of digestive diseases, and the qualities of one particular form of milk are of such superior nature that its universal use has been forecast, it may be interesting to examine those qualities.

Made of whole cow's milk, concentrated to double strength, Pet Milk, the original evaporated milk, furnishes all the food substances milk can be relied upon to supply. Sterilized in the sealed container, it is completely and surely free from bacterial life, more readily digestible, and especially suited to the individual who has been sensitized to milk. Irradiated by ultra-violet rays, it is a good source of vitamin D. Distributed in a highly economical manner, it is, by virtue of this economy, less expensive than other forms of milk.

When prescribing milk, specify Irradiated Pet Milk.

Samples and literature will be sent on request.

(Attach prescription form or letterhead to confirm. Offer limited to physicians of Continental U. S.)

disease, and are usually apathetic and mentally depressed. The posture and gait may suggest peritoneal irritation. In such cases the suspicion of a small bowel lesion should be readily confirmed by finding a tender mass in the right lower quadrant, but its absence does not entirely exclude ileitis as a possibility in cases presenting such a clinical picture.

The diagnosis is made on the basis of the clinical picture and X-ray findings, using first the barium enema and then the barium meal with frequent observations and films during the eight hours following the meal.

The differential diagnosis is concerned mainly with tuberculosis, Hodgkin's disease and lymphosarcoma, carcinoma, right sided colitis and amebic colitis.

As regards treatment, extensive resection of the involved areas seems to offer the best hope of a lasting cure. Other therapeutic measures that have been advocated are side-tracking operations, and medical treatment with nonroughage diet and anti-spasmodics.

The paper is discussed by Dr. William R. Tindall of Shelbyville.

MULHOLLAND, H. B.

Intravenous Liver Extract in the Therapy of Pernicious Anemia. Report of a case. Ann. Int. Med., 11:671-674, Oct., 1937.

A case of pernicious anemia is reported which failed to respond to the administration of oral liver, intramuscular extract, ventriculin, and blood transfusions, but with intravenous liver extract responded with a prompt and complete remission.

The report covers the period from Nov. 19, 1934, up to the time of writing. During this time there were two exacerbations of the condition. The first was marked by a hemoglobin of 22%, red count of 1,900,000 and white count of 3,000. The patient at this time responded satisfactorily to the use of oral and intramuscular liver extract. About one year later he had gradually lost ground until the hemoglobin was 35%, the red count 1,740,000 and the white count 2,800. He was given liver by mouth, iron and ammonium citrate, intramuscular liver extract, ventriculin and blood transfusions over a period of some 50 days, all to no avail. He was then given 20 c.c. of liver extract intravenously which was followed by a chill and a temperature of 101° F. Improvement was seen at once, and with each succeeding intravenous injection (five in all) the reactions decreased in severity to slight flushing of the face and a little shortness of breath. The blood picture returned to normal and the patient is being maintained at home in a good state of health with a normal blood picture by the intramuscular injection of 2 c.c. of liver extract once a week.

The author was unable to find in the literature mention of a similar case of pernicious anemia. He says that one can only speculate as regards the reason for this patient's failure to respond to the ordinary therapeutic measures. He refers to Minot's statement as to the need of adequate quantitative treatment in pernicious anemia and says that that is the possible explanation of the behavior of this particular case.

Hanes M. Fowler, Fort Wayne.

DILLON, EDWARD S. AND DYER, WALLACE W.

Factors Influencing the Prognosis in Diabetic Coma. Ann. Int. Med., 11:602-617, Oct., 1937.

This report is based on the records of 268 cases of diabetic acidosis admitted to the Philadelphia General Hospital during the years 1931 to 1936. Of the 268 cases, 117 died, a mortality of 43.7%.

The cases are classified according to the presence or absence of complicating diseases, and also according to the severity of such complications.

They grouped the cases according to the outcome and correlated these findings with the data obtained upon the patient's admittance to the hospital in an effort to determine what inference regarding prognosis could be drawn from the information obtained within an hour or so after admittance.

The presence of complications is an important factor in determining the prognosis as evidenced by the fact that of 139 cases with complications 85 died, a mortality of 61.2% for that group.

The mortality for all cases in which the blood sugar was above 700 mg. per 100 c.c. was 57.7%, whereas for the cases in which it was 400 or lower it was 29.1%. In the group of uncomplicated cases the average blood sugar for those recovering was 487 and for those who died it was 713. So when the blood sugar is very high a higher mortality is anticipated.

The mortality rate increases with the degree of chemical acidosis as measured by the carbon dioxide combining power of blood. This fact is more clearly evident in the uncomplicated cases.

As the blood urea nitrogen increases above 20 mg. per cent the mortality increases rapidly. In the total series the mortality for cases with 20 mg. and below was 22.1%, whereas for those with more than 20 mg. the mortality was 62.4%. The average blood urea nitrogen for the uncomplicated cases that recovered was 20.5 mg. per cent and for those that died was 44.7 mg. per cent.

There is no correlation between the degree of leukocytosis and mortality. In 191 cases in which a white count was made upon admission it was above 10,000 in all but 16 cases. It usually drops rapidly as treatment progresses.

The total mortality for patients up to 30 years was 16.4 per cent while for those over 50 years it was 74.7 per cent. The average age of those without complications that recovered was 27.1 years and for those that died it was 41.8 years.

As regards sex, the total mortality was 29.6 per cent for the males and 49.7 per cent for the females.

The importance of the mental state as regards prognosis is very great. The total mortality for those patients who were conscious upon admittance was 28.0 per cent and for the unconscious it was 81.0 per cent. In the uncomplicated cases 5.4 per cent of the conscious cases died, whereas 73.0 per cent of the unconscious died.

The length of time the patient has been in acidosis is an important consideration, as the expected mortality increases rapidly with the duration of the acidosis.

The authors conclude that the clinical data are much more important in rendering an accurate prognosis than are the laboratory findings. It is more important to know the complications present, the mental state, the age of the patients, and the duration of the acidosis, than it is to know the blood sugar, the carbon dioxide combining power and the urea nitrogen. The latter factors are indispensable, however, in properly gauging doses of insulin and glucose in treating the patients.

GAGE, MIMS.

"The Surgical Treatment of Peptic Ulceration." South. Surg., 6:392-404, Oct., 1937.

In a thoughtful presentation, with an excellent list of references, the author gives an interesting approach to the determination of cases suitable for operation and surgical procedures indicated. The etiological factors most resistant to medical or surgical relief are "tissue susceptibility" and "constitutional predisposition." On the other hand, "hypersecretion and hyperacidity," "focal infection," and "gastric trauma" present factors that can be controlled. Most ulcers will heal if these controllable factors are managed by a rigid medical regimen which includes complete abstinence from tobacco, alcohol, condiments and highly seasoned foods, strict adherence to a bland diet with two-hour feedings, and thorough elimination of foci of infection, especially infected teeth. Chemical alkalies are of insignificant importance as compared with physiological neutralization accomplished by frequent food ingestion and regurgitation of alkaline duodenal secretions. Relief of

This important story comes down fundamentally to this:

A New, Brilliantly Effective Agent for the Treatment of Gastrointestinal Dysfunction

THE delicate functional balance characterizing the coordination between the various organs of the gastrointestinal tract, has this diagnostic and therapeutic significance:

(1) It explains why so many physicians insist that the multiplicity of common complaints—from "indigestion" to chronic constipation—reflect a much broader functional disturbance than the superficial symptoms themselves might indicate.

(2) It justifies their long search for an adequately comprehensive therapeutic agent—which affords a sound physiologic approach to the correction of the multiple underlying causes.

That is why such unusual professional welcome has been accorded the new ethical product, Tri-Costivin.

* * *

In Tri-Costivin, for the first time, full regard is given to the requirements for *good digestion*—through the inclusion of high potencies of vitamins B_1 and $B_2(G)$† for the promotion of appetite, increase of hydrochloric acid secretion, and improvement of stomach tonicity. Bile extract is supplied to increase the contractile action of the gall-bladder, and duodenum gland extract (hormone cholecystokinin) to stimulate duodenal and gall-bladder function. The inclusion of gall-bladder tissue extract (hormone cholezysmon) serves to intensify the action of the pancreatic enzymes and to promote fat digestion.

Good assimilation usually follows on proper digestion — if the intestinal mucosa is in healthy condition. The vital dependence of intestinal health on a normal acid-base equilibrium has led to the incorporation in Tri-Costivin of lacto-banana powder, and Trilactic* (trade mark) with calcium lactate . . . effective agents for the re-establishment of the friendly aciduric type of flora. Absorption of fats is promoted also by the gall-bladder extract, bile salt, and vitamin B_1 and $B_2(G)$ content.

For *good elimination*, a healthy tonus of the intestinal musculature is indispensable. Here, Trilactic, lacto-banana powder, and vitamins B_1 and $B_2(G)$ add a positive stimulus to peristaltic vigor. Agar karaya gum is included also to provide soft gelatinous bulk to the stool.

* * *

Tri-Costivin contains no cathartics or laxatives to cause irritation of the intestinal mucosa. Its striking success as a therapeutic weapon lies solely in the brilliant rationale of its physiologic approach to the underlying causes of dysfunction of the digestive tract as a whole.

Details of the research which culminated in the pharmaceutical triumph represented by the production of Tri-Costivin — and protocols of clinical investigation on this important new product — have been reprinted in the book, "The New Physiologic Approach."

Write for it, and for samples of Tri-Costivin. They are available to the physician on request.

---

†Each daily dose contains not less than 650 Sherman Chase units (325 International) of Vitamin B_1, and not less than 125 Sherman Borquin units of Vitamin $B_2(G)$.

*Trilactic is a significantly new, stable, condensation product of lactic acid in tri-molecular form, capable of producing complete inhibition of B. coli, Bargen diplococcus, streptococcus viridans, and B. welchii.

The efficacy of TRI-COSTIVIN

(Trade Mark Reg. U. S. Pat. Off.)

is due to the fact that it supplies in scientific balance the eight essential factors indicated for the treatment of gastrointestinal dysfunction . . . as evidenced by impaired digestion or assimilation, by autointoxication or chronic constipation.

Tri-Costivin is advertised only to the profession, and is distributed through a selected list of ethical pharmacies—in plain containers of 266 gms. with slip label which the pharmacist is instructed to replace with a prescription label. Dosage: 2-4 tsp. twice daily with meals, followed by water.

PROFESSIONAL LABORATORIES, Inc.
155 East 44th Street, New York, N. Y.

pylorospasm by the use of belladonna is to be recommended. Injection treatments are useful only in proportion to the psychic effect obtained and the ulcer regimen followed.

Surgical treatment is reserved for the complications which are, in order of importance, perforation, hemorrhage, stenosis, and penetration. Duodenal ulcers are best treated by pyloroplasties (Finney, Horsley, or Judd type) or gastro-duodenostomies (Hoffman or Rienhoff type). These procedures are physiological in that the acid gastric chyme is received by the duodenal mucosa which is resistant to its digestive action rather than the jejunal mucosa which is prone to ulceration. Gastro-jejunostomy is, however, safe and indicated where a chronic cicatrizing ulcer has resulted in gastric retention, gastritis, and hypoacidity. Entero-enterostomy should never be done in conjunction with gastrojejunostomy, or gastric resection either, since it establishes duodenal drainage with the strong probability of ulcer formation.

The surgical treatment of gastric ulcers is demanded by the same indications as in duodenal ulcers plus the ever-present possibility of malignant change. This must be suspected in all ulcers which do not show demonstrable roentgenological evidence of healing under medical regimen. Surgical procedures should accomplish removal of the tissue susceptible area and restoration of the gastro-intestinal opening so that there will be constant reflux of alkaline duodenal juices into the stomach. Gastrojejunostomy, though commonly used, is less effective than a partial gastrectomy. While the Billroth I or Schoemaker's modification are more physiological the Polya modification of Billroth II is the most popular and is very satisfactory technically and therapeutically.

Jejunal ulcer demands surgical treatment which consists of subtotal gastrectomy, resection of the involved segment of jejunum with end-to-end anastamosis and a gastrojejunostomy.

After any surgical treatment the patient should be made to understand that he has an "ulcer diathesis" with no guarantee against recurrence or severe hemorrhage if he neglects controlling the controllable factors.

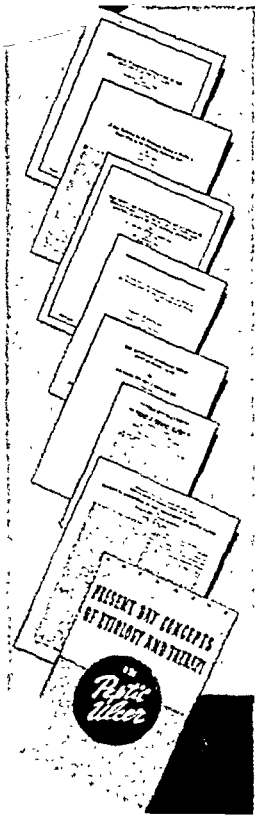
ROUSE, MILFORD O. AND PATTERSON, CECIL O.

"The Clinical Significance of a Mobile Colon." South. Med. Jour., 30:963-968, Oct., 1937.

The usual symptoms of a mobile colon are recurring pain in the lower abdomen, usually on the right side, and obstinate constipation. The actual attack may be confused with acute appendicitis but can be differentiated in a number of ways. There is usually a history of pain and constipation dating back to childhood, attacks of pain most likely occur after several days elapse without a bowel movement or when an unusually large bulk of food has been ingested 6 to 24 hours previously, and relief has been obtained in such attacks by the emptying of the large bowel by purgation, enema, or abdominal massage. As a rule there is no initial epigastric pain, usually no nausea, vomiting, or fever, the white count is not increased, there is no marked tenderness or rigidity at McBurney's point, and the distended cecum and ascending colon may be palpated. If doubt still exists after a cleansing enema exploration should be done rather than risk the danger of overlooking an acute appendicitis. If relief is obtained by the enema X-ray studies can be made later and subsequent treatment determined. If exploration reveals a harmless appendix surgical correction of the anomalous mobile cecum should be done if the case is an extreme one or has resisted adequate medical care. This care consists of increasing the body weight, bed rest in selected cases, abdominal exercises, the wearing of a comfortable abdominal support, tonic physiotherapy and psychotherapy.

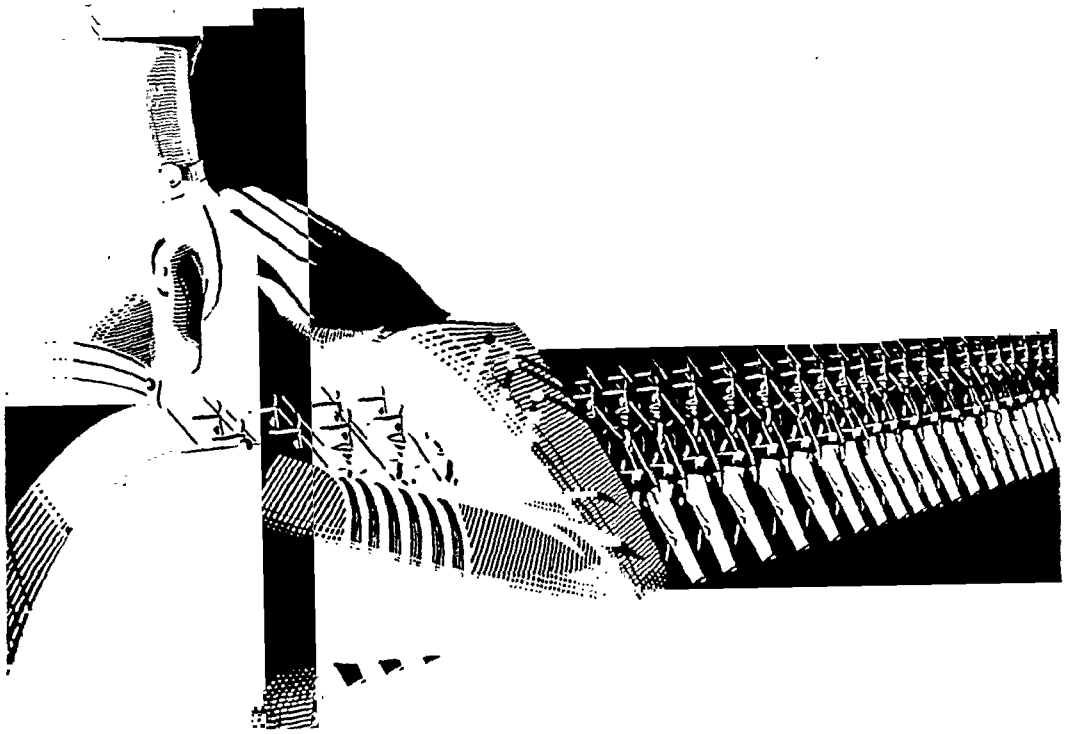
Obstipation, frequent abdominal pain

FIRMLY ESTABLISHED ON A SOUND, SCIENTIFIC BASIS



Creamalin

HAS REVOLUTIONIZED PEPTIC ULCER THERAPY



The broad scientific background of Creamalin, based upon published articles, attests the therapeutic efficacy of this unique colloidal cream of aluminum hydroxide. These investigations concur in one important point: that Creamalin induces healing in peptic ulcer with greater rapidity than any other agent heretofore used.

Creamalin neutralizes 12 times its volume of N/10 HCl in less than 30 minutes. It does not produce secondary rise in HCl secretion, and cannot lead to alkalosis or plasma pH changes. In consequence, it overcomes peptic ulcer pain and discomfort immediately, and produces radiographically visible healing in 3 to 5 weeks when taken orally, and in 7 to 10 days when given by the Creamalin Automatic Drip Control, a device especially designed for continuous drip administration.

Reprints of published articles, and a copy of the brochure "Present Day Concepts of Etiology and Therapy in Peptic Ulcer" sent to physicians on request.

BERNHEIM, A. R. AND LONDON, I. M.

Arteriosclerosis and Thromboangiitis Obliterans. J. A. M. A., 108:2102, June 19, 1937.

The authors report successful treatment of a large number of patients with peripheral vascular disease by means of a diet high in calcium and vitamins, elimination of the use of tobacco, employment of sodium citrate in severe cases, and proper care of the extremities. On this regime 83.8 per cent of 99 cases of arteriosclerosis, and 79.6 per cent of 54 cases of thromboangiitis obliterans showed improvement.

The high-calcium, high-vitamin diet was given because of its favorable influence on vasospasm, but it was also used when the vasospastic element apparently was absent. The chief sources of calcium were milk and cheese, but occasionally calcium salts were employed. Concentrates of vitamins A (19,000 units) and D (1900 units) were added daily, vitamin B was given in the form of wheat germ or yeast, and vitamin C was supplied in orange juice or tomato juice. Lactose was added to the diet of patients suffering from constipation (except diabetics), from 2 to 6 heaping tablespoons a day being effective in the majority of cases.

Sodium citrate was used in severe cases, either by vein or by mouth, in order to reduce the viscosity of the blood. The high calcium diet prevents depletion of the body through sodium citrate, and not only has an anti-vasospastic influence, but produces a beneficial effect on general health. It does not adversely affect the viscosity of the blood, nor does it lead to increased arteriosclerosis.

Other measures, including complete withdrawal of the use of tobacco, freedom from worry, reduction of physical exertion, and thorough care of the extremities are described in detail, and a number of case reports are presented.

THEOBALD, G. W.

Effect of Calcium and Vitamins A and D on Incidence of Pregnancy Toxaemia. Lancet, 232:1397, June 12, 1937.

Fifty pregnant women who were requested to take daily throughout pregnancy 20 grains of calcium lactate, 11,000 units of vitamin A, and 450 units of vitamin D were compared with 50 women whose diet was not supplemented in this manner. All were apparently healthy at the beginning of the experiment. About half of the women in each group were primigravidae, or pregnant for the first time.

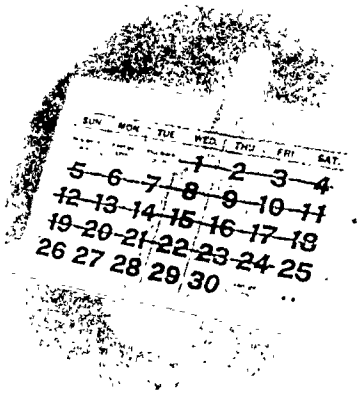
In only 13 cases of the 50 women on the high-calcium, high-vitamin diet were toxic symptoms found, whereas 28 of the 50 untreated women showed albuminuria, hypertension, or both. Other symptoms, such as hyperemesis, oedema, headaches, cramps, and insomnia occurred in 21 of the untreated cases, but in only 10 of those receiving calcium and vitamins.

The author believes that the improvement noted was due to the nature of the diet, and that all pregnant women should have these protective substances.

GUNDERSON, F. L.

Nutritional Economics of Dietary Calcium. Am. J. Pub. Health, 27:570, June, 1937.

The daily human need for calcium is widely recognized as ranging from 1.4 to 0.68 grams, or an average of 1.0 gram plus or minus 0.4 gram (expressed as elemental Ca), depending on the age and the needs for growth, pregnancy, or lactation.

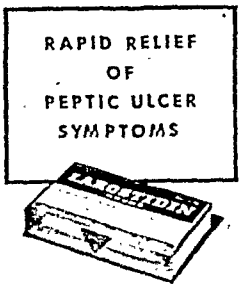


Evaporated milk and American cheese are the cheapest food sources of

SHORTEN

THE

PEPTIC ULCER



REGIME

LAROSTIDIN may be depended upon to hasten a favorable clinical response in the medical treatment of peptic ulcer. Its use as an adjuvant allows wider latitude in diet, and the patient may remain ambulatory in most instances. The vicious circle of despondency, anorexia, gastric discomfort, and malnutrition, is interrupted, so that it is not unusual to see these patients make appreciable gains in weight and nutrition.

The usual course of Larostidin therapy consists of 21 consecutive daily injections. Stubborn cases, such as those with a long history of distress and frequent exacerbation, may require additional injections.

Larostidin is the Roche sterile standardized solution of l-histidine monohydrochloride (4%), specially adjusted for intramuscular injection. Ampuls 5 cc., cartons of 6.

calcium, since one gram from these products costs only 6.4 cents. Close behind are whole milk at 9.4 cents a gram, and powdered milk at 10.3 cents a gram. A similar amount of this mineral obtained from vegetables or fruits will cost from two to 25 times as much as milk, as shown in a table compiled by the author.

The calcium of milk and dairy products is highly regarded for its biological availability, and these foods also furnish liberal quantities of other important nutrients, such as protein, fat, and vitamins.

Calcium pharmaceuticals cost the consumer from about one to 18 cents per gram of calcium (of lower biological value than that of milk. Ed.). The author suggests that various inexpensive carbohydrate foods might be fortified with calcium salts, a procedure which, with increased milk consumption, would provide more adequate calcium for American diets.

VAUGHAN, W. T. AND PIPES, D. M.

Is There a Correlation Between Food Dislikes and Food Allergy? J. Allergy, 8:257, March, 1937.

Dislike of foods is not correlated with allergy to those foods, according to the authors, who investigated 500 patients by means of questionnaires and followed up 19 allergic cases with skin tests. In only about 20 per cent of the 500 patients with food dislikes was there a correspondence between the dislike and the foods causing the allergic symptoms, while in the 19 tested, there were only 7 instances in which a dislike was accompanied by a positive skin reaction to the food.

In a previous series of 100 cases, it was reported that 46 showed evidence of food allergy, while 66 expressed food dislikes. The 7 foods most frequently disliked were in their order of frequency: spinach, turnips, cabbage, carrot, okra, lamb, and squash. The foods in the same series most frequently found responsible for allergic symptoms were, in order: cucumber, watermelon, raspberry, strawberry, tomato, onion, cabbage and cantaloupe.

The Nutritional Significance of the Curd Tension of Milk. I. The production and properties of "soft curd" milks. J. A. M. A., 108:2040, June 12, 1937. II. The relation of curd tension to the digestibility of milk. J. A. M. A., 108:2122, June 19, 1937.

Newly developed laboratory methods for the quantitative measurement of the curd tension of milk have shown that there is a wide variation in the curd tension of untreated milk from different cows. No precise standard exists at present for a "soft curd" milk. Natural soft curd milk appears to be a less concentrated milk, having a relatively low content of fat, casein and calcium phosphate.

Pasteurization of milk has little effect on the nature of the curd, but softening of the curd may be accomplished by boiling, dilution, addition of acids or alkalis, and the addition of various cereal waters. Homogenization of whole milk usually lowers the curd tension, and commercial methods of preserving milk by evaporating or drying also usually yield a product that exhibits a low curd tension.

The variety of milk preparations that yield soft curds have been shown to be well tolerated and well utilized by infants, children and older persons. Thus, "evaporated, sweetened condensed and powdered milks—all of which usually form soft, flocculent curds—have been used with clinical success in the feeding of normal infants." In general, milk that has a low curd tension leaves the stomach more quickly than milk that does not have this property. Such digestion as takes place in the stomach is more quickly accomplished when the curd is soft.

Numerous references to the scientific literature are included in this report, prepared by the Council on Foods of the American Medical Association.

B. COLI VACCINE

DETOXIFIED WITH SORICIN

It has been demonstrated that colon bacillus vaccine therapy, if judiciously used in properly selected cases, constitutes a valuable therapeutic aid.

B. Coli Vaccine (Merrell), used in conjunction with Soricin Tablets or Soricin Capsules for the treatment of obstinate cases of:

- chronic functional diarrhea
- chronic headaches associated with chronic constipation or colon distress
- chronic "toxic vertigo"
- "unstable colon" or mucous colitis

B. Coli Vaccine (Merrell) is now available to physicians in the graduated dilutions.

Physicians are invited to write for complete descriptive literature

The Wm. S. Merrell Company

CINCINNATI, U. S. A.

on diets in which casein from cow's milk served as the protein constituent, even when the ratio of calcium to phosphorus in the diet was 9:1, when the phosphorus content of the diet was less than 0.2 per cent, and when extractable fat-soluble factors were removed from the diet.

BOOHER, L. E.

The Concentration and Properties of Vitamin H. J. Biol. Chem., 119:223, June, 1937.

Vitamin H is defined as a relatively heat-stable component of the vitamin B complex, which is essential for growth and for the prevention of erythredemic dermatosis in rats. It represents the residuum necessary in addition to vitamins B_1 and riboflavin (lactoflavin) to complete the growth-promoting activity of the vitamin B complex.

A 30-fold concentration of this vitamin was extracted from low lactose whey powder containing 5 units per gram, and a 60-90 fold concentrate was obtained from rice polishings containing 12-13 units per gram.

Pasteurization and the Nutritive Value of Milk. Edit. Lancet, 232: 1417, June 12, 1937.

Recent feeding experiments with calves have shown that these animals thrive as well on pasteurized milk as on raw milk, showing no signs of rickets or anemia, and no physical differences on either type of milk.

The dangers of raw milk as a vehicle of infection and the safety given by efficient pasteurization are demonstrable facts that cannot be gainsaid, declares this editorial, which points out that repeated tests have revealed no appreciable difference between the nutritive values of pasteurized and raw milks.

WEISMAN, J. I.

Pasteurized Versus Raw Milk in Undulant Fever. N. E. J. M., 216: 977, June 3, 1937.

In 1930 when the Essex Sanatorium relied in part upon raw milk for its supply, blood tests on 243 patients and employees revealed that 38 or 15.2 per cent contained agglutinins showing the presence of undulant fever. Pasteurization of all milk was then put into effect. Reexaminations of 312 individuals at the hospital, made in 1932, showed that all were negative in titers ranging from 1:25 to 1:200. Included in this group were 23 patients formerly positive with respect to undulant fever.

Pasteurization, says the author, should be made available to 100 per cent of the population, and the public should be educated concerning the dangers of raw milk. All milk cows should be tested yearly for *Brucella abortus* infection and eliminated if found diseased. Contact with the disease is also a source of infection.

Misinformation for the Public. Edit. The Health Officer, 2:6, May, 1937.

"The United States Public Health Service joins with the American Medical Association and the American Public Health Association in condemning *Coronet's* type of gross misinformation on matters vital to the public health," says this editorial in an official publication of the federal government, which thus comments upon "the piece of balderdash" entitled "Is Milk Cancer's Ally?" appearing in a recent issue of the pocket-sized and "pocket-minded" magazine, *Coronet*.

"Let those concerned with public health education, in particular," concludes this editorial, "be alert to the use of dangerous, inaccurate and sensational material having no foundation whatsoever in scientific fact."

Restore
NORMAL
BOWEL ACTIVITY

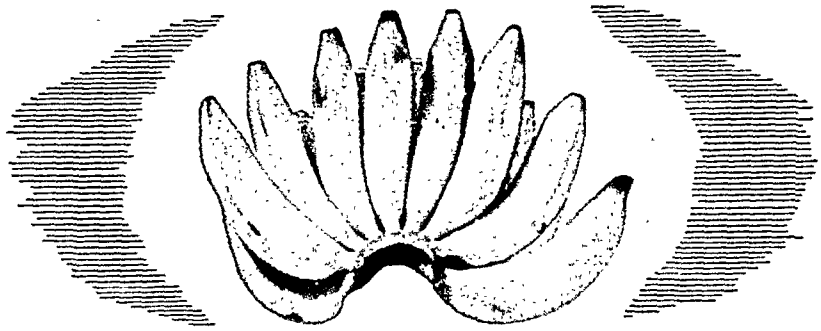
WITHOUT IRRITANT DRUGS, artificial bulk, roughage or other agents preferably avoided by the Physician.

Restoration of normal physiological bowel activity can be fully expected as a natural result of the combined effects of ZymenoL:

a. Catalytic activity of the enzymes, Invertase and Zymase, of Brewers Yeast checks both putrefaction and excess fermentation. Fecal mass becomes soft and bulky. Less toxic. Less irritating.

b. Natural Vitamins B-G of Brewers Yeast, as scientifically known, aid restoration of intestinal tonicity.

c. Mineral Oil (Agar Agar Emulsified) is mainly a carrier for the Brewers Yeast products but also lubricates and further assures soft fecal bulk.



Regular bowel movement occurs from natural impulses without gripe, strain or irritation.

• Sugar Free • Safe for Infants and Children
• No Leakage • Less Expensive
• Only Teaspoon Dosage

Yeast Enzymes in Oil Emulsion

OTIS E. GLIDDEN & CO., INC. - Evanston, Illinois

Useful... IN MANY INVALID AND CONVALESCENT DIETS

RIPE BANANAS are a natural, soft, bland food . . . with a delicate flavor . . . popular with most persons . . . nourishing . . . easily digested . . . non-irritating . . . do not readily ferment in the intestines . . . create intestinal conditions unfavorable to the growth of putrefactive bacteria . . . yield alkaline mineral residues in the body.

Because of these attributes, together with their soft fibre, pectins, high content of sugars, satiety value, low content of protein and fat, their vitamins (good source of A-B-C-G) and essential minerals, ripe bananas are prescribed by an increasing number of physicians in many invalid diets, including: ulcerative colitis; peptic ulcer; cardiac; diabetes; liver disorders; nephritis; tuberculosis; as well as in various post-operative and convalescent diets.

In the field of corrective diets, physicians are finding that ripe bananas help combat diarrhea and spastic constipation; also that in combination with milk they constitute a basis for planning a variety of effective, safe reducing diets for persons who are overweight.

STONE, HARVEY B.

Method of Intestinal Anastomosis with a New Clamp. S. G. O., Vol. 65, No. 3, pp. 383-384, Sept., 1937.

The author describes a new clamp for aseptic intestinal anastomosis. It consists of two pieces, the hinged jaws and compressing handle. Close to the outer surface of each jaw tip a square pyramidal hole is sunk to receive the points of the compressing handle. The compressing handle is made like any forcep but the blades are curved like ice tongs and fashioned to fit the tips of the hinged jaws. The jaws may be secured to the compressing handle as a straight instrument or at right angles to either side.

Five figures illustrate the clamp and show its dimensions and how it may be used.

SOMMER, H. AND MEYER, K. F.

Paralytic Shell-Fish Poisoning. Arch. Path., 24:5-360, Nov., 1937.

From the author's summary of a further detailed study of paralytic shell-fish poisoning, the following data of important interest to all medical readers are noted. The authors tabulate and discuss 243 cases of paralytic shell-fish poisoning, with sixteen deaths that occurred between Ventura County, California, and Juneau, Alaska, from 1927 to 1936. Of these, 234 cases were caused by the coast mussel. Nine cases were caused by the Washington clam. They worked out methods for the detection and the quantitative estimation of the poison in shell-fish. Toxin curves for these nine years were constructed from the analyses of mussels collected from many places along the California-Oregon coast; and curves for mussels, sand-crabs and Washington clams from localities near San Francisco obtained since 1931 are detailed. The poison has also been found in small quantities in seven species of edible clams in addition to the shell-fish mentioned.

Poisonous mussels can not be distinguished from non-poisonous ones except by animal test. They never show increased toxicity in the laboratory, but usually show detoxification at a given rate. They may take up poisons from sea water, and evidence is presented which points to the water of the open ocean as the carrier of the poison. As the latter is absorbed by the silicates of the sand, it is not likely to occur free in the water itself. During the poison season it has been found in the residue from filtration of sea water. Whether it is contained in the plankton or in the microscopic sand is not at present decided.

Four different principles toxic for mice have been demonstrated in alcoholic-acid extracts of shell-fish and plankton.

The authors discuss briefly measures for the prevention of shell-fish poisoning and state that thus far treatment of poisoned individual must be purely symptomatic.

MENNE, F. R., BEEMAN, J. A. P. AND LABBY, D. H.

Cholesterol-induced Arteriosclerosis in Rabbits, with Variations Due to Altered Status of Thyroid. Arch. Path., 24:5-612, Nov., 1937.

The authors report a study of the effects of alterations in metabolism, as produced by changes in thyroid function, on the deposition of cholesterol in the arteries of rabbits fed large amounts of cholesterol over comparatively long periods of time. Observations were made under different conditions, namely (a) normal conditions (controls), (b) following thyroidectomy and after administration of iodine to inhibit thyroid function, and (c) during administration of dessicated thyroid in such a manner as to produce

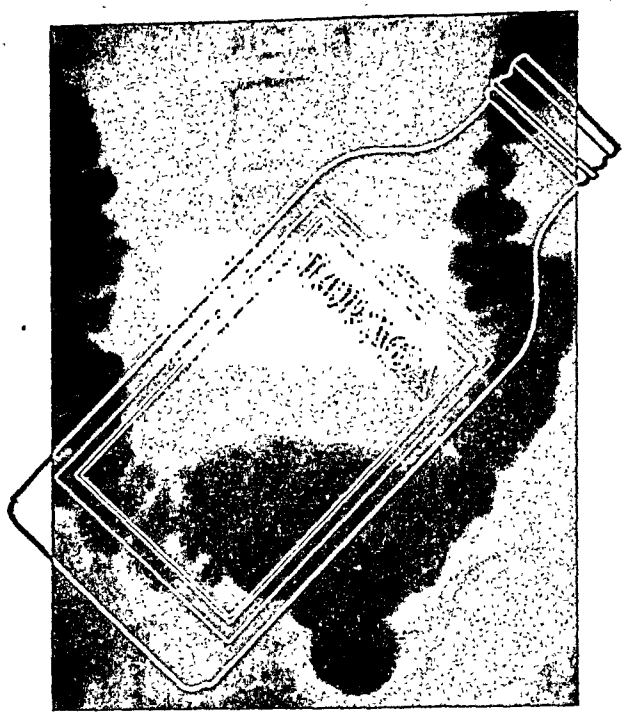
THE BUFFERED NEUTRAL ANTACID

TRI-CALSATE

gives ALL the advantages of the alkaline antacids without their disadvantages. How? Tri-Calsate is a powerful neutralizer of gastric HCl but does not cause a rebound in acidity nor alkalize the stomach contents. The buffering effect of its end salts protects against a harmful alkalosis, thus eliminating a major disadvantage of the alkaline antacids.

As no carbon dioxide is evolved during the reaction in the stomach, gastric distention and belching are eliminated.

Non-toxic, non-irritating, palatable and economical. Available on prescription at your pharmacy or direct in 4-oz. and 18-oz. bottles.



Avoid the Vicious Circle of Alkali Neutralization

PERSUASION WITHOUT URGING

There are occasions when the colon needs "persuasion" without "urging" to evacuate its contents, especially in children. This gentle prodding can be well accomplished with LORAGA, the plain mineral oil emulsion with agar-agar, noted for its exceptional palatability. The fine ingredients of Loraga are so thoroughly emulsified that freedom from oily after-taste is achieved without artificial flavoring and disguise. Loraga may be taken undiluted or diluted, it may be added to milk or to any other liquid or semi-solid food. It contains no sugar, alcohol or alkali. A good intestinal softener and lubricant, that unlike plain mineral oil, mixes thoroughly with the intestinal contents and stays mixed. It forms no pools, it causes no leakage.

Loraga is available in 16-ounce bottles.

LORAGA

Please write on your letterhead for a trial supply.

William R. Warner & Co., Inc., 113 W. 18th St., New York City

intermittent periods of progression and regression in metabolism.

Experimental arteriosclerosis was observed in all groups but it was more marked in those rabbits in which the metabolic rate had been depressed. The authors were led to believe by their studies, as other workers in experimental cholesterol arteriosclerosis in rabbits have been, that the two primary conditions necessary to the development of atherosclerosis are (a) an excess of cholesterol or of cholesterol esters in the blood, and (b) the stress due to mechanical factors of the circulation. The authors recognize the complexity of the problem of human atherosclerosis, but believe these two factors are dominant in the etiology of the latter condition.

There are many discrepancies which naturally must be explained, and the reviewer is inclined to remind his readers that some investigations of human atherosclerosis have shown no correlation between the concentration of cholesterol in the blood serum and the lipid content of the aorta; that the incidence and severity of atherosclerosis are not directly affected by the level of cholesterol in the blood serum.

(Lande and Sperry, *Arch. Path.*, 22:3, 302).

SOMMER, H., WHEDON, M. A., KOFOID, C. A. AND STOHLER, R.

Relation of Paralytic Shell-Fish Poison to Certain Plankton Organisms of the Genus Gonyaulax. Arch. Path., 24:5-537, Nov., 1937.

The above study is one of a series of studies on shell-fish poisoning by K. F. Meyer and Associates of the George Williams Hooper Foundation, University of California.

The authors in this paper give a detailed biological, chemical and epidemiological study of the shell-fish poison from plankton and methods for its extraction and demonstration. Frequent samples of plankton collected during the summer of 1935 yielded amounts of poison roughly proportional to the numbers of the dinoflagellate Gonyaulax Catenella present. On an average 3000 of these organisms yielded 1 mouse unit of poison. The facts point to certain species of the genus Gonyaulax as the source of paralytic shell-fish poison. Other toxic substances in the plankton may be present.

(Plankton—a zoological term for the floating or drifting organic life of the sea, as distinguished from the coast or the bottom forms of sea life).

BEHREND, MOSES.

Carcinoma of Colon. Treatment Depending on Location of Lesion. S. G. O., Vol. 65, No. 4, pp. 505-514, Oct., 1937.

As a matter of fact, the author states, there are no specific signs which would lead one to suspect the existence of a grave lesion of the colon early in its course. Any change in bowel habits must be looked upon with grave suspicion. The author is of the conviction that some types of carcinoma of the colon exist and cause symptoms for five years before they are diagnosed. The majority of carcinomas of the colon are found in the sigmoid, recto-sigmoid junction, and rectum. Carcinoma of the colon is definitely not a disease of the aged; no age group seems exempt from it. Males, generally speaking, are more prone to it than females.

Digital, sigmoidoscopic and X-ray examinations of the colon should be made in suspicious cases. Digital examinations should be made in several positions. While carcinoma may be present in multiple parts of the colon, it is uncommon.

Gently Laxative

. . . Antacid

HALEY'S
M-O
REG. U.S. PAT. OFF.

In the presence of a gastric hyperacidity there is often a sluggish bowel. Haley's M-O combines the gentle laxative and effective neutralizing properties of genuine Phillips' Milk of Magnesia with the soothing, lubricating action of mineral oil in a fine, palatable emulsion.

Each tablespoonful contains Phillips' Milk of Magnesia 3iii and pure mineral oil 3i.

3-YEAR INVESTIGATION ON SLEEP..

An extensive series of sleep experiments have recently been conducted in a leading University

THIS STUDY SHOWS THAT OVALTINE ALONE, OF ALL THE THINGS TESTED, IMPROVED THE *QUALITY* OF SLEEP

Three years ago an extensive investigation was begun at a well known University, to determine the influence of certain factors on sleep. 36 men and women were used as subjects in this study, which extended over a total of 6,800 sleep nights.

A wide variety of different factors were tested for their effect on sleep. One phase of the general problem was to study the influence of sandwiches, hot milk, two barbiturates, and Ovaltine. (Ovaltine was included in the study at the recommendation of the investigators.)

Statistical evaluation of the results shows that Ovaltine was the only test procedure which improved the quality of sleep. *It decreased the amount of tossing and turning during the night.* (Motility, i. e., movements during sleep, is recognized as an objective criterion of the restfulness of sleep). In addition, *Ovaltine caused an increase in the number of mornings when the subjects reported they felt well rested on awakening.* These results were obtained when Ovaltine was taken hot or cold, with water, or milk, thereby indicating that it was Ovaltine itself that caused the improvement in sleep.

Ovaltine was the *only* test procedure that accomplished these two favorable results. Sandwiches had no effect on the quality of sleep. Hot milk had no effect except to increase the amount of dreaming. The two barbiturates used gave the effects for which they are known—one a quick sedative action and the other a prolonged depressant effect. But neither drug improved the quality of sleep as did Ovaltine.

These findings with Ovaltine are merely confirmation, from a new and scientific method, of facts long known about Ovaltine. The experience of medical men established the use of Ovaltine for sleep many years ago.

Ovaltine is a nourishing food, not a drug. Its action is, therefore, entirely natural. It can be used regularly, night after night, with no danger of forming an undesirable drug habit.

When you wish to recommend a sleep aid to some patient, why not give Ovaltine a trial? It is a safe and drugless aid to sound, restful sleep.

Copr. 1938, The Wander Company

The author is of the opinion that powerful deep X-ray therapy in these cases does more harm than good.

Pre-operatively the bowel should be cleansed with castor oil and later warm enemata while the patient is on a non-residue diet. Infusions of glucose are given as needed. All cases are digitalized pre-operatively. This does no harm and frequently has been beneficial in the author's experience.

Immunization by intra-peritoneal vaccination is of very questionable value in the author's opinion.

Spinal anesthesia is the anesthetic of choice in all cases. In over 300 cases the author has not had a single death from the use of neocaine.

Wherever the Mikulicz operation can be performed it is undoubtedly the safest to do. Primary colostomy and anastomoses as secondary procedures are appropriate in certain instances.

Infection by the colon bacillus is the bete noire of operations upon the large bowel and to some degree complicates the course of every patient operated upon. Because of the frequency of late infections in the groins the author now makes a separate incision and drains that area. Drainage of the pelvis is also instituted following operations on the sigmoid and rectum.

The author's mortality has been about ten per cent. Sixteen figures and a bibliography accompany the article.

N. M. Percy, Chicago.

CAREY, J. B.

Gastroscopic Observation of the Post-operative Stomach. S. G. O., Vol. 65, No. 4, pp. 447-452, Oct., 1937.

The author proposes the use of the gastroscope as a means of determining precisely the condition of the stomach pre-operatively and post-operatively in those cases with a recurrence or persistence of symptoms. The presence of unabsorbed suture materials and the types and degrees of gastritis common in the post-operative stomach may be seen. Superficial erosions and hyperrugation may be readily seen by the gastroscope, whereas the X-ray examinations for those conditions is notoriously difficult.

Because of the similarity of symptoms and often of roentgen findings in peptic ulcer and chronic hypertrophic gastritis, is is suggested that gastroscopy should always be done in such cases before operation.

Fifteen case reports, six figures, and a bibliography accompany the article.

N. M. Percy, Chicago.

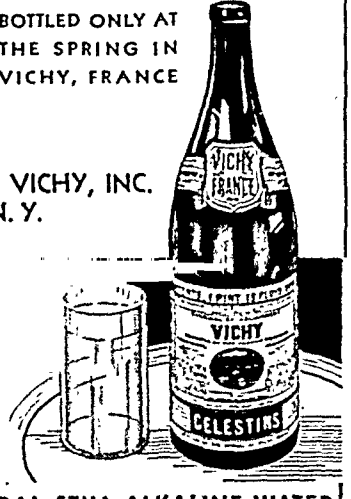
FELLER, M. K., COOK, D. D. M., WALTER, OTIS M. AND ZHITNOFF, N.

Enterectomy in the Surgical Treatment of Hepatic Cirrhosis or Portal Obstruction with Ascites. S. G. O., Vol. 65, No. 30, pp. 331-335, Sept., 1937.

Fuller and Cook, reasoning that if a diminished volume of blood is required to pass through a cirrhotic liver, there may be less ascitic fluid formed, proposed obliteration of a portion of the portal bed to accomplish that end. This smaller volume containing a higher concentration of ostomically active particles should tend toward a slower absorption of water into the capillary bed and furnish a venous volume more concentrated and less in fluid volume.

Following this reasoning, a patient who had formed ascitic fluid at the rate of 0.951 liters per day for a long period of time, was chosen for operation. Beginning 12 inches below the duodenojejunal juncture, 6 feet 8 inches of small intestine were excised and a lateral anastomosis made between the ends of the bowel.

During the first 262 days after operation the formation of ascitic fluid con-



Gastro-Intestinal Toxemias

BECAUSE of its antacid properties, Vichy Celestins has been found useful for gastro-intestinal toxemias, particularly those of the fermentative type. In disturbances due to overeating, faulty diet or alcoholism, Vichy Celestins also has a marked corrective influence.

A valuable FREE booklet on the Therapeutic Value of Vichy, with medical bibliography, will be sent to any physician on request.

CEVITAMIC ACID MERCK

Crystalline Vitamin C

• In Enforced Dietary Restriction
• Gastro-Intestinal Disease

Patients with necessary dietary restrictions, such as exist in the Sippy, ketogenic, and certain other diets of insufficient vitamin C content, constitute an important group in which the use of vitamin C in concentrated form may be of value.

Stringent adherence to fruit-free diets in the protracted treatment of peptic ulcer, colitis, urticaria, and other conditions may result in mild or even frank scurvy, unless care is exercised to ensure an adequate intake of vitamin C.

In the presence of gastro-intestinal disease, impaired absorption may cause vitamin C deficiency despite a presumably adequate intake of the vitamin.

When there is persistent vomiting, diarrhea, or any other condition preventing the utilization of an adequate amount of vitamin C, the parenteral administration of Cebione will be of value.

PRESENTING

DUOCHOL

(PLESSNER)

for Dependable Choleresis
and Cholagogue Action

Duochol (Plessner) presents a valuable addition to the physician's armamentarium in the management of hepatobiliary disease. Its rational formula offers a means of dependable, specific therapy in a number of biliary tract and liver derangements, especially when the undesirable irritant action of cathartics must be avoided.

Duochol exerts its influence upon the entire biliary apparatus. Secretion of bile is augmented appreciably. Because it contains the two most potent cholagogues known, Duochol intensifies gallbladder evacuation. Thus drainage of the entire biliary tree is stimulated. In consequence, food intolerance is corrected, epigastric and right upper abdominal discomfort is quickly relieved, and postprandial eructations and bloating are promptly overcome.

Duochol (Plessner) is indicated in chronic cholecystitis, toxic hepatitis, catarrhal jaundice, and stone-free cholangitis. Because it is free of irritant cathartics, it may be safely administered during pregnancy when latent gallbladder disease frequently becomes activated.

Composition

Each Duochol tablet contains highly purified bile salts, 2 gr.; sodium salicylate, 2 gr.; ext. cascara sagrada, ½ gr.; together with oleoresin capsicum and oil of peppermint.

Notable for Its Economy

The reasonable price of Duochol (Plessner) places it within the reach of all patients. This point is of importance when treating hepatobiliary disease, since therapy is usually protracted.

Samples on Request

Generous test quantities of Duochol (Plessner), together with appropriate literature, sent to physicians on request.

Availability

Duochol (Plessner) is supplied in bottles of 100 and 500 tablets. Available through all pharmacies upon prescription.

THE PAUL PLESSNER CO.

DETROIT, MICHIGAN

stantly diminished until it ceased forming entirely. The patient has now been free from ascites for 29 months and has resumed a fairly normal life, which he could not do before operation. No dietary restrictions are imposed and the patient has no diarrhea.

One table and a bibliography accompany the article.

N. M. Percy, Chicago.

MILLER, GAVIN.

Subtotal Gastric Resection for Peptic Ulcer. S. G. O., Vol. 65, No. 4, pp. 489-494, Oct., 1937.

The author discusses gastric resection from the standpoint of mortality and enumerates some aids in reducing that mortality. He observes that the more widely practiced such a difficult technical procedure becomes the less satisfactory the results will be.

If a heart, lung or kidney condition exists, making operation an unduly dangerous procedure, it should not be undertaken. Blood transfusion should be given for any degree of anemia. Infusions of glucose should be given preoperatively in order to build up a sufficient glycogen reserve.

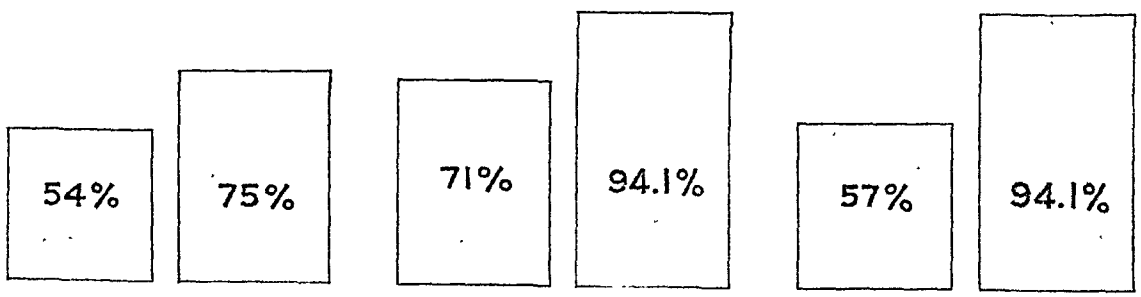
Local anesthesia or spinal anesthesia with splanchnic block are followed by less shock.

The author prefers a high midline incision because less blood is lost; it allows ample exposure, and may be closed securely. If no ulcer is found a pyloroplasty may be done, if pylorospasm is thought to be the cause of the symptoms. Care should be taken to leave the blood supply of the omentum intact; a large omentum without blood supply may be a cause of shock later. The end of the duodenum should be inverted and placed retroperitoneally and then covered with a piece of omentum. This, the author believes, is very important since it tends to localize any leakage from the duodenum. As the jejunum is brought through the mesocolon, care should be taken to avoid kinking or twisting it in any way. A no-loop type of anastomosis following the Hofmeister Finsterer modification of the Billroth *II* operation is performed. The "fatal angle" is reinforced by Finsterer's angle suture. The right edge of the slit in the mesocolon is sutured to the anterior wall of the stomach. Throughout the anastomosis the locked stitch, or the baseball stitch, are used to reduce hemorrhage.

Post-operatively glucose and saline solutions are given intravenously. The carbon dioxide rebreathing bag is given routinely for a few minutes several times daily during the first few days after operation. At the slightest sign of nausea, vomiting, or epigastric fullness a nasal catheter is inserted.

The author prefers the Hofmeister Finsterer Modification of the Billroth *II* operation over the Polya type because he believes that after the latter

THIS SIPPY MODIFICATION IS ACTUALLY MORE EFFICIENT



FEW ulcer patients fail to rebel at the standard Sippy regimen and its 29 dreary daily administrations.

Unfortunately, most modifications designed to meet such objections from the patient are of reduced therapeutic efficiency.

The simplified procedure that utilizes Klim is not only more acceptable to the patient but is actually of *greater* therapeutic efficiency than the standard regimen. The finely divided curd and 27% higher protein content of Klim provide greater control over gastric acidity. Thus, hourly administrations—only 14 daily—are possible, instead of the usual 29.

Try Klim in your next ulcer case. Clip and send coupon for further information, and complimentary supply of Klim for trial.

COMPARATIVE EFFICIENCY OF CONTROL

FIRST DAY

Percentage control of 46 patients using the first day Sippy Regimen

Percentage control of 44 patients using the alkalinized powdered milk once an hour.

SEVENTH DAY

Percentage control of 14 patients using the routine seventh day Sippy Regimen.

Percentage control of 17 patients using the alkalinized powdered milk with six additional feedings

FOURTH WEEK

Percentage control of 14 patients using the routine fourth week Sippy Regimen

Percentage control of 17 patients using the alkalinized powdered milk with three meals.

PEMBERTON, JOHN DeJ. AND WAUGH, JOHN M.

The Elliott Treatment as an Adjunct to Operation in Sigmoidal Diverticulitis. S. G. O., Vol. 65, No. 2, pp. 249-251, Aug., 1937.

The authors report a case of sigmoid diverticulitis with vesicosigmoided fistula which was treated by colostomy and later resection by the method of Mikulicz. A transverse colostomy was made and the patient was allowed to rest for about five months, during which time the inflammatory mass did not decrease in size. Elliott treatments were started rectally and were continued at average intervals of one day for 13 treatments. After two weeks the mass had decreased appreciably in size and resection was carried out successfully.

GLENN, FRANK.

Total Gastric Resection — An Experimental Study. S. G. O., Vol. 65, No. 4, pp. 540-544, Oct., 1937.

In order to overcome some of the difficulties and unsatisfactory results encountered in total gastric resection the author has devised a new operation for total excision of the stomach, and has practiced it on twelve dogs. The operation is performed in two stages. In the first stage a loop of jejunum is brought up and sutured to the posterior wall of the esophagus and the crura of the diaphragm. An entero-anastomosis is then made between the two limbs of this loop of jejunum and the abdomen closed.

Two weeks or more later the second stage is performed. The abdomen is opened through the same wound and the stomach is cut off just distal to the esophagojejunal approximation. The anastomosis between the esophagus and duodenum is then completed and the stomach is excised by cutting across the duodenum. The stump of the duodenum is then inverted and the abdomen closed without drainage.

Three of the animals died of peritonitis. Those who survived seemed to develop a marked anemia.

From these experiments the author gains the impression that the esophagus lends itself less well to anastomosis than any other part of the intestinal tract and any suturing of the lower end of the esophagus must be done with meticulous care. Motion of the diaphragm disturbs the relations at the lower end of the esophagus.

Eight figures accompanying the article illustrate the operation and show some results.

N. M. Percy, Chicago.

NEW HOPE FOR Age-Old Problems

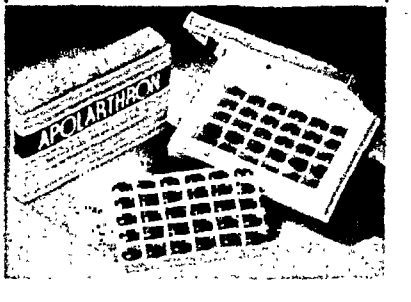
Massive Doses of Vitamin D for Arthritis and Psoriasis*

Physicians throughout the nation increasingly report eminently satisfactory results with APOLARTHRON therapy as an adjunct to other appropriate measures for arthritis. APOLARTHRON is a NATURAL vitamin D preparation of extremely high potency and also contains natural vitamin A. The cost of APOLARTHRON per VITAMIN unit is less than any other preparation available.

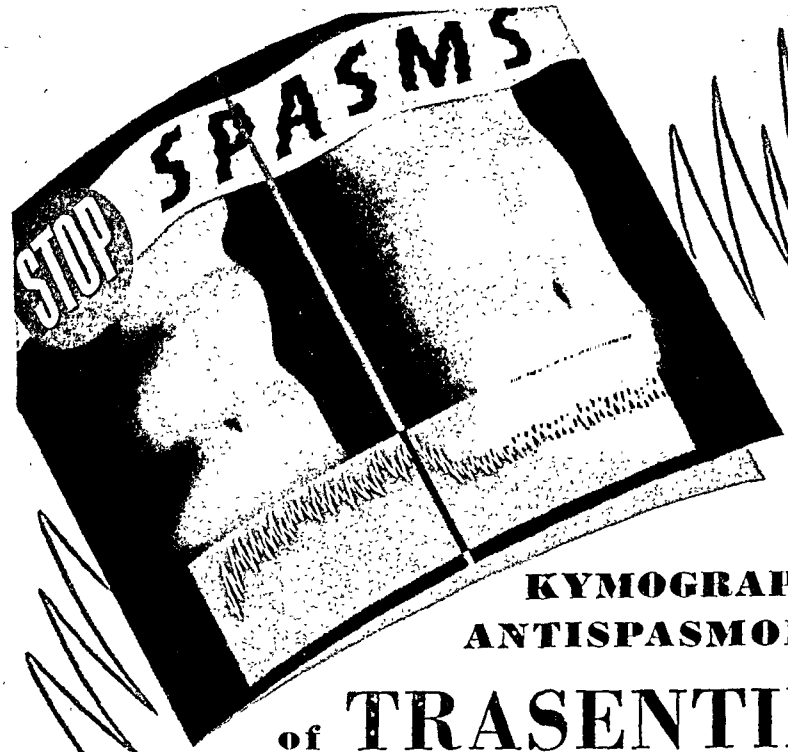
EACH CAPSULE CONTAINS 25,000 U.S.P. UNITS NATURAL VITAMIN D

30,000 U.S.P. UNITS NATURAL VITAMIN A

APOLARTHRON



Available on Prescription in Boxes of 60 Capsules, $5



The suggested dose for arthritic cases is from two to not more than six capsules a day. Systemic improvement is frequently noted within a few weeks and general symptomatic relief, pain greatly diminished if not entirely absent, lessening of swelling, and increased mobility of the joints within a variable period of time.

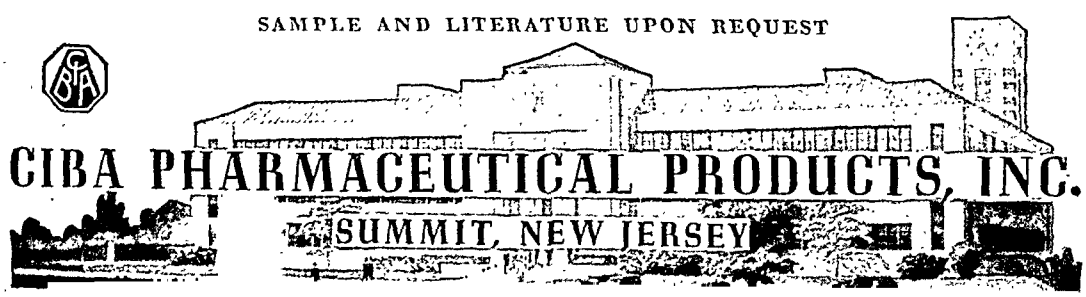
The

KYMOGRAPH RECORDS ANTISPASMODIC ACTION



of TRASENTIN *"Ciba"*

TRASENTIN, "Ciba" arms the physician with an antispasmodic of unusual value. It acts quickly to check all types of spasms of the hollow viscera. Exerting atropine-like relief in nerve fibre contractions, Trasentin is decidedly less toxic to the heart and pupil; it does not interfere with salivary flow. Controlling smooth muscle spasms like papavarine, Trasentin does not cause permanent suppression of contractions.

Trasentin is truly worthy of trial. You will appreciate its prompt efficiency, high tolerance and relative safety in—gastro-intestinal spasms (ulcer or subacute gastritis, cardio-spasm, pylorospasm, spastic obstipation), biliary tract spasms (as in gallstone colic), spasms of the urinary tract (incident to inflammation or calculi, tenesmus of the bladder), spastic dysmenorrhea.

Trasentin (hydrochloride of diphenylacetyldiethylaminoethanol) is available in Tablets and Ampules.

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

At Last! A BALANCED PHYSIOLOGY

Edited by PHILIP BARD

With the Collaboration of

HENRY C. BAZETT, Professor of Physiology, University of Pennsylvania.

GEORGE R. COWGILL, Associate Professor of Physiological Chemistry, Yale University School of Medicine.

HARRY EAGLE, Passed Assistant Surgeon, United States Public Health Service and Lecturer in Medicine, Johns Hopkins University School of Medicine.

CHALMERS L. GEMMILL, Associate in Physiology, Johns Hopkins University School of Medicine.

MAGNUS I. GREGERSEN, Professor of Physiology, College of Physicians and Surgeons, Columbia University; Formerly Professor of Physiology, University of Maryland School of Medicine.

ROY G. HOSKINS, Director of Research, Memorial Foundation for Neuroendocrine Research, Research Associate in Physiology, Harvard Medical School.

J. M. D. OLMSTED, Professor of Physiology, University of California.

CARL F. SCHMIDT, Professor of Pharmacology, University of Pennsylvania

MACLEOD'S *New 8th Edition*

Physiology in Modern Medicine

1051 Pages, 355 Illustrations. Price, $8.50.

The New EIGHTH Edition of Macleod's "PHYSIOLOGY IN MODERN MEDICINE," revised under the editorship of Dr. Philip Bard, can be depended upon to be a balanced physiology. It correlates properly the principles of physiology with their clinical application. It is an ideal text for medical students as well as a dependable reference book for practicing physicians and surgeons.

Little of the Seventh Edition remains. The death of Doctor Macleod made necessary an unusually extensive revision of this book. The greater part of the book has been entirely rewritten. Each major subdivision is the work of a writer who is actively engaged in the study of some phase of the subject he treats. This arrangement has much to recommend it. The ever increasing bulk of original literature in physiology has made it most difficult for one, or even two or three, individuals to present in adequate fashion the facts and conceptions which should be made available to students and practitioners of medicine. Further, the treatment of each subject by one who has personally launched an experimental attack in some sector of that general field is likely to result in the placing of stress on actual experimental evidence. This has the very great advantage that it may stimulate the reader to engage in the weighing of evidence, and to achieve an understanding by the selection and coordination of significant facts, in short, to do precisely what every student and practicing physician must do if he hopes to become even mildly competent in his chosen profession.

THE C. V. MOSBY CO., AJDDAN-2-58
3525 Pine Blvd., St. Louis, Mo.

Gentlemen: Send me the new Eighth Edition of Macleod's "PHYSIOLOGY IN MODERN MEDICINE," charging my account. The price is $8.50.

IN PEDIATRIC PRACTICE

It's Individualized Care

PROPERTIES OF KARO

Uniform composition
Well tolerated
Readily digested
Non-fermentable
Chemically dependable
Bacteriologically safe
*Non-allergic
Economical

*Free from protein fibels to produce allergic manifestations

•

COMPOSITION OF KARO

(Dry Basis)

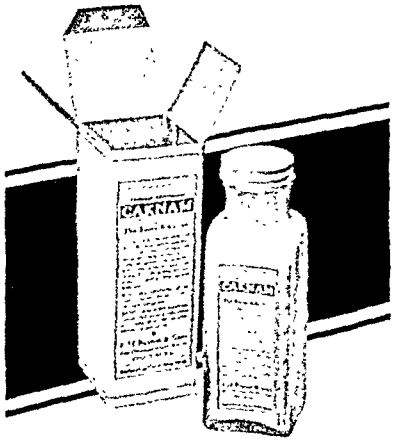
Dextrin	50%
Maltose	23.2%
Dextrose	16%
Sucrose	6%
Invert sugar	1%
Minerals	0.8%

•

KARO EQUIVALENTS

1 oz. vol.	10 grams 120 cals.
1 oz. wt	28 grams 90 cals.
1 teaspoon	15 cals
1 tablespoon	60 cals.

Mothers want their babies treated as individuals, not as cases; their babies followed, not their charts; their physiques treated, not the labelled conditions; and the doctoring done economically.



When infant feeding materials prescribed are within the reach of every budget, mothers will appreciate the physician and the babies will thrive. Karo is the economical milk modifier. It costs 1/5 as much as expensive modifiers.

For further information, write
CORN PRODUCTS SALES COMPANY
Dept. DN-2, 17 Battery Place, New York, N. Y.

★ Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

Restore
THE ALKALI RESERVE

CAKNAM

Caknam supplies the four bases, calcium, potassium, sodium and magnesium in true physiological proportions. Rich in citrates—entirely free from tartrates and sodium chloride. Granular effervescent. Available on prescription in 3½ oz. bottles.

Write for trial package and complete literature.

Manufacturing Pharmaceutical Chemists
469 E. Ohio St. Chicago, Ill.

For bland diet therapy, especially ULCER cases

. . . PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastrointestinal disorders is a deficient diet. Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastrointestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than does farina and is an excellent source of vitamins B_1 and G. Also rich in calcium and phosphorus.

Requires no cooking. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Can also be used in a variety of appetizing dishes to enhance their vitamin and mineral values.

Samples and literature sent on request of physicians.
